To produce the most rapid quenching, the cooling medium must be kept in contact with the surface of the metal, and that portion of the cooling medium immediately in contact with the surface must be kept cool. With gases, such as air, there is no difficulty in maintaining close contact. The heat capacity and thermal conductivity of air are quite low, however, so very rapid and uniform circulation and large volumes of air are required to keep the air cool immediately in contact with the surface of the metal. Therefore, gases are not generally suitable or economical for rapid quenching.

Liquids have much higher heat capacities than gases; the specific heat of water is higher than that of most other liquids. The problem of maintaining contact between a liquid quenching medium and the object to be quenched is one of keeping gases from adhering to the surface of the object. Gases may be carried into the quenching medium by the object itself (adsorbed on the surface or trapped in pockets); or may come from the quenching medium by liberation from solution—for example, air dissolved in water—or by vaporization of the liquid itself. Gases arising from these sources and adhering to the surface of the object, insulate the object from the liquid and thus retard cooling. Circulation of the liquid against the surface helps to remove gases, and also tends to prevent the liberation of gases or vapors from the liquid, by preventing the overheating of the liquid in contact with the surface. When water is boiled before it is used for quenching, a negligible amount of air remains in solution.

If it is desired to cool certain portions of an object more slowly than the rest, as with holes and keyways in steel to be hardened, these portions may be shielded from the full action of the cooling medium by the application of clay, asbestos, sodium silicate, or other insulation.

The effect of a quenching medium on the properties of a metal depends on the rate of cooling produced. Except when the cooling rate is affected, there is no evidence of any special effect caused by the composition of certain local waters, extraordinary aqueous solutions, or odd mixtures of oils that have been used or proposed.

It should be noted, however, that the *average* rate of cooling from the quenching temperature to that of the quenching medium is not a sufficient indication of the effect on the metal. The rate of cooling at all temperatures on the way down must be considered. For example, if a certain object made of an alloy tool steel is found to crack when quenched in cold water for hardening, slower cooling is indicated. The object may be quenched successfully in a certain oil without cracking. Equally slow cooling through the higher temperature range, may be obtained by quenching in boiling water, but the object may still crack, because the cooling rate is too rapid at lower temperatures, possibly from 700 to 300 F.

Careful studies have been made concerning the rates at which steel, in particular, can be cooled by various quenching mediums.[10, 11] Detailed data concerning rates and other factors that influence the process of quenching, are in-

cluded in other articles in this Handbook (pages 615 to 629).

When the ratio of the surface of an object to the volume is large, as in wire and thin sheet, extremely rapid cooling can be obtained by a quenching method that cools the surface rapidly; for example, a jet of cold water of ample volume and under high pressure. With heavier sections, however, the cooling rate is limited by the rate of conduction of heat from the interior to the surface. Hence, the center of a large section of steel cannot be cooled rapidly by any method. If the composition of the steel is such that rapid cooling is necessary for full hardening it is impossible to cool the center of a large section rapidly enough for such hardening. This is called "mass effect".

Different quenching mediums may be used in sequence to produce different rates of cooling. For example, to reduce distortion and strains, a tool may be cooled in air for a short time before being quenched in water; or a crankshaft of alloy steel may be quenched in water for a measured time and then be removed and allowed to cool in air or oil, in order to prevent cracking.

Recrystallization

By Robert F. Mehl*

METALS that have been strained by cold working are not stable, but tend to revert to a strain-free state. This article will consider the processes by which the effects of cold work may be relieved; among them recrystallization is the chief. The cold working of metals in industrial practice is familiar to the engineer; so is the annealing of cold worked metals for softening, either to facilitate further working or to provide more suitable properties for use. The examples are exceedingly numerous; for instance, the annealing of cold rolled low-carbon steel sheet (see the article on "Effect of Cold Work on the Properties of Iron"). In order to understand the processes by which metals hardened through cold work may thereafter be softened by annealing, it will first be necessary to consider the effect of cold work on the nature of metals.

The Nature of Cold Worked Metals. Cold work consists in the plastic deformation of a metal at such temperatures and at such rates that no recrystallization occurs during the deformation process. Under such conditions the metal is strain hardened. The compression of iron at room temperature, for example, is cold work; the compression of iron at higher temperatures in the absence of recrystallization is also cold work. Only when such temperatures are reached that recrystallization (which leads to softening) occurs during the working process, can the term "hot work" be properly employed. In general, these temperatures are high in metals melting at high temperatures and low in metals melting at low temperatures—occasionally as low as room temperature or below. Since permanent plastic deformation is required (for metals do not recrystallize without prior cold work), it will be obvious that the deformation must be beyond the yield point.

Such deformation produces fundamental structural changes in the metal. At low degrees of deformation, slip lines appear in those grains in which the slip planes are most favorably oriented for yielding under the resolved shear stress; in metals which readily form mechanical twins, like zinc at ordinary temperatures or iron at low temperatures, twin bands also appear. As the degree of deformation becomes greater, slip lines appear in an increasing number of grains, the grains tend to rotate, the crystal planes to become curved, and the grains to become sensibly elongated in the direction of flow. It is a result of the fact that the directions in the crystal grain by which flow can take place during deformation are determined by crystal symmetry and are therefore not random, that cold and hot deformation are accompanied by the generation of preferred orientations, which may be described in crystallographic terms, accompanied by corresponding directional properties. This deformation is accompanied by an increase in the strength properties: hardness, yield point or strength, tensile strength; and a decrease in the ductility properties: elongation to fracture, reduction of area at fracture, drawing capacity, impact strength. Deformation is accompanied also by a slight decrease in density, a slight decrease in electrical conductivity, and a decrease in maximum permeability, as well as by an increase in electrode potential and the general tendency to corrode, an increase in coercive force, a slight increase in the coefficient of thermal expansion, and a slight increase in compressibility.

The atoms in an annealed metal are in a continuous state of thermal vibration about mean positions that are symmetrically disposed on a crystal structure. Apart from relatively minor imperfections, this is a geometrically perfect arrangement. The perfection of arrangement, however, is grossly altered by deformation. The crystallographic planes become curved and twisted; atoms no longer have precise mean positions on the crystal lattice, but are distorted to positions less symmetrically disposed, with resultant distortion of atom shapes and energy distribution, and increase in the internal energy of the metal.

The nonhomogeneous character of cold deformation creates a pattern of residual strains. In commercial forming operations, the friction of rolls or of dies, or the complexities introduced by multiple types of deformation or by heat treatment, create residual "macroscopic stresses" (Heyn stresses). These macroscopic stresses are characterized by a gross distribution in such a way that one section of a piece may be in tension while another is in compression; thus, for example, the center of a cold drawn copper wire is in compression while the outside is in tension. Furthermore, a pattern of stresses on a fine scale, "microscopic stresses", characterized by minute regions in which tensile (and compression) stresses occur, also are formed as a result of slip on atom planes, of the bending of slip planes, of slip on intersecting slip planes, and of the impedence to normal slip at grain boundaries. Such a pattern of stresses will obviously be characterized by points of unusually high energy peaks, which are the points of least stability in the cold worked metal where processes relieving the effects of cold deformation presumably will originate. The greater the amount of cold deformation, the greater will be the number of such peaks, and presumably the greater the number of peaks of extremely high energy.

The heating of cold worked metals results in a softening and accordingly a renewed ability to suffer cold work. This heating also relieves both microscopic and macroscopic residual stresses, either of which may be harmful in special cases, though generally cold worked materials find widespread and wholly satisfactory applications. Macroscopic

* Director, Metals Research Laboratory and Head, Department of Metallurgy, Carnegie Institute of Technology, Pittsburgh.

stresses can measurably decrease the fatigue strength of materials when such stresses are tensile on the surface, can increase fatigue strength when such stresses are compressive on the surface, and in a wholly similar way can be conducive to failure in stress corrosion as in season cracking; and can lead to the yielding of structural members at loads below the normal yield strength. Any softening process that will obviate these effects is important practically; it will be seen that both the process of recovery and that of recrystallization will perform this task.

The Effect of Annealing on Cold Worked Metals. The changes in properties that follow upon annealing are in the direction of the restoration of the properties obtaining before cold deformation. But the ways in which the various properties change on annealing are not simple.

Three types of mutually distinguishable processes occur on annealing a cold worked metal. These are: (1) recovery, (2) recrystallization, and (3) grain growth, as illustrated in Fig. 1. Recovery is a change in the properties—particularly those determined by the state of strain—of a cold worked metal at low annealing temperatures; a change unaccompanied by any detectable change in the microstructure of the cold worked metal. Recrystallization, occurring at higher temperatures, is a process of the formation and growth of new unstrained grains, supplanting entirely the cold worked structure. Grain growth, occurring in completely recrystallized metals, is merely a continued growth of recrystallized grains.

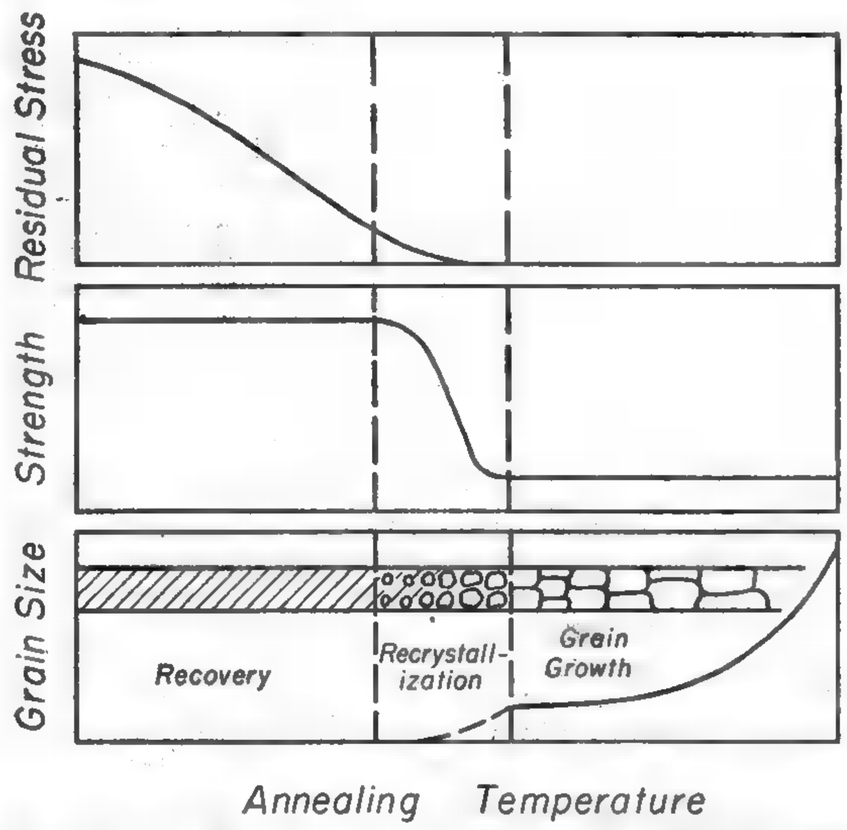

Fig. 1 Schematic representation of recovery, recrystallization and grain growth (adapted from Sachs).

These three processes all depend on time; they are not instantaneous. The rate at which each operates increases with increasing temperature, following an exponential law. When the temperature to which a cold worked metal is subjected is sufficiently high, these processes operate with such rapidity as to appear to be instantaneous, but at lower temperatures the time dependence is readily detected. The rates, however, vary widely from metal to metal and depend greatly on composition, purity, grain size of the sample before deformation, and the amount of deformation. Generally, metals with low melting points exhibit high rates at low temperatures, as in the case of tin. Furthermore, the three processes sometimes overlap and are difficult to distinguish, while in other cases they can be clearly separated. The accompanying changes in properties are not always parallel, that is, the properties do not change concomitantly (Fig. 5), and this fact often permits the production of unusual property combinations.

Recovery, recrystallization, and grain growth are all processes leading to softening. It is conventional to study these by heating cold worked samples to a series of increasingly elevated temperatures and holding for a certain time period, usually between 15 min and 2 hr, and subsequently measuring the properties at room temperature.

The selection of a constant time period of annealing eliminates time as a variable, and the results must be viewed with this limitation. In a narrow temperature range the change in properties is rapid, as shown in Fig. 2 for copper of various degrees of purity, but this range may readily be displaced to lower temperatures by increasing

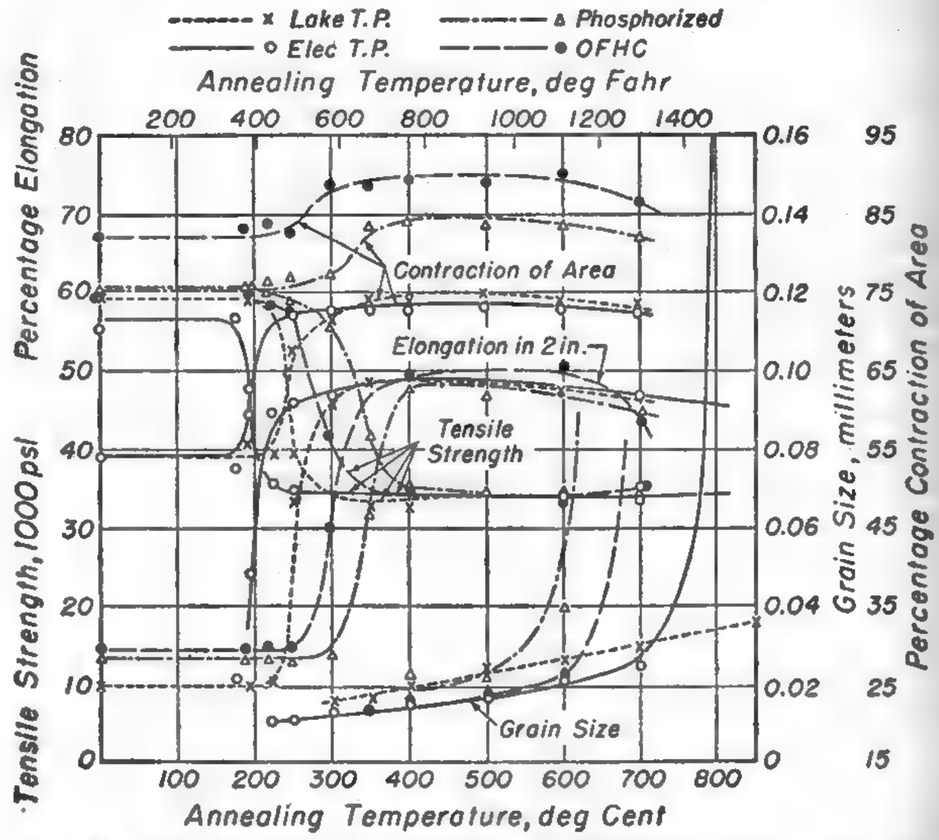

Fig. 2 Effect of annealing on tensile properties and grain size of tough pitch lake, tough pitch electrolytic, phosphorized (0.02% P), and oxygen-free high-conductivity copper. Wires cold drawn to 62.5% reduction in area and annealed one hour (Pratt). Tested at room temperature.

the time of annealing (Fig. 3). Doubling the annealing time lowers the softening temperature by approximately 10 C. The temperature of rapid softening is also decreased by an increasing degree of cold work (Fig. 4).

These curves of softening do not distinguish with absolute certainty the three processes described above. Of the three processes, recovery should be considered first, since it is the process which occurs first on heating.

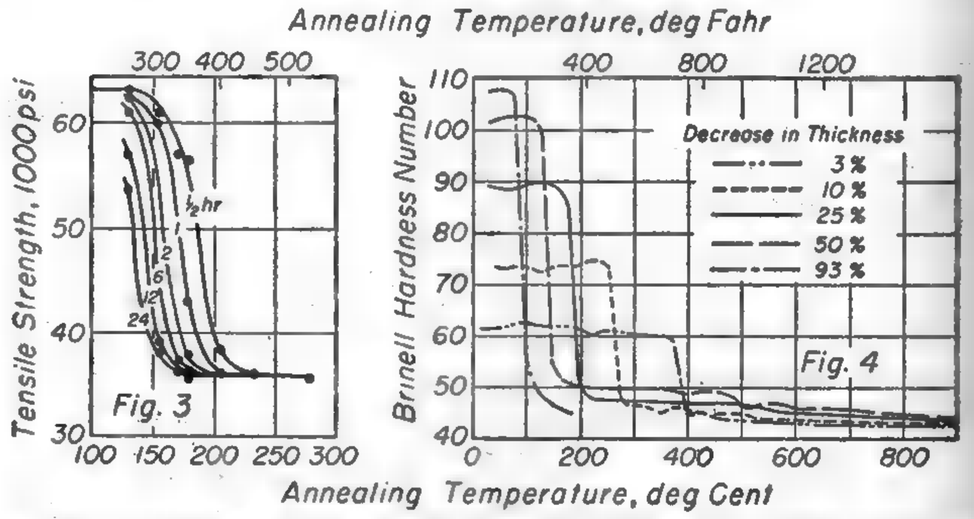

Fig. 3 Influence of annealing time on softening of copper wire, reduced 93% by cold drawing to 0.26-mm diam (Alkins and Cartwright) Tested at room temperature.

Fig. 4 Influence of percentage reduction in thickness on the softening temperature of cold rolled, high-purity copper (Köster). Annealed for one hour at temperatures shown. Tested at room temperature.

Recovery. The elongation of single crystals is characterized by a steadily rising stress-strain curve. If the load is removed and immediately reapplied, the stress continues from the point of interruption. However, if time elapses between release and reapplication of load, or if the piece is slightly heated, the stress begins at a low value; that is, some strain hardening has been lost, though no recrystallization has taken place. This is recovery, sometimes termed "crystal recovery". The process is most striking in single crystals but occurs also in aggregates.

The effect of recovery on several physical and mechanical properties in iron is shown in Fig. 5. The Brinell hardness decreases rapidly upon recrystallization, and only a very slight decrease as a result of recovery occurs before this, but the thermoelectromotive force and the electrical conductivity decrease at much lower temperatures, and the

change in these is complete before there is any detectable change in grain structure, any recrystallization. This behavior, then, illustrates a change which occurs on heating cold worked metals without recrystallization. It will be seen that the properties do not change in a parallel way.

Recovery is especially marked in the relief of residual stresses, as shown by the curve for "spring-back" in Fig. 5. The tendency to season-crack in brass, the magnitude of macroscopic stresses, and the general tendency to crack on treatment are greatly decreased by annealing to induce recovery without recrystallization. Such stresses in cold worked steel can be largely eliminated by annealing at 850 F, at which temperature steel does not recrystallize. Stress relief can be more completely attained by annealing at higher temperatures, and this is the usual commercial practice. (*See* "Relief of Residual Stresses", page 237.)

The process of recovery in metals is doubtless widespread, though experimental studies have not been sufficiently extensive to say when recovery may be separated from recrystallization and when these two processes overlap. If overlapping occurs, recovery cannot be distinguished from recrystallization. In iron, nickel, palladium and platinum, recovery may be readily distinguished from recrystallization, for the changes in properties on heating are not parallel (Fig. 5); but in copper, silver and gold, the properties change more nearly simultaneously during annealing. Whatever may be the underlying cause of these differing behaviors, it is evident that the type of crystal structure is not important, but that the position in the periodic table is.

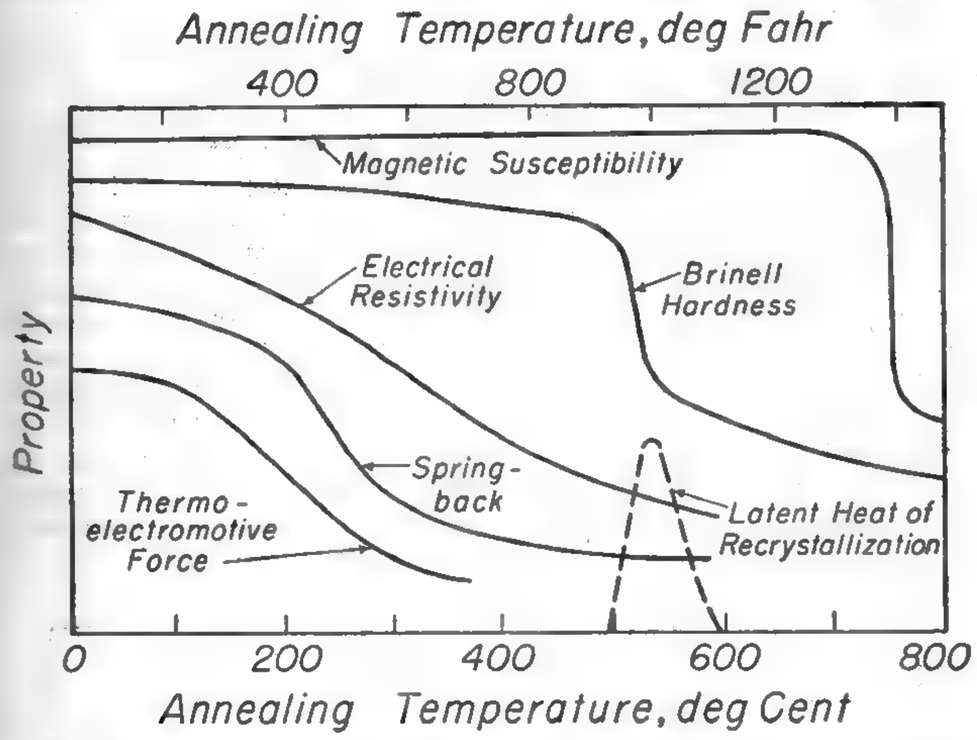

Fig. 5 Recovery and recrystallization in iron. Annealing time one hour; cold rolling 95 to 98%. "Spring-back" is the increase in diameter of a roll of strip after removing from mandrel around which it has been held (adapted from Tammann).

The causes for recovery are not clear. Recovery is doubtless a change in the residual stresses in worked metals, affecting primarily the elastic properties, and also the electrical, magnetic, and miscellaneous properties, like velocity of solution in acids, but having relatively little effect on the properties involving strength and ductility. This reduction in stress may be associated with the straightening of bent slip planes, and perhaps with the healing of microscopic cracks adjacent to points of severe curvature of slip planes; however, it cannot be pictured as a complete relief of stress, but only as a partial relief of some special sort of stress, since a metal which has recovered does not lose its capacity to recrystallize, and in some instances an entirely undiminished capacity for recrystallization has been demonstrated. The reasons for strain hardening in cold working are not well understood, and until the cold worked condition itself can be more adequately described, it is unlikely that recovery and the types of stresses causing recovery and recrystallization can be understood clearly.

Recrystallization. When a cold worked metal is heated to a sufficiently high temperature, or for a sufficiently long time at a somewhat lower temperature, new grains appear and grow, until ultimately a new grain structure has completely replaced the old. This is recrystallization. The changes that accompany recrystallization are in the direction of the restoration of the properties characteristic of the metal before cold deformation, though these properties may not be exactly reproduced, because the final grain size may be different from the initial grain size. The softening temperatures illustrated in Fig. 2, as shown by the rapid increase in elongation and decrease in strength, are temperatures at which recrystallization occurs, and generally such changes in properties can be safely considered as evidence of recrystallization; but when the material has partially recovered before recrystallizing, the changes in strength properties do not sharply define the beginning of recrystallization; and when grain growth after recrystallization is pronounced, the strength properties continue to change after the completion of recrystallization and thus do not sharply define the completion of recrystallization. In such instances microscopic studies are required, in order to define the beginning and the ending of recrystallization, though frequently X-ray diffraction methods are superior.

The complete removal of the effects of cold work and the possibilities of controlling grain size, and thus particularly the behavior of the material toward further working, make recrystallization a process of immense practical importance. Unusually large grains are often highly undesirable, for they lead to an unattractive rough appearance of drawn objects (for example, the familiar "orange peel" effect), and to tears in large worked sections. It is therefore of the greatest importance to know what factors govern the temperatures and times of recrystallization and what factors govern the final grain size.

The process of recrystallization involves continuous formation of nuclei of new crystals and the growth of these nuclei until the system is constituted entirely of the new grain structure. The rate of formation of nuclei and the rate of growth of these nuclei are thus the basic factors determining the rate of recrystallization, and it is necessary to inquire how these may vary with temperature, with time, with initial grain size, with degree of deformation, and with composition and purity.

Recrystallization is thus not an instantaneous process but one with a time dependence. It is, in this sense, similar to the formation of pearlite from austenite, giving rate curves of a completely analogous form. Most recrystallization data, however, have been obtained by employing short and fixed annealing times, as stated above, and thus give no clue to this time dependence.

The new nuclei appear to form at grain boundaries, slip lines, deformation markings of various sorts, and twinning planes, as may be seen in slightly deformed samples, though this is probably also true in heavily deformed samples. Recrystallization can thus be detected most conveniently metallographically, but the sharpening of X-ray diffraction spots and the appearance of new sharp spots has frequently been used as a trustworthy criterion. The mechanical properties are not always trustworthy, as stated above.

Apart from composition and purity, four factors determine the grain size after recrystallization: (1) the amount of cold deformation, (2) the temperature to which the cold worked metal is heated, (3) the time for which the metal is held at this temperature, (4) the original grain size.

Several fundamental laws of recrystallization are now well recognized: (1) Recrystallization occurs at a higher temperature, the smaller the degree of deformation or, more accurately, the smaller the degree of strain hardening. (2) Increasing time of annealing displaces recrystallization to a lower temperature. (3) The final grain size depends chiefly on the degree of deformation and to a lesser extent on the annealing temperature; the final grain size is larger, the smaller the degree of deformation. (4) The larger the original grain size, the greater the amount of cold deformation to give equivalent recrystallization temperatures and times. In addition to these major factors, it should be noted that (*a*) the rate of heating to the recrystallization temperature is a further variable, and (*b*) the amounts of cold work to give equivalent strain hardening vary with the temperature at which deformation is performed.

The first law may be illustrated by a diagram in which the beginning of recrystallization is plotted against an-

nealing temperature for hot worked iron (Fig. 6). Here it may be seen that recrystallization does not occur below 460 C, and that the temperature of beginning of recrystallization increases with decreasing deformation until the A_3 temperature is encountered. This diagram, obtained for deformation at the temperature of recrystallization, differs only in degree from a diagram for deformation at room temperature and recrystallization at the designated temperature; the general form is the same, as indeed it is for all metals and alloys. Therefore, for degrees of deformation and annealing temperature to the left of and below the curve of beginning recrystallization, no recrystallization occurs, no change in the grain structure can be detected; in this range recovery occurs.

The exact position of such a curve will vary with a number of factors: with the type of deformation, with the original grain size, and with purity. Even slight differences in purity have a wholly disproportionate effect. Data on recrystallization are given elsewhere in this Handbook; see, for example, the article on the "Effect of Cold Work on the Properties of Iron", and other articles on the properties of various metals and alloys. It is ordinarily difficult to determine the applicability of published data to a given material, since important variable factors have frequently been disregarded.

When samples are heated which have been deformed to increasing degrees, the grain size developed is especially instructive (Fig. 7). It is seen that a deformation of approximately 7% is required before any change in grain size occurs; this degree of deformation at which grains suddenly grow to a large size, is known as the "critical deformation".

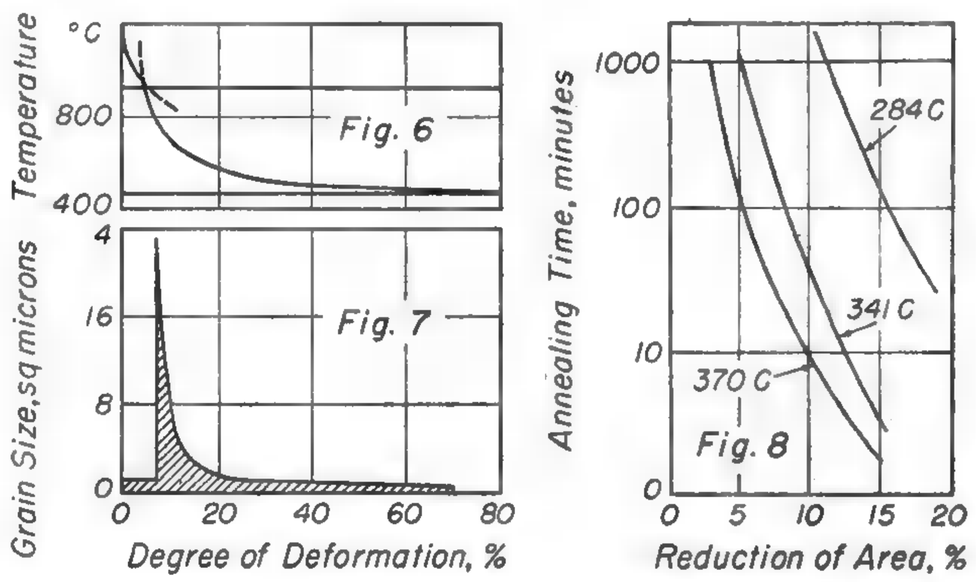

Fig. 6 Influence of temperature and degree of deformation at temperature on curve of initial recrystallization of low-carbon steel (Hanemann).

Fig. 7 Influence of degree of deformation on grain size developed at 950 C in low-carbon steel (Hanemann).

Fig. 8 Influence of degree of deformation and time of annealing upon recrystallization temperature of copper deformed by elongation in tension (adapted from Sachs).

The formation of large grains during recrystallization at the minimum deformation is caused by the occurrence of a minimum of recrystallization nuclei during the time available for recrystallization. At degrees of deformation smaller than this, the number of recrystallization nuclei becomes disappearingly small. With increasing degrees of deformation, an increasing number of points of high stress (high energy) are present, leading to recrystallization from a greater number of nuclei, and finally to a greater number of grains, and thus to a continually smaller grain size. The degree of deformation at which very large grains form, the "critical deformation", will be displaced to lower deformation for increasing times of annealing, because increased time will permit the formation of nuclei in lower ranges of deformation; and it will be displaced to higher deformation for larger original grain size, because, as stated elsewhere, a larger original grain size suffers less strain hardening for an equal degree of deformation and thus provides a lower rate of nucleation and rate of growth on recrystallization.

The influence of degree of deformation on the recrystallization temperature and time is illustrated in Fig. 8. This figure shows that, for a constant annealing temperature, shorter times are required for recrystallization at higher degrees of deformation, and shows also that with increasing temperatures, lower degrees of deformation and shorter times are required for recrystallization. Such generalizations are applicable when the type of deformation is simple, as, for example, increasing amounts of compression; but when several types are superimposed, or when reversed deformation occurs—alternate compression and elongation, bending and unbending—the recrystallization tendency is decreased even though reversed deformation may continue to work harden. The reason is not clear.

The effect of original grain size on recrystallization can be readily understood. The amount of strain hardening which a given amount of compression, elongation, or torsion introduces into a metal increases as the grain size decreases. When, in a given metal at a single temperature, equivalent amounts of strain hardening are introduced, requiring large amounts of deformation for large-grained metals and small amounts of deformation for small-grained metals, the recrystallization behaviors are apparently identical.

The relationships among degree of deformation, annealing temperature, and resultant grain size have frequently been assembled into a three-dimensional chart, of which Fig. 6 and 7 are sections. Such a diagram for iron is given in the article on the "Effect of Cold Work on the Properties of Iron", elsewhere in this Handbook. Charts of this sort are commonly derived from data obtained by using constant (and short) annealing times, and do not show the time variable; furthermore, the factor of original grain size is not represented. A five-dimensional chart would be required to show all these relationships. This limitation of three-dimensional diagrams, the occasionally extreme effects of minor amounts of impurities, and the complications introduced by the complexities of industrial forming processes with resultant complexities in residual stress distribution, render such charts of little direct practical use. They should be used only to indicate the recrystallization behavior of a material in a qualitative way. Such charts frequently show the grain size of the recrystallized metal to be the greater, the higher the temperature of recrystallization; but at least in some cases this effect is associated with grain growth following recrystallization, for since the rate of recrystallization increases very rapidly with increasing temperature, increasing time is left available for grain growth at the higher temperature.

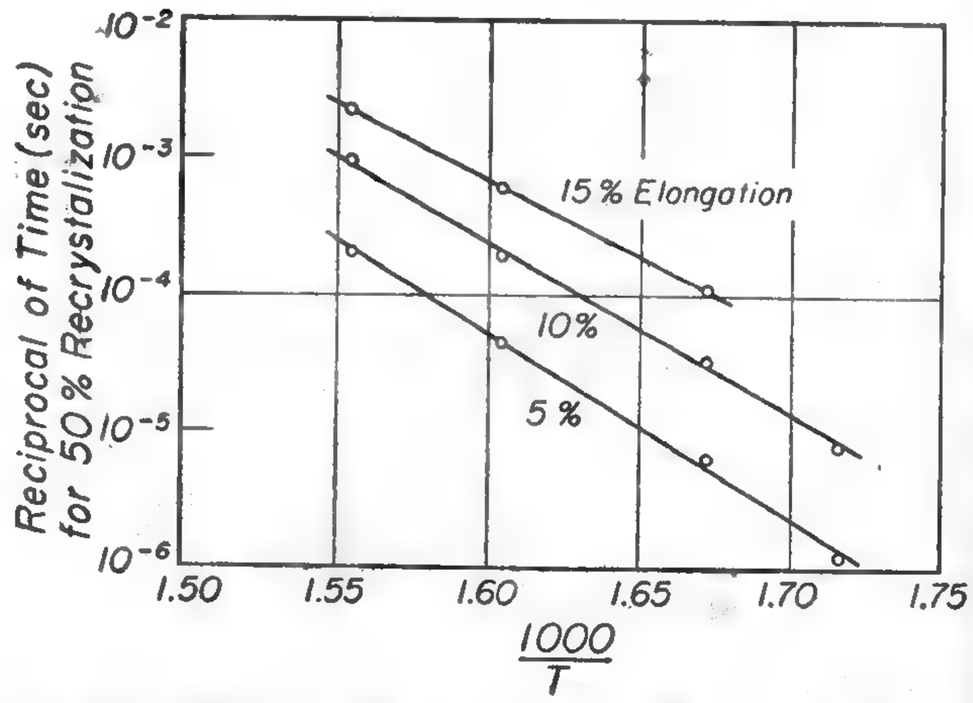

Fig. 9 Plot of reciprocal time for 50% recrystallization versus reciprocal of the absolute temperature for high-purity aluminum for 5, 10, and 15% cold work by tensile elongation. (Compare with reference article by W. A. Anderson and R. F. Mehl.)

The effect of temperature on the rate of recrystallization may be given either in diagrams of the form of Fig. 6, 7 or 8, or may be expressed more fundamentally in terms of rates of nucleation and growth. Whether the times for beginning recrystallization, or half or full recrystallization, or rates of nucleation and growth are employed, it is always observed that the rates vary exponentially with the reciprocal of the absolute temperature; that is, a plot of the logarithm of the rate versus the reciprocal of the abso-

lute temperature is a straight line. The slope of this curve, which is the temperature coefficient of the process, furnishes the "energy of activation of recrystallization". Figure 9 shows a plot of the logarithm of the reciprocal of the time required for 50% recrystallization—thus a measure of the rate of recrystallization—plotted against the reciprocal absolute temperature. This is for high-purity aluminum. The rate is evidently higher with increasing amounts of deformation. This fundamental law is widely applicable. Since time, percentage deformation and original grain size are variables, each determining the occurrence of recrystallization, it is evident that metals do not possess a "recrystallization temperature" of the nature of a physical constant; therefore the term should be avoided.

Recrystallized metals, like cold worked metals, can exhibit preferred orientations and directional properties, though they may not be identical with those which characterized the cold worked metal before recrystallization. Relatively little is known concerning the inheritance of preferred orientations during recrystallization, and no generalizations can be made.

Impurities in solid solution exert a pronounced effect upon recrystallization temperatures. The relatively minor variations in composition in the several varieties of copper represented in Fig. ▮ can be seen to have caused a difference of 100 C in the softening temperatures, and more extreme cases have been noted. Increasing concentrations in solid solution become increasingly less effective until, in a completely isomorphous system, a maximum recrystallization temperature is reached at an intermediate composition, which may be several hundred degrees Centigrade above those of the component metals. It has frequently been stated that impurities which do not form solid solutions have little effect on softening and recrystallization temperatures. This generalization is somewhat doubtful, for at least in the case of aluminum alloys, such impurities are employed to raise the temperatures required for recrystallization, and when present in a sufficiently fine state of subdivision are more powerful in this respect than elements in solid solution.

Grain Growth. Figure ▮ shows softening and recrystallization to have been completed at 400 C, but shows also an increasing grain size on heating beyond this temperature. This phenomenon in an essentially completely recrystallized and strain-free structure is known as grain growth. Presumably there is a tendency for the grain boundary area and thus the internal energy to decrease, or perhaps, as suggested recently, for certain relationships to obtain among the angles formed by the grain facets of maximum stability. Grain growth proceeds by the absorption of grains, usually of smaller by larger grains, and undoubtedly accompanies and overlaps recrystallization, at least to some degree. It is especially noticeable following the recrystallization of severely deformed aggregates, for the grain size after recrystallization in this instance is small and grain growth is readily noted; whereas in samples recrystallized after slight deformation, the grain size is large and the subsequent grain growth is minor. Grain growth continues with time, with the grain size increasing linearly with the logarithm of the time; and the rate of grain growth increases with increasing temperature, as may be inferred from Fig. 2, but the laws are not well known and need systematic study. Slow heating favors the growth of large grains, which under some circumstances may become very large.

Impurities in solid solution have a minor effect on grain growth, but undissolved impurities exert a pronounced effect. In very pure substances, grain growth proceeds steadily, with the average grain size increasing with increasing annealing temperature (Fig. 2.). But if undissolved impurities, such as ThO_2 in tungsten, iron in aluminum, lead in zinc, are present in the proper amount, the grain size is then small at low temperatures and suddenly increases in a narrow temperature range, forming unusually large crystals; when the amounts are larger, grain growth may be entirely obviated. Thus immiscible impurities may be used either to suppress grain growth at relatively low temperatures or to create unusually large grains at higher temperatures.

References

The bibliography on recrystallization is extraordinarily voluminous. It is unnecessary to reproduce all of it here. The most complete summary of this subject is the excellent and comprehensive monograph by W. G. Burgers, Rekristallisation Verformter Zustand und Erholung, III, "Handbuch der Metallphysik", lithoprinted by Edwards Brothers, Ann Arbor, Michigan, 1944. An extensive bibliography on the recrystallization of iron and steel has been given by H. F. Kaiser and H. F. Taylor: The Effect of Cold Deformation on the Recrystallization Properties of Armco Iron, Trans ASM, 27, 227 (1939). Recent work may be illustrated by the following papers: W. A. Anderson and R. F. Mehl, Trans AIME, 161, 140 (1945); L. W. Eastwood, R. W. James and R. F. Bell, Trans AIME, 133, 124 (1939); R. S. French, Trans AIME, 156, 195 (1944); D. Harker and E. R. Parker, Trans ASM, 34, 156 (1945); J. K. Stanley, Trans AIME, 162, 116 (1945).

The Martensite Transformation

By A. R. Troiano* and A. B. Greninger*

THE TERM "martensite" was proposed in 1895, by F. Osmond[1] in honor of the German metallurgist A. Martens, and at that time was used to designate the "constituent or structure" found in hardened steel. Later, as it became known that the hardness of quenched steel is a property of a needlelike constituent formed when austenite is allowed to transform at low temperatures, the use of the term was reserved for the constituent itself. During recent years it has been demonstrated that martensite results from a particular type of transformation completely unlike the normal transformation of phases by nucleation and growth. Furthermore, this martensite type of transformation has been found in a number of alloy systems, including nonferrous alloys, and undoubtedly occurs also in pure metals and compounds. The transformation has thus come to be recognized as a basic type of reaction in the solid state, and it is logical that investigators, both in this country and abroad, have adopted as general terms for any alloy, "martensite transformation" and "martensite" to designate the process and product respectively. The matter is therefore no longer confined to the metallurgy of steel.

* Professor of Metallurgy, University of Notre Dame, Notre Dame, Indiana.
* General Electric Company, Chemical Department, Richland, Wash.

It is the intent of this article to describe the known salient characteristics of the martensite transformation and to show how it differs basically from the more familiar process of transformation by nucleation and growth.

Transformation by Nucleation and Growth. It is desirable to review briefly the main facts concerning nucleation and growth. For binary alloys, phase transformations in the solid state are of four types, each associated with a characteristic region of the phase diagram. These four types of transformation are as follows: allotropic, precipitation, eutectoid and peritectoid. All these transformations proceed by (*a*) formation of *nuclei,* and (*b*) subsequent *growth* of these nuclei. They all depend on *time* and *temperature.* If they occur in an alloy, composition changes and diffusion are necessarily a part of the transformation process.

These transformations, especially the eutectoid, are most conveniently studied by allowing the reaction to proceed isothermally at some temperature below the equilibrium level. Under these conditions the reaction-rate curve (percentage transformed versus time) has a characteristic S-shape, although in certain instances the incubation period may be very short. The curves of beginning and end of transformation, plotted on temperature–log time coordinates have equally characteristic C-shapes, as shown

in Fig. 1. In this figure, the reader may note (*a*) that at temperatures just below the equilibrium temperature, the transformation begins only after a long delay; (*b*) that as the reaction temperature is lowered, the isothermal reaction rate increases to a maximum value (corresponding to the "nose" or "knee" of the curve); and (*c*) that

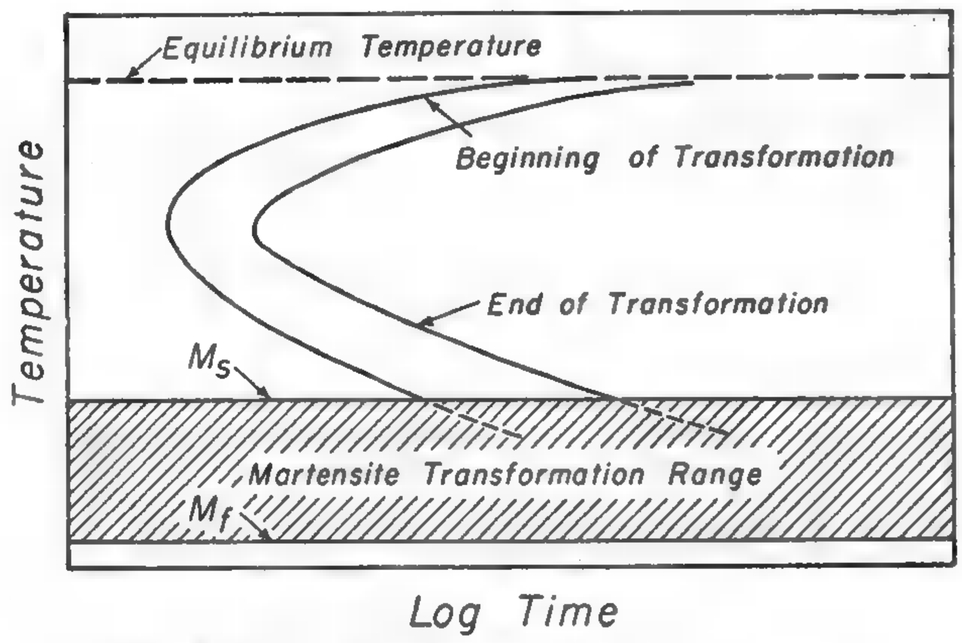

Fig. 1 Schematic representation of simple C-curve and martensite temperature range

for temperatures below the nose, the reaction rate is lower, the lower the temperature, approaching a zero rate at low temperatures, where diffusion for most alloy systems is negligible. It is in this temperature range, below the nose of the C-curve, that in certain alloys the martensite transformation, a diffusionless process, makes its appearance to complicate the simplified picture of the decomposition of a metastable phase.

Whether or not a solid solution, stable at high temperatures, may be retained intact at lower temperatures depends on the minimum incubation time—that is, the time interval at the nose of the C-curve during which no transformation occurs. The slowest cooling velocity (measured at the temperature of the minimum incubation period) that will accomplish this result, is termed the "critical cooling velocity" for the alloy. Actual values of this velocity for different alloys, range from the maximum to the minimum that can be produced experimentally. For example, in a 0.1% C iron-carbon alloy, this velocity is greater than 5000 °C per sec; for eutectoid beta copper-aluminum, approximately 1 °C per min; and for many alloys, furnace cooling will exceed the critical cooling

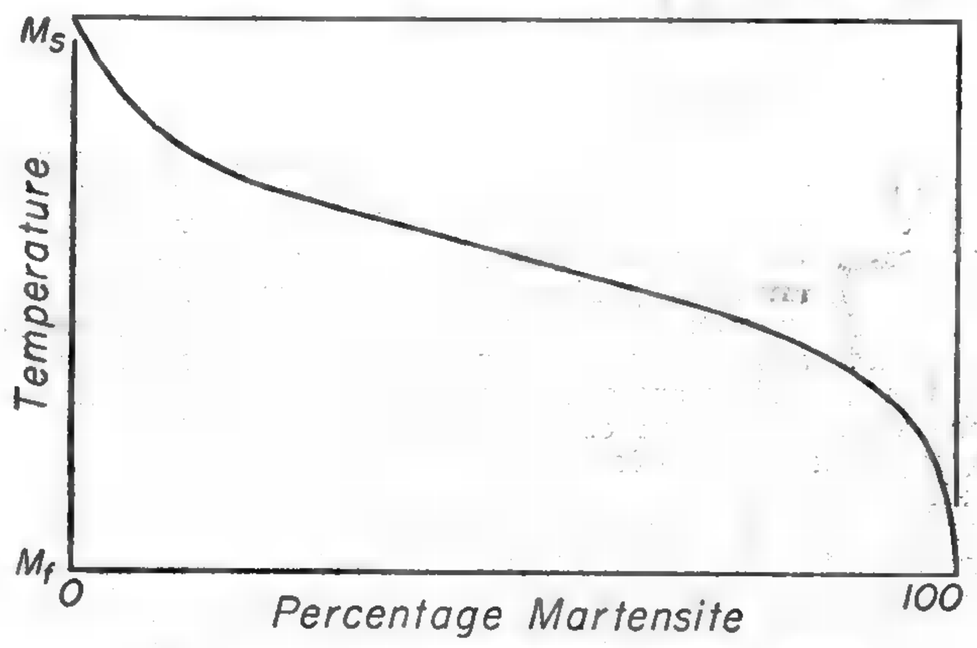

Fig. 2 Schematic representation of percentage of martensite formed as a function of temperature

velocity. For a given alloy, the critical velocity is also sensitive to variations in grain size of the parent phase.

Characteristics of the Martensite Transformation. The behavior of the martensite transformation is in sharp contrast with the diffusion type of transformation described above. The salient characteristics of the martensite transformation are the following:

1 The transformation is diffusionless and involves no change in chemical composition. A large array of evidence supports this fact. Measurements of the lattice constant indicate that the martensite has the same composition as the parent solid solution in both steel[2,3,4] and other alloys.[5,6] There is no nucleation followed by growth; rather, small discrete volumes of the parent solid solution suddenly change crystal structure. The most recent measurements[7] of the speed of formation of martensite have determined the time of formation of a single plate of martensite in an iron-nickel alloy to be approximately 7×10^{-5} sec. Goniometric measurements have shown that the transformation occurs by a process of homogeneous shear.[8] It follows (as shown also by X-rays[8]) that each platelike volume, after transformation, is a single crystal of martensite. All martensite crystals have a typical acicular microstructure. The regularity of the structure depends more on the temperature of formation than on the composition.[9] In general, the lower the temperature of formation, the more perfect is the acicular microstructure.

2 The transformation progresses only while the specimen is cooling; that is, more and more discrete volumes of the parent solid solution suddenly transform. The transformation ceases if the cooling is interrupted.[10,11,12] Thus, the transformation is independent of time[13] and depends for its progress only on the decrease in temperature. The amount of martensite existing at a given temperature in the martensite range is characteristic of the temperature and independent of the time at temperature.

The amount of martensite formed per degree of decrease in temperature is not a constant. The number of martensite needles produced at first is small. As the temperature continues to decrease, this number increases; and finally, near the end, it decreases again.[14,15,45] (Fig. 2)

3 The martensite transformation for a given alloy cannot be suppressed nor can the temperature of its beginning be depressed by the maximum cooling velocity obtainable.[11,12,16,17,18*] In other words, the temperature range of formation of martensite is characteristic of a given alloy and cannot be lowered by increasing the cooling velocity. The thermal arrest associated with the temperature of the beginning of formation of martensite in steel, has been known generally as Ar″. More recently the term M_s has been applied to the temperature of the start of martensite formation; and correspondingly the term M_f indicates the temperature of the finish. Both of these "critical" temperatures are of immediate commercial as well as fundamental importance, especially in steel. The variation of M_s with composition, in both plain carbon and alloy steels, has been the subject of considerable fruitful research in recent years. A few data exist concerning the effect of composition on the M_f temperature;[19,20] more are needed. The influence of composition on M_s and M_f in iron-carbon and copper-aluminum alloys is shown in Fig. 3. The influence of common alloying elements in steel on the M_s temperature is considered in the article on page 611.

4 All recorded martensite transformations have been shown to be reversible below the equilibrium temperature, except those in plain carbon and relatively low-alloy steels. In the steels mentioned above, the speed of the decomposition of the martensite is probably too great to allow an observation of reversibility by ordinary experimental means. However, reversibility has been observed[21] in the martensite of a high-nickel steel in which M_s was below room temperature. Apparently, in this alloy, the nickel content was high enough and the temperature low enough to slow down the decomposition of martensite sufficiently to allow it to go back into the original single crystal of austenite.

Some of the other systems in which reversibility has been definitely observed include the copper-aluminum,[22,23] the copper-zinc,[11,24] the copper-tin,[23] the iron-manganese,[17] and the iron-nickel[25] systems. In these and other systems, a single crystal of the parent solid solution will transform, in part at least, to many regularly oriented crystals of martensite, and during rapid reheating, will transform back again to a single crystal of the same initial orientation. A hysteresis effect is associated with this phenome-

* For a summary of the publications on this subject for steel, the reader may consult reference 16.

non; two examples are epsilon martensite in iron-manganese alloys,[17] and gamma-prime martensite in copper-aluminum alloys.[22]

■ All metastable phases that have M_f appreciably below room temperature, will also produce martensite during deformation at room temperature. This phenomenon is quite consistent with the fact that martensite forms by a process of homogeneous shear. Two well-known alloys in which this behavior is utilized extensively in industry are 18-8 Cr-Ni stainless steel and Hadfield's manganese steel. In addition, certain martensitic structures may themselves be transformed to a different crystal structure by deformation. This has been demonstrated clearly for epsilon martensite in the iron-manganese system,[17] and for beta-prime martensite in the copper-aluminum system.[26] In fact, it is apparently possible in some alloys to form more than one martensite structure directly from the metastable parent solid solution, by deformation.[17,26]

6 Martensite is probably never in a condition of real equilibrium, although many martensitic structures may persist indefinitely at or near room temperature. In general, the structure can be considered as a transition between the unstable phase and the final equilibrium condition. More than one transitional (martensitic) structure may exist at the same time. As illustrated above, it is possible, by deformation, to go from one transitional structure to another. Also, more than one martensitic structure can be formed directly from the parent solid solution and can coexist, as the result of quenching as well as of deformation; for example, iron-manganese alloys that contain approximately 15% Mn will form both alpha martensite and epsilon martensite during quenching.[17]

Examples of martensite crystal structures are the body-centered tetragonal martensite of the iron-carbon and related alloy steel systems,[27] the close-packed hexagonal gamma-prime and pseudohexagonal beta-prime structures of the copper-aluminum system,[26,28] the face-centered tetragonal structure of the copper-zinc[11] and the beta-prime structure of the copper-tin systems.[11,12]

In some instances, such as the gamma-to-alpha martensite in iron-nickel[6] and iron-manganese[17] alloys, the crystal structure is body-centered cubic, the same as the phase in equilibrium at low temperature, but is supersaturated, except for the relatively dilute solid solutions where the alloy has a composition within the homogeneous alpha-phase field.

7 The martensitic structure always has a greater hardness than the parent solid solution from which it is formed. However, extreme hardnesses are associated with martensite only in steel that contains appreciable amounts of carbon. The martensite structures often age harden during tempering. In steel it is possible to increase slightly the hardness of the as-quenched martensite.[29] For Fe-Co-W alloys, the increase in hardness on tempering is most striking.[30]

8 The martensite plates always form parallel to a given crystallographic plane of the parent lattice, and there is always a unique relationship between the lattices of martensite and the parent phase. Rarely does the martensite plate delineate a plane of low indices in the parent lattice. For example, in medium-carbon steels martensite delineates the {4 4 10} planes of the austenite; [31] in copper-tin, the {266} planes of the beta phase;[11] in copper-zinc, the {2 10 10} planes of the beta phase;[11] in copper-aluminum, the {244} and {266} planes of the beta phase.[26] In the copper-zinc system, the martensite plates possess the same orientation regardless of whether they are formed by quenching or by deformation.[11] The orientation habit is independent of the temperature of formation of the martensite for a given alloy; in other words, the martensite plates formed near M_s delineate the same plane of the parent lattice as those formed near M_f.[31]

Stabilization. In certain alloys, particularly alloy steels, the aging of the metastable solid solution (austenite, in steel) will result in a lowering of M_s. In alloy steels, where M_f is near or below room temperature, this effect will manifest itself further in an increase in the amount of austenite retained at room temperature. This phenomenon has come to be known as "stabilization", which may be defined as a lowering of the temperature range of martensite formation (or of a part of that range), resulting from aging, without change in composition of the parent solid solution.*

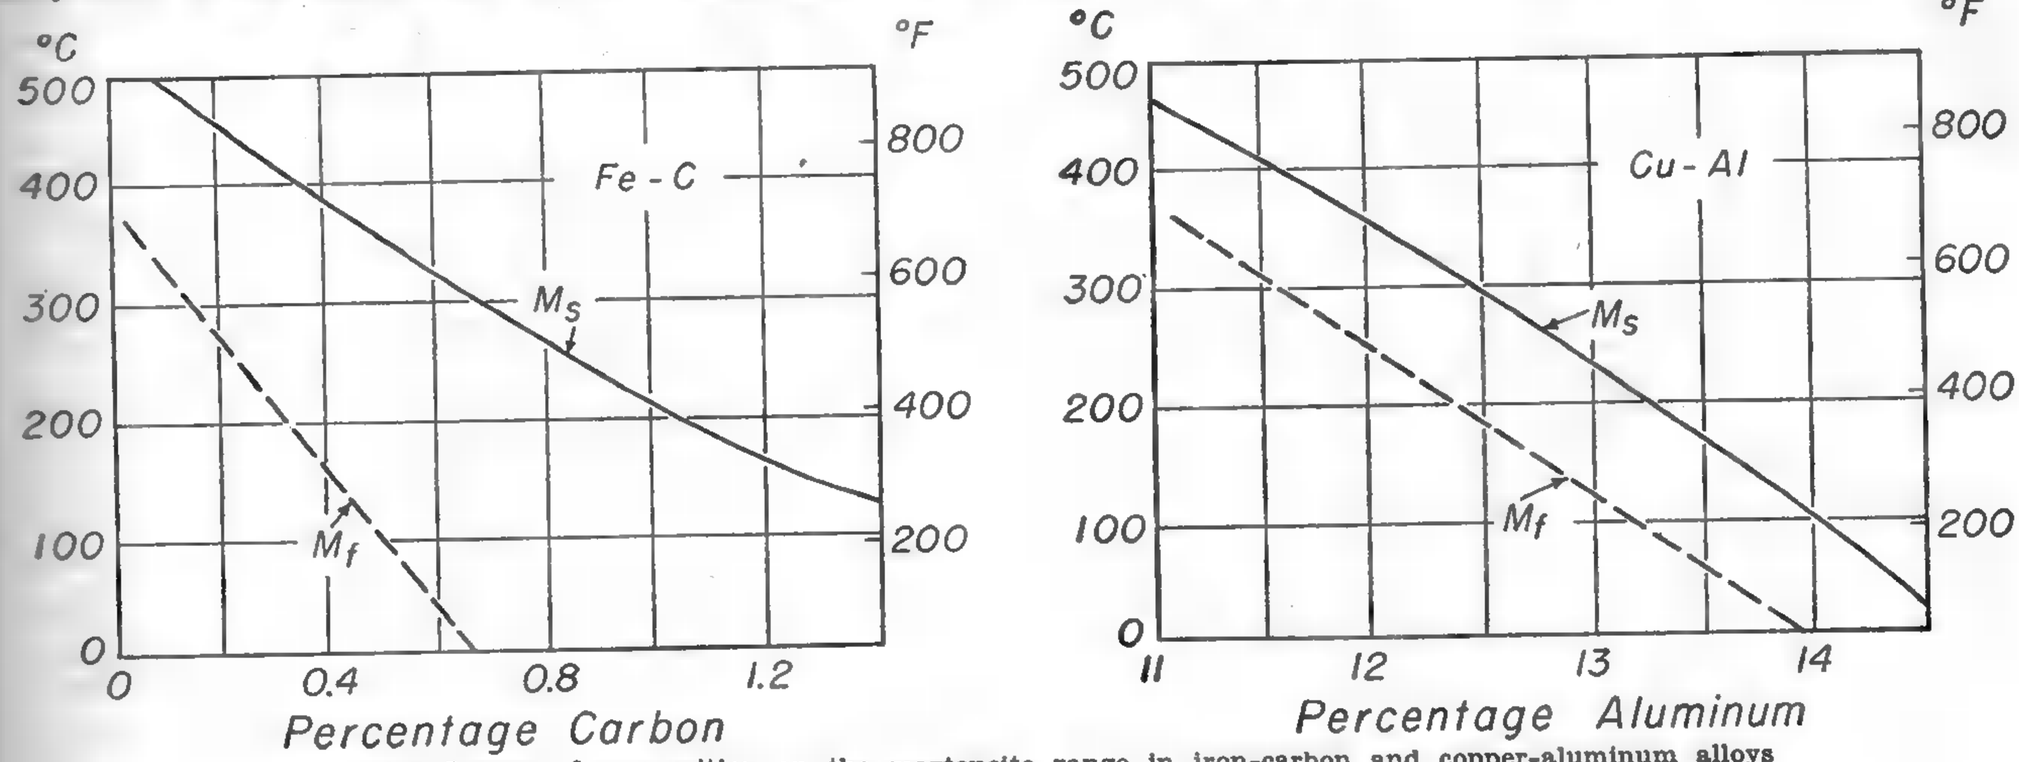

Fig. 3 Influence of composition on the martensite range in iron-carbon and copper-aluminum alloys

In steel, the time and temperature may or may not involve partial transformation of the austenite. Specifically, stabilization of austenite has been observed under the following conditions:

1 After partial transformation to martensite, followed by aging with or without further decomposition of the austenite to bainite, the subsequent formation of martensite during further cooling does not begin immediately, but starts at some lower temperature.[32,33] The amount of lowering is a function of the aging temperature and time.

■ After partial transformation to bainite, the M_s point is lowered.[31,34,35] The amount of lowering depends on the duration of holding at the bainite transformation temperature. In this connection, it is important to note that further aging in alloy steels, after the partial transformation to bainite has ceased, will continue to lower M_s.[36,37]

3 After aging at temperatures in the bainite range, but before any observable decomposition of austenite occurs, the M_s temperature is lowered in certain steels.[9,38] As in the previous citations, the amount of lowering depends on the temperature and duration of aging.

4 In certain systems where reversibility can be observed, such as iron-nickel[39] and copper-zinc alloys,[11] it has been found that heating and cooling several times

* Certain data (for instance, concerning high speed steel[37]) indicate that there is no appreciable effect of stabilization on M_f; while other data indicate that stabilization will lower M_f. For example, 3% Cr ferrite, after stabilizing, will retain gamma at room temperature,[19] yet M_f is well above room temperature.

through the martensite transformation temperature range will result in greater retention of the parent solid solution at any given temperature. This may also be considered evidence of stabilization of the parent solid solution.

There is similarity in the effect of temperature and time in all examples of stabilization. Qualitatively, for a given alloy, long times at low temperatures enhance stabilization. It appears logical to assume that the primary factors influencing stabilization are the temperature and duration of aging, and that the role of any decomposition is fortuitous and at most can exert only a secondary effect.

Martensite Transformation in Single Metals. Martensite transformations have been observed in many systems and they undoubtedly exist in many others where they have not yet been detected or where their presence has not been recognized by the investigator. There is ample reason to believe that even allotropic transformations of pure metals and compounds may occur by the martensite mechanism; for example, hexagonal cobalt can be formed by deformation of face-centered cubic cobalt at room temperature.[40,41,42] In addition, high-temperature X-ray work on cobalt shows (*a*) that the proportion of the cubic and hexagonal phases depends only on the temperature, and not on the time at temperature, and (*b*) that the transformation is reversible (with hysteresis) below the equilibrium temperatures.[43] Another example is hexagonal zirconium, which can be formed by deformation of the metastable body-centered cubic phase at room temperature.[42] The time for transformation of a given discrete volume of beta to alpha zirconium has been measured as approximately 3×10^{-4} sec.[7] In addition, published micrographs of metals that have allotropic modifications (for example, titanium[44]) suggest the existence of a martensite transformation.

In discussing the effects of combined shear and high hydrostatic pressure on phase transformations, Bridgeman states:[46] "It is also probable that there are certain reversible transitions which occur only under shearing stress, and will not occur at all with pure hydrostatic pressure; lithium is a probable example of one of these." It is further stated in this article that under conditions of constant, continuously applied shearing force the flow is sometimes interrupted by "snapping". Recently a low-temperature transformation has been found in lithium.[47] Normally body-centered cubic lithium, plastically deformed near minus 196 C, will partially transform to a face-centered cubic modification. The transformation is accompanied by audible clicks and exhibits reversibility with hysteresis.

It is apparent from the above discussion that the martensite type of transformation is an important mode of transformation in the solid state. Despite the relatively large amount of reliable data concerning this transformation, its characteristics and general ubiquity are not fully appreciated.

Fuels and Fuel-Heated Industrial Furnaces

By M. H. Mawhinney*

THIS section is a discussion of fuel-heated furnaces that operate at temperatures up to about 2400 F, and the fuels that are used in such furnaces. The classification includes furnaces for heat treating and for heating for rolling and forming operations, but does not include furnaces for the melting of metals.

Principles of Combustion. The combustion of fuel—solid, liquid or gaseous—consists of the rapid oxidation of the combustible portion to produce heat. The heat energy theoretically available depends on the net calorific value of the combustible content, and the temperature produced (theoretical flame temperature) depends on the gaseous products of combustion, which must be heated by this available energy. When the combustible elements (usually carbon and hydrogen) are combined with the theoretically correct amount of air, the resulting products of combustion are confined to carbon dioxide, water vapor and nitrogen (from the air). Any oxygen in the flue gases serves as a measure of the fuel-air mixture on the lean side (excess air), and carbon monoxide in the flue gases indicates the richness (excess fuel) of the mixture.

Fuels are usually sold on the basis of the "higher heating value" in Btu per unit of volume or weight, which is the gross chemical energy in the fuel. The "lower heating value" is the net useful Btu available after subtracting the heat which is necessary to convert the water in the flue gases to steam.

For most fuels (except producer gas and blast furnace gas) the amount of air required for combustion is about 1 cu ft for each 100 Btu of lower heating value. Table I shows the physical characteristics of the principal fuels used in heating furnaces.

Fuels for Heating Furnaces. Where metallurgical requirements are rigid, the most suitable fuels are clean gases and light fuel oil. The gaseous fuels are the most satisfactory for control of temperature and for maintenance of proper atmosphere in the furnace, but almost equal results are obtainable with light fuel oil, if care is used in furnace design and in supervision of operation.

For rougher forms of heating (forging, forming and rolling) solid fuels, heavy fuel oil and dirty gases may be used, although the specifications in this class of heating

are becoming more exacting, so that considerable care and supervision are needed to meet the requirements when the fuels used are unsuited to steady automatic control.

Solid Fuels. In the United States almost all the solid fuel used in heating furnaces is bituminous coal. This fuel may be hand-fired, stoker-fired, or fired in powdered form. Both stokers and powdered coal can be automatically controlled to maintain a satisfactory temperature in a furnace for heating steel in preparation for any forming operation. The principal objections to the use of stokers and powdered coal are the ash content that is carried into the furnace and the labor required for handling the coal and the ashes produced. For metallurgical furnaces, coal in any form should always be fired with forced draft from a fan, in order to maintain proper control over the furnace atmosphere and pressure.

Liquid Fuels. The principal liquid fuels for heating furnaces are oil, coal tar and pitch (topped coal tar). Properties of these and other fuels are given in Table I.

Industrial fuel oils may be conveniently divided into two classes, light fuel oil (No. 3) and heavier oils. The lighter grades of industrial fuel oils are recommended for all types of heat treating furnaces at temperatures below 1700 F (quenching, tempering, normalizing and annealing) and for any other furnaces where individual burners are required to burn less than 10 gal of oil per hr. The heavier oils can be used where the consumption is more than 10 gal per hr per burner in furnaces heated to temperatures higher than about 1700 F (for forging, rolling and so on).

In general, light fuel oils can be used without any preheating, except in the storage tank, but heavy oils require additional preheating to reduce viscosity (resistance to flow) below about 200 Saybolt-Universal seconds (about 200 F for Bunker C).

By-product tar is in approximately the same classification as the heaviest fuel oils, and requires considerable preheating. Pitch, which results after approximately 15% of the lighter oils have been distilled from by-product tar, is exceedingly heavy and very difficult to use satisfactorily in any heating furnace. It is ordinarily used in the open hearth furnaces for steel melting, where temperatures and rates of firing are high, and is preheated to about 350 F.

A recent development in fuels is the so-called colloidal fuel, made by mixing finely powdered coal with heavy fuel oil. A mixture containing 40% by wt of coal will weigh about 10 lb per gal and have a heating value of about 170,000 Btu per gal. The handling of this fuel is similar to that of heavy fuel oil, except that corrosive action, power required for pumping, and clogging of burners are somewhat increased by the coal content.

Dirty Gases. This classification includes blast furnace gas, coke-oven gas, and hot producer gas made from either bituminous or anthracite coal.

Blast furnace gas is not used alone as an industrial furnace fuel, but is sometimes mixed with coke-oven gas to produce a useful fuel (about 250 minimum Btu per cu ft of mixture for annealing and 350 Btu for heating billets). The supply of gas from the blast furnace is not steady; another disadvantage is that large pipes are required for its transportation. It contains considerable moisture and much dust; ordinary wet cleaning leaves 0.25 grains of dust per cu ft of gas and cyclone cleaning leaves 0.10 grains. Delivery pressure of this gas from the blast furnace is between 2 and 6 in. of water pressure.

Coke-oven gas is widely used in the steel mills for all types of heating, in spite of its dust and tar content. It is delivered from the coke ovens at a uniform rate and at a pressure of about 2 to 3 psi. The sulfur content is 500 to 550 grains per 100 cu ft, which is objectionable in some cases. The tar content seriously interferes with the use of devices for automatic control of furnaces.

Producer gas made from bituminous coal is exceedingly dirty and is used only in soaking pits and large heating furnaces in modern plants. Large brick-lined mains are required, which must be burned out regularly (about once a week) to remove the accumulation of tar and soot. Hot gas made from anthracite coal is entirely different, containing dry dust in considerable quantity, but no tar or soot. About 50% of the original sulfur content of the coal is removed in the ashes from the gas producer, but approximately 60 to 80 grains of sulfur remain per 100 cu ft of hot producer gas made from either bituminous or anthracite coal.

Clean Gases. This group includes natural gas, artificial gases made from coal or oil, liquefied petroleum gases and clean anthracite producer gas.

All these fuels can be controlled accurately and are ideal for heat treating furnaces at all temperatures, for operations requiring close regulation of temperature and furnace atmosphere. With the exception of clean anthracite gas (30 grains of sulfur per 100 cu ft) all these fuels have a sulfur content of less than 15 grains per 100 cu ft of gas.

The liquefied petroleum gases are shipped and stored in liquid form under relatively high pressure. Butane and propane are the common industrial fuels in this group. The gas may be withdrawn from the top of the container or liquid may be withdrawn and vaporized by controlled heat. The gases are handled and burned in the same manner as the other clean fuel gases, except that since butane requires 30.47 and propane, 23.82 volumes of air per volume of gas burned, high-pressure injector burners are not suitable, unless the gases are first mixed with air. Such a mixture is usually preferable to straight gas for distribution in a plant, because utilization is more efficient and condensation in the mains is reduced by mixture with air.

Methods of Applying Heat. Methods of heating furnaces by combustible fuels include:

1 *Recirculation.* A recirculating system is used for lower temperatures (usually lower than 1300 F) where gas or oil is burned in a separate chamber and the resulting products of combustion, together with air, are circulated vigorously in the furnace by a fan; or where circulating fans are arranged below the arch of a direct-fired furnace with suitable alloy baffles to provide circulation around the metal.

2 *Indirect Firing.* Indirect firing is used extensively for temperatures up to 1900 F, where combustion chambers are located below the heating chamber (underfired), beside (sidefired) or above (overfired), and are separated from the heating chamber by suitable baffles.

3 *Direct Firing.* Direct firing is almost always used for temperatures higher than 1900 F, with the burners firing directly into the heating chamber, usually above the charge. When the clean gaseous fuels are used, direct

Table II. Burner Systems for Heating Furnaces

Fuel	Designation	Approximate Pressure per sq in. Fuel	Air	Comments
Oil and tar	Steam atomizing	10 to 40 lb	½ to 4 oz	Steam at 60 lb min
	Low-pressure	10 to 40 lb	8 to 16 oz	40 to 50% induced air
Hot producer gas	Mixing type	2 in. water	4 oz to 5 lb	Scrapers or steam jets for cleaning tar and soot
Blast furnace gas	Proportioning	3 oz	8 to 16 oz	Automatic air-gas mixing
Clean gases	Blast type or nozzle mixing	4 to 8 oz	3 to 16 oz	Separate air and gas control
	Luminous or radiant	3 to 8 oz	3 to 8 oz	Separate air and gas control
	Low-pressure proportioning	3 oz	8 to 16 oz	Air inspirates gas at zero pressures
	High-pressure	10 to 25 lb	Atmosphere	Gas injects combustion air
	Complete premix	4 to 8 oz	Atmosphere	Mixture is supplied to burner from premix blower

firing is often employed for temperatures lower than 1900 F and as low as 1000 F with satisfactory results.

4 *Full Muffles and Retorts.* Either full muffles or retorts of metal, surrounding the heating material and heated from the outside, are employed to permit the use of a protective atmosphere around the charge while it is being heated. The words "muffle" and "retort" are frequently confused in furnace engineering. Generally, a muffle is defined as a permanent container within the furnace, into which work is introduced for heating; while a retort is a container loaded outside the furnace and then charged into the furnace or covered by a bell-type furnace.

■ *Radiant Tubes.* Radiant tubes of alloy or refractory, with combustion inside the tubes, are used in conjunction with tightly sealed furnace casing and openings in order that protective gas may be introduced into the furnace around the heating material. This arrangement of fuel-heated furnace competes directly with electric furnaces employing resistor elements.

6 *Cup Burners.* Patterned combustion, employing special cup-shaped burners of high-temperature radiant design, sometimes replaces large furnaces in special heating processes and competes with electric induction heating.

Burner System for Heating Furnaces. The various types of burners commonly used are given in Table II.

Muffles. Carbofrax muffles are used for high-temperature annealing of stainless steel in an atmosphere of air; but where a protective atmosphere is used at lower temperatures, as in the bright annealing of metals, a tight muffle or retort of heat-resisting alloy is usually employed. The construction and maintenance of such muffles in any size is seriously complicated by warpage from uneven expansion and contraction.

The use of a muffle decreases the heating capacity of a furnace about 20%, as compared with an open-fired furnace, and the fuel consumption is increased by the necessity of higher temperatures outside the muffle, with consequently higher losses by radiation.

Pot Furnaces. Pot furnaces are frequently used for heat treating. Although costly and troublesome because of the necessity for pot replacement and because of losses of liquid heating medium, pot furnaces have the advantages of ability to heat steel without oxidation of the charge, to heat rapidly and uniformly and, if desirable, to treat only a portion of the work piece, without affecting the remainder. Heat treating salts and lead are commonly used as the heating mediums.

Pot furnaces are being heated to an increasing extent by electric induction current; electrodes are immersed in the salt. In this arrangement the heat is not forced through the walls of the pot, as in fuel-heated pots; therefore the life of the pot is greatly increased. At high temperatures the pot can be eliminated and the salt can be held directly within the brick lining of the furnace chamber.

Material Handling in Furnaces. The selection of the best method for conveying material through furnaces involves difficult problems. The rules listed below should always be followed:

1 The method of conveying material must not interfere with the heating characteristics of the furnace.
2 The advantage of simplicity of design of hot conveyers should not be overlooked in a desire to save labor.
3 In the selection of means for conveying, those which will damage the material under consideration must be eliminated. There must be no scratching, damage to threaded parts, sagging or denting of coils and tubular products.

The various furnaces for industrial heating include:

Batch. The batch types include stationary hearth, solid bottom; stationary hearth, roller bottom; car bottom; bell type, round or rectangular; and pit type.

Semicontinuous. These include stationary hearth or car-bottom furnaces in conjunction with handling forks or peels or special cranes to reduce the interval between charges to a few seconds or minutes, so that virtually continuous operation is obtained from a series of batch-type furnaces.

Continuous. These include pushers, direct or on pans or shoes; tunnel kiln with cars; chain conveyer or moving fingers; mesh belts; slat conveyers; walking beam; roller hearth; rotating hearth; rotating retort; strand or strip furnaces; and miscellaneous special types.

Furnace Materials. For estimating comparative operating costs of different designs of fuel-heated furnaces, it is safe to assume that firebrick linings will last for 5 yr at temperatures below 1900 F and for 1 yr above 2000 F. This does not apply to doorjambs, piers, and bridgewalls, which will require additional patching. The life of metal parts that are properly designed for stress and for usual furnace conditions will be approximately as follows:

Working Temp, deg Fahr	Cast Iron	Heat-Resisting Alloys
Below 1400	5 yr	....
1700	1 yr	3 yr
1800	5 mo	2 yr
1900	1 mo	1½ yr
2000	not used	6 mo

The nickel and chromium contents of certain heat-resisting alloys commonly used in furnace parts include:

Furnace Temp Below 1400 F		Furnace Temp Above 1400 F	
Nickel, %	Chromium, %	Nickel, %	Chromium, %
25	20	68	18
18	8	60	12
8	18	38	18
..	28	35	15
..	18	30	10
		12	28
		11	25

Remainder, iron

All doors and other openings in furnaces should be surrounded by iron castings protected from the heat by refractories. The doors are usually iron castings lined with brick or plastic insulation and should be counterweighted. In small sizes the doors may be operated by hand. Large doors should be operated by motor, air pressure, or oil-hydraulic pressure cylinders.

Flues are provided in a fuel-heated furnace to permit the escape of the products of combustion of the fuel. The size of these openings should be such that they can be adjusted to maintain a slight pressure (about 0.010 in. water) in the furnace to exclude air. Required flue area varies with the rate of firing, temperature, arrangement and location of flues. The best plan is to provide ample flue area and damper regulation to permit control of the furnace pressure under all conditions. Flue areas may be determined with the aid of the following table:

Table III. Flue Areas, in Square Inches per Unit of Fuel Burned per Hour

Fuel and Unit	Furnace Temperature, deg Fahr 1000	2000
Bituminous coal, lb	1.47	2.01
Fuel oil, gal	14.20	19.40
Butane or propane, cu ft	0.30	0.41
Natural gas, cu ft	0.11	0.15
Coke-oven gas, cu ft	0.05	0.06
Artificial gas, cu ft	0.06	0.08
Raw producer gas, cu ft	0.02	0.02

The use of stacks with heating furnaces has been almost entirely discontinued, because modern burners do not require stack draft and because the usual failure to control the stack draft by proper damper operation, results in large quantities of excess air in the furnace at low fuel rates.

Determination of Furnace Size.* The size of furnace required depends on the amount of material to be heated per hour, the heating time required, the size of the pieces to be heated, and the amount of heat that can be liberated without excessive damage to the furnace. The efficiency and refractory life obtained depend on the correctness of the furnace size.

The heating time in the furnace depends on the nature of the heating process. For thorough heating only, the time may be estimated from such rules as 5 min for each ⅛ in. of thickness of flat plates of steel (heated from one side) and 20 min per in. of diam for round steel bars. These rules apply when the furnace temperature is above 1400 F. At 800 F, without forced circulation, the time is

* From Combustion Furnace Section, by M. H. Mawhinney, "Marks' Mechanical Engineers' Handbook", 3rd Ed, McGraw-Hill Book Co.

increased about 100%, and below 800 F it may require as much as three times as long to heat thoroughly as it does above 1400 F. The time required for heating varies also with the material to be heated. Brass requires about one half as long as steel to heat, and copper requires 40% as long. The above rules represent the time in which the material will conduct heat to its interior; they can be misleading in that they do not express the ability of the furnace brickwork to transmit the necessary heat. The rules also assume that the material is fully exposed to the heat of the furnace. Piling of material in a furnace lengthens the heating to an extent that cannot be estimated numerically, but must be determined by actual trial. Besides simple thorough heating, additional time is frequently required for holding at temperature.

The weight of material in the furnace at any time is the product of the weight of material discharged per hour, multiplied by the heating time in hours. When the weight and sizes of pieces involved are known, the area required in the furnace can then be fixed. The width and length of the furnace to produce this hearth area are determined by the method of firing to be used and the method of manipulating the material.

The life of a furnace at a given temperature and the size required in some applications depend on the rate of heating, which may be expressed in pounds per square foot of hearth area per hour. The maximum rate allowable for heating steel is about 40 lb per sq ft per hr for heat treating furnaces and about 80 lb per sq ft per hr for furnaces used for heating steel for rolling or forming. These are upper limits which should not be exceeded if satisfactory life is to be obtained from the refractories. These rates are for the heating of mild steel, and may be about twice as great for heating brass, 2½ times as great for copper, and only 0.7 as great for certain alloy steels with low conductivity. These maximum allowable rates should be used for checking the calculation of furnace size from physical dimensions and heating time, because material cannot be heated properly at higher rates.

Example of Calculation. If a furnace is required to heat 20 pieces per hr, weighing 30 lb each and requiring a heating time of ½ hr, the furnace must be large enough to hold ½ × 20 = 10 pieces. If each piece requires a hearth area of 2 sq ft, the area of the hearth will be 2 × 10 = 20 sq ft for a single layer of pieces in the furnace. If the furnace is of the batch type, a size of 4 ft wide by 5 ft deep would probably be about right for convenient handling. Checking the rate of heating, 20 pieces per hr × 30 lb ÷ 20 sq ft = 30 lb per sq ft per hr. For this rate an underfired furnace would be satisfactory, but with direct heating a smaller furnace could be used, if the pieces could be more densely piled without interfering with satisfactory heating.

The allowable rate of heating, expressed in lb per sq ft of hearth area per hr, varies with the temperature. At lower temperatures of about 1000 F, the usual rate in a directly heated furnace is about 25 lb per sq ft per hr, compared with the allowable rate of 40 lb given above for heat treating at 1500 to 1600 F. When forced circulation is utilized, this rate may be increased to equal the rate at higher temperatures in either fuel-heated or electric furnaces. At heat treating temperatures of 1500 to 1600 F or higher, forced circulation will not increase the rate of heating sufficiently to be worth while, because the amount of heat transferred by convection at these temperatures is relatively small.

Economy of Furnaces. The heat input to a heating furnace is distributed in various ways, depending on the type of furnace. Ordinarily, the heat balance includes useful heat to the material; heat to conveyer, shoes or pans; radiation and absorption by the furnace lining; radiation through openings; sensible heat in waste flue gases; and heat in unburned fuel in fuel-heated furnaces. Miscellaneous additional items include heat to water-cooled parts, radiation from cars of car-bottom furnaces while charging, or conduction from metal parts extending out of the furnace.*

* The methods of calculating these various losses may be found in "Industrial Heating Furnaces", by W. Trinks, and "Practical Industrial Furnace Design", by M. H. Mawhinney, both published by John Wiley & Sons, Inc.

It is customary to line electric furnaces with a greater quantity of insulation than is used in fuel-heated furnaces, on account of the higher cost of electric current per unit of heat. However, because of the absence of waste gases in electric furnaces, this smaller amount of radiation appears in the heat balance as a greater percentage of the heat input.

Table IV gives the average fuel economies for typical heating furnaces, expressed in Btu per pound of material heated in fuel-heated furnaces, and in kilowatt hours per ton for electric furnaces. The values given represent good operation at efficient rates of production, and are for operation without recuperators or other heat-saving devices. To estimate the fuel consumption, divide the economy given in Btu per pound by the lower heating value of the fuel under consideration (from Table I). The values of Table IV are typical figures and will vary for different furnaces.

Table IV. Fuel Economies for Heating Furnaces

Operation	Average Temperature, deg Fahr	Average Economy Good Operation Fuel, Btu/lb	Electric, kwhr/ton

(a) Economies for carburizing furnaces are fuel per gross weight, including boxes and compounds. The values will vary with the depth of case required.

Furnace Atmospheres. Atmosphere in a fuel-heated furnace may be the products of combustion of the fuel; in an electric, muffle or radiant-tube furnace, it may be a special protective atmosphere surrounding the work.

Atmosphere in Fuel-Heated Furnaces. In general, it has been found that scaling or oxidizing gases in a furnace atmosphere are carbon dioxide, water vapor, and oxygen (resulting from an excess of combustion air or infiltration from the outside), while reducing constituents are carbon monoxide, hydrogen and unburned hydrocarbons from the fuel. The scaling action of the atmosphere for any temperature and for any duration of contact depends on the relative amounts of these two types of gases in the atmosphere of the furnace. The so-called neutral atmosphere, where the theoretically correct quantity of air is introduced with the fuel, resulting in the complete absence of oxygen or carbon monoxide in the atmosphere, is in reality a scaling atmosphere, because the proportions of carbon

dioxide and water vapor are high. To reduce the scaling of carbon steel to 50% of that resulting with this atmosphere requires an excess of fuel necessary to produce about 2% CO in the flue gases at 1700 F and about 14% CO at 2300 F. To eliminate scaling in a combustion furnace is practically impossible. Sulfur in the fuel also increases the amount of scaling of steel.

Besides causing scaling, the atmosphere of a fuel-heated furnace will also frequently decarburize steel. Moist hydrogen and water vapor are principally responsible, with carbon dioxide and infiltrated air contributing to this result. Where decarburization of steel is to be avoided as much as possible, an oxidizing atmosphere is usually the best, with about 3% O_2 in the flue gas. The reasons for this are that all hydrogen is converted to water vapor in this atmosphere (eliminating the moist hydrogen combination) and that the additional scale formed on the steel not only inhibits decarburization but removes a part of the decarburized skin when scale is removed from the steel after heating.

The conditions which reduce scaling and decarburization, in their probable order of importance include: (1) minimum temperature in the furnace, (2) minimum time in the furnace, (3) positive furnace pressure, to exclude free air, (4) low hydrogen content in fuel burned, (5) air-fuel ratio slightly oxidizing.

Factors 4 and 5 must necessarily be considered together, because the nature of the different industrial fuels is so variable. The best fuel for heating steel is that which contains a minimum of hydrogen and at the same time can be accurately controlled. Table I shows that coal is very low in contained hydrogen; but coal in most forms (hand-fired, powdered, or in raw producer gas) is difficult to control, particularly at low and intermediate temperatures, so that the desired ratio of air to fuel cannot be consistently maintained. Washed producer gas from anthracite coal and coke satisfies both requirements. Coke-oven gas is high in hydrogen and contains large amounts of objectionable sulfur which, together with some difficulty in control, makes it an undesirable fuel in its usual form. Artificial gases, natural gas and liquefied petroleum gases are relatively high in hydrogen, but this disadvantage is largely offset by their accuracy of combustion control. Light fuel oil is relatively low in hydrogen and is a very desirable fuel, if care is taken in the control of combustion.

Heating in Protective Gas. The heating of steel while it is surrounded by a protective gas atmosphere is a highly important development in furnace design. This is accomplished in electric furnaces with sealed outer shells, alloy muffle or retort furnaces, or furnaces heated by radiating tubes instead of electric elements.

Protective furnace atmospheres are discussed in the article on page 294, where the principles involved in the preparation and purification of atmospheres are described.

Automatic Control of Furnaces. Automatic control of furnaces involves control of temperature, fuel-air ratio, and furnace pressure.

Automatic temperature control comprises a thermocouple or other measuring device at the furnace, a controlling pyrometer operated by the thermocouple, and a fuel valve operated by the pyrometer. The pyrometer may be indicating only or recording, and may be arranged for two-position (high-low) operation or for proportioning (multi-position) control, if it is desirable to eliminate the fluctuation between maximum and minimum control temperature, which is characteristic of two-position control. There are many different types of controlling instruments from which to choose and the accuracy of these instruments is being constantly improved by the application of electronic and other new principles to their operation.

The methods of fuel and air control commonly used for fuel-heated furnaces include:

1 Manual adjustment of fuel and air valves for high and low settings with two-pipe burner systems, using oil or gas fuel, and having two-position control.
2 Proportioning valves depending on constant air and fuel pressure and a constant ratio of air and fuel orifices at all settings. These are used with two-pipe burner systems, oil or gas fuel, and with either two-position or proportioning controllers.
3 High-pressure gas burners or injectors, where the gas injects a constant ratio of air for combustion. A control valve is required for gas only; the system can be used with any type controller.
4 Low-pressure proportioning systems for gas, which is reduced to zero pressure and automatically inspirated at constant ratio by the air flow. A control valve for air only is required and all types of controllers can be used.

Table V. Comparison of Fuels

Fuel and Unit of Measure	Furnace Temp, deg Fahr	Net Btu per Unit	Cost per Unit Prepared or Delivered, cents	Units Equiv to One Kwhr	Cost Equiv to One Kwhr, cents	Cost per Million Btu As Delivered, cents	Cost per Million Btu Left in Furnace after Flue Gas Losses, cents

	2000	....	...	126.5	0.290	...	87

5 Cross-connected control, in which air pressure in the air line beyond the control valve is transmitted to a governor in the fuel line (gas or oil fuel) to regulate the fuel in constant proportion to the air. An air valve only is required and may be actuated by any type of control.
6 Balancing systems, in which a change in flow of air or fuel through an orifice causes a change in pressure drop, which is transmitted by one of many devices to the valve controlling the other medium (fuel or air) to bring the pressure drop into balance. One control valve is required with any type of controller.
7 Premixing of fuel (gas) and air in a compressor, with proportioned air and gas valves in the suction inlet. By this arrangement, an air-gas mixture is transmitted through all manifolds, and the control valve controls the mixture.

Automatic control of pressure involves the control of a flue damper to maintain a constant pressure in the furnace at all times, in spite of fuel rate variation, door operation or other changes. Equipment is available for this purpose, which operates on a number of different principles to accomplish the same result.

Control of furnace temperature is discussed more fully in the article on page 174.

Comparative Costs of Fuels. In comparing the costs of furnace operation, the major items for consideration are fuel, furnace efficiency, charges on the investment, labor and maintenance.

The last four items depend largely on the construction of the furnace, the type of conveyer or other mechanism used for handling, and the type of combustion equipment employed. An accurate comparison of fuel cost must include a consideration of the percentage of heat lost in the flue gases. For example, all the heat liberated in an electric furnace at all temperatures goes to heating the metals, the furnace lining, radiation through openings, and such losses. In contrast, a fuel-heated furnace involves an additional loss in the flue gases leaving the furnace. Table V gives the amounts of different fuels which equal 1 kwhr of electric heat at different temperatures, after correcting for flue gas losses. The comparative cost is also shown in the table, based on assumed fuel costs which are given. The Btu equivalent of 1 kwhr used in this table is 3415.

The figures in Table V afford a comparison of the cost of heating with various fuels, assuming perfect combustion and the same furnace construction in all instances. In actual practice, more insulation is generally used on electric furnaces because of the relatively high Btu cost of electricity, so that in many instances the relative cost of electricity as compared with other fuels is slightly less than is indicated by the table.

The cost of fuels is a guide in their selection, but should never be used alone to determine the best fuel for any given conditions. The relative convenience and cost of preparation should be carefully studied. Of even more importance is the kind of heating possible with various fuels, including accuracy of control and nature of surface obtainable. The fundamental purpose of a furnace is to heat a given material properly, and frequently the savings from the use of a cheap fuel are quickly lost in the cost of material spoiled by improper heating. The nature of subsequent operations, such as cleaning and machining, the probable percentage of rejections in finished work, and the continuity of service obtainable with the different fuels must all be taken into account, if fuel costs are to be compared accurately.

Fuel to Heat Cold Furnace. It is often desirable to know the approximate quantity of fuel required to heat a furnace from cold to operating temperature. This may be calculated from the data in Table VI. These values are based on the usual practice of firing hard at the start and cutting down on the fuel rate as the furnace comes up to temperature. The values vary somewhat with furnace design.

The following illustrates the use of Table VI for calculating the quantity of fuel oil required to heat a firebrick furnace having 1000 sq ft of interior area, from cold to 1500 F in 4 hr.

$$\frac{4 \text{ hr} \times 6800 \times 1000 \text{ sq ft}}{140{,}000 \text{ Btu per gal}} = 194 \text{ gal oil}$$

Furnaces lined with the so-called "light refractories" which are made to combine a part of the advantages of both firebrick and insulating bricks, will heat in about one half the time required for firebrick, with the same rate of heat input.

Table VI. Rate of Heat Liberation (Btu fired per sq ft of interior per hr) Required to Heat Firebrick-Lined Furnace to Temperature in Given Time

Hours to Final Temperature Ready for Operation	Operating Temperature, deg Fahr		
	1000	1500	2000
2	6000	12000	....
4	4200	6800	13500
6	3300	5100	8000
8	2700	4300	6000
10	2200	3800	5200
12	1800	3300	4800
14	1600	3000	4500

Operation of Gas and Oil Burners. There are several fundamental facts that are important to remember when lighting furnaces equipped with oil or gas burners. For all fuel-heated furnaces, observe the following rules:

1 Open all doors before lighting the furnace.
2 Always purge the furnace by means of air from the blower before lighting, making sure that all fuel valves to the furnace are closed during this purging cycle.
3 When lighting oil burners or gas burners of the blast type (two pipe), turn the air on first, then the fuel.
4 When lighting gas burners of the proportional-mixing, low-pressure type, always open the gas supply valve wide; all regulation of fuel is by the air flow and the ratio-adjusting screw on the mixer.
5 When shutting off an oil burner or a gas burner of any type, always shut off the fuel first.

Because of rapid ignition of most gaseous fuels, there is generally little difficulty in keeping gas burners lighted. However, care must be taken when lighting oil burners. When the finely divided atomized oil strikes cold surfaces in the furnace, condensation takes place and separated carbon, burning with insufficient air, causes dense smoke. Small quantities of oil should be burned with excess air, until the burner block becomes red hot, in order to assist in vaporization of the oil and to maintain ignition. A baffle in the form of a steel bar inserted from the outside and projecting in front of the burner will assist in lighting most oil burners, because it keeps the velocity of the atomized oil below that of ignition, and affords the mixture an opportunity to light before passing through the furnace chamber.

When lighting a furnace that has several burners, it is best to light properly one or two at a time, rather than to attempt to light all burners at once. The reason is that unburned combustion gases constitute an effective fire extinguisher, and several improperly adjusted burners will interfere with the lighting of the others.

A newly constructed furnace should be slowly dried out with gradually increasing temperature to avoid spalling and cracking. This process should take two or three days, while the moisture in the brick and clay is slowly converted to steam and released without damage to the brick structure. When a large furnace is to be heated to 2000 F, a good schedule of drying is as follows: 10 hr below 500 F; 11 hr below 1000 F; 8 hr below 1500 F; and 8 hr below 2000 F, giving a total time of 34 hr.

After the furnace has been heated to the required temperature and the doors have been closed, the total flue area should be partially closed until a pressure of about 0.01 in. water exists in all parts of the furnace. Temperature uniformity may be partially controlled by closing the proper flues when regulating to the proper pressure. In general, the flues at the hotter portions of the furnace should be closed to force more gas and heat toward flues left open in the colder portions of the furnace.

Electrically Heated Industrial Furnaces

By R. M. Cherry* and William Adam, Jr.*

ELECTRIC FURNACES may be classified according to the medium in which the work material is heated, or according to the design of the heating chamber, of the electrical arrangements, and of the method of moving the work material into, through and out of the furnace. In the metal industries the heating medium is usually a gas or a liquid salt, either of which may be heated by the resistance of a conductor ("heating unit") through which an electric current is passing. Liquid salt frequently is heated by an electrode that is immersed in the bath.

Resistance Furnaces. The resistance furnace consists essentially of a heating chamber containing heating units that may be mounted on the furnace walls, roof, floor or door, depending on the application; means for controlling the amount of heat; means for supporting the work pieces in the furnace, or conveying them through the furnace; an inside lining of insulating refractory backed by suitable heat insulation; and frequently a cooling chamber and protective atmosphere.

The heat is transmitted to the work by radiation and convection; the higher the temperature, the greater the amount of radiant heat.

Resistance furnaces are used for annealing, normalizing, hardening, tempering, carburizing, nitriding, brazing,

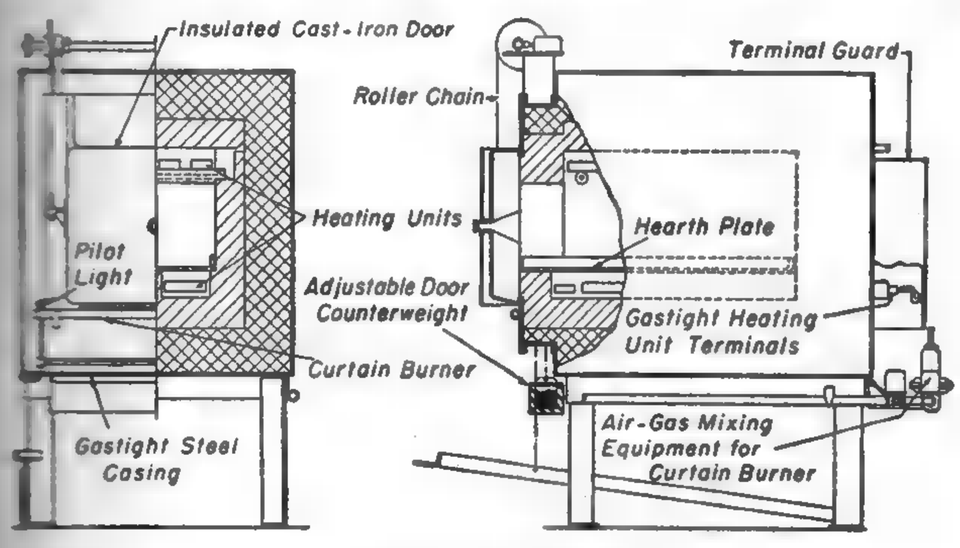

Fig. 1 Typical box furnace

porcelain enameling, hot dip galvanizing, sintering and other treatments.

Heating Units. The heating units are made of metal in ribbon, rod or cast form, or of a nonmetallic material such as silicon carbide, usually in the form of a round bar.

Nickel-chromium and nickel-chromium-iron alloys are used for the heating units of furnaces that operate at temperatures up to 2100 F, with or without protective atmosphere. For temperatures up to 2500 F, the silicon carbide

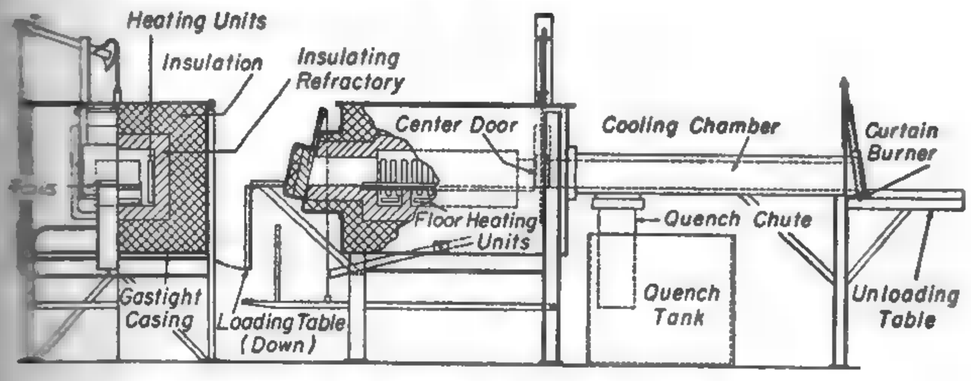

Fig. 2 Typical box furnace with a cooling chamber

heating unit may be used with or without a protective atmosphere.

Pure molybdenum is suitable material for units where a protective atmosphere is used and where operating temperatures above 2100 F are required. Large production furnaces are made for temperatures up to 2500 F, and small laboratory furnaces for temperatures up to 3000 F.

* Assistant Manager, Industrial Heating Division, General Electric Company, Schenectady
* Vice President, Ajax Electric Company, Inc., Philadelphia

Most resistance furnaces are used at temperatures below 2100 F, and the nickel-chromium and nickel-chromium-iron alloys are used for the heating units.

The design of these metallic heating units is important since it involves supporting, placing and spacing the heating units, and also the thickness of material to be used for these units and the amount of heat to be dissipated per unit area. The life of these heating units is determined largely by the thickness and by the maximum temperature of the heating unit at its hottest point. The maximum temperature at any point on the unit, for a given furnace temperature, will depend on the amount of heat dissipated per unit area (watts per square inch of heater surface), the shape and spacing of the heating unit, and the muffling effect of the supports used. The less the supports for the heating unit interfere with radiation and convection, the lower the temperature of the heating unit at points of support.

The nickel-chromium and nickel-chromium-iron alloys depend on a coating of oxide as protection against further oxidation. Therefore the heating unit must be thick enough so that the oxide coating that is formed, will be thin in comparison with the thickness of the unit.

The allowable heat density, or watts per square inch, will depend on the operating temperature and on whether or not forced convection is used.

Types of Furnaces. There are many standard types of furnaces. The differences depend largely on requirements for charging metal into the furnace and discharging.

The selection of the size and type of furnace for a given application, depends primarily on the particular heating process involved, the expected rate of production, and the most efficient means of moving the given parts to,

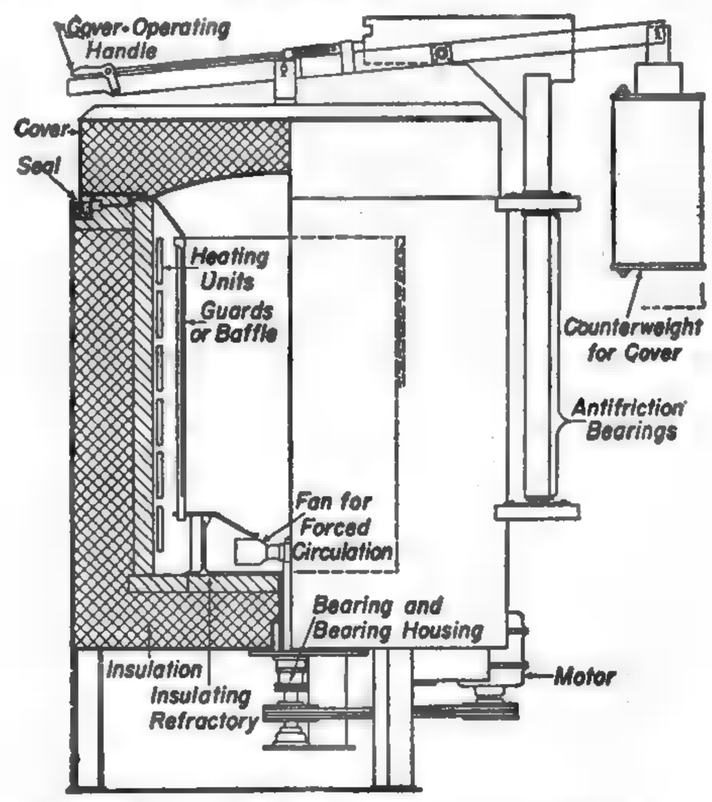

Fig. 3 Typical cylindrical pit furnace with a fan

through, and from the furnace. Some of the common types of furnaces are discussed below.

Box Furnace (Fig. 1 and 2). This type has a heating chamber in the shape of a box, a door at one or both ends, and a hearth for supporting the work pieces. The furnace may be provided with a cooling chamber and with a fan for heating by forced convection. The parts to be treated are charged and discharged manually, either individually or in containers.

Box furnaces are used principally in the hardening of carbon and alloy steels, in the preheating and hardening of high speed steel, and in annealing, normalizing, pack carburizing, porcelain enameling, brazing and tempering.

Pit Furnace (Fig. 3). This type of furnace may be either circular or rectangular with the opening in the top and with an insulated cover. The furnace may be equipped with a fan at top or bottom for circulating the atmosphere

or for heating by forced convection, and may have a retort.

The work may be supported on a load platform in the bottom of the furnace, or may be suspended from the top of the furnace or loaded in containers.

Pit furnaces are used chiefly for the hardening, tempering, annealing, normalizing and gas carburizing of steel, and the heating of aluminum and magnesium alloys.

Car Furnace (*Fig. 4*). The car furnace is essentially a large box furnace with the bottom and hearth mounted on wheels so that the car can be withdrawn for loading and unloading.

Car furnaces are used chiefly for the annealing and tempering of alloy steel bar stock, tubes and forgings; the annealing of steel castings; the annealing and aging of iron castings; the stress relieving of welded structures;

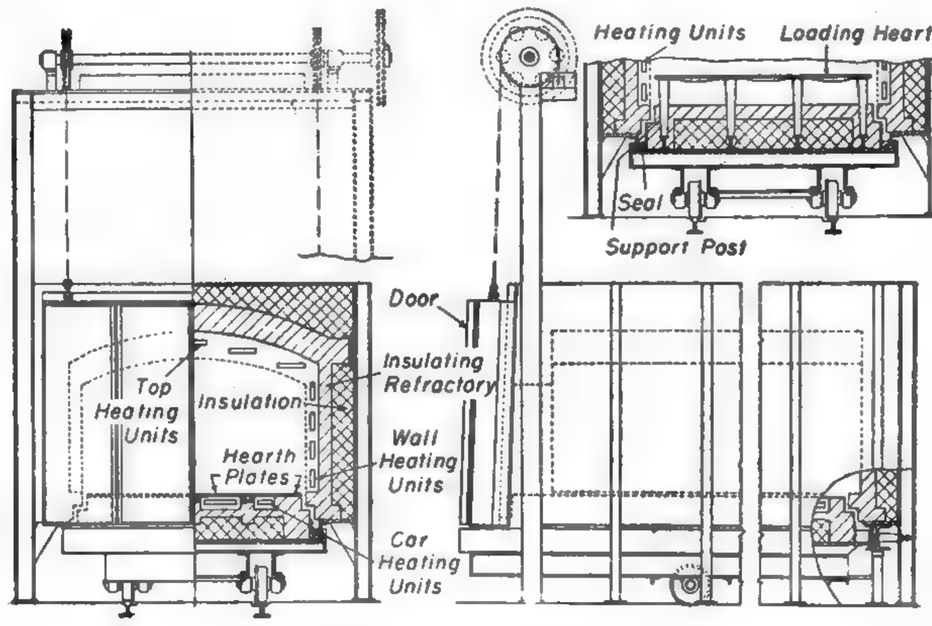

Fig. 4 Typical car furnace

and for nitriding with fan circulation in a retort mounted on the car.

Bell Furnace (*Fig. 5*). The bell furnace may be either circular or rectangular and may be provided with a fan for heating by forced convection.

The material to be heated is loaded on bases and the heating chamber of the furnace is raised and moved from base to base; or the furnace may be lifted and the bases moved. This furnace may be used with or without an inner retort, depending on the application. When an inner retort is used, three or more bases are ordinarily required to provide for heating, cooling and loading or unloading.

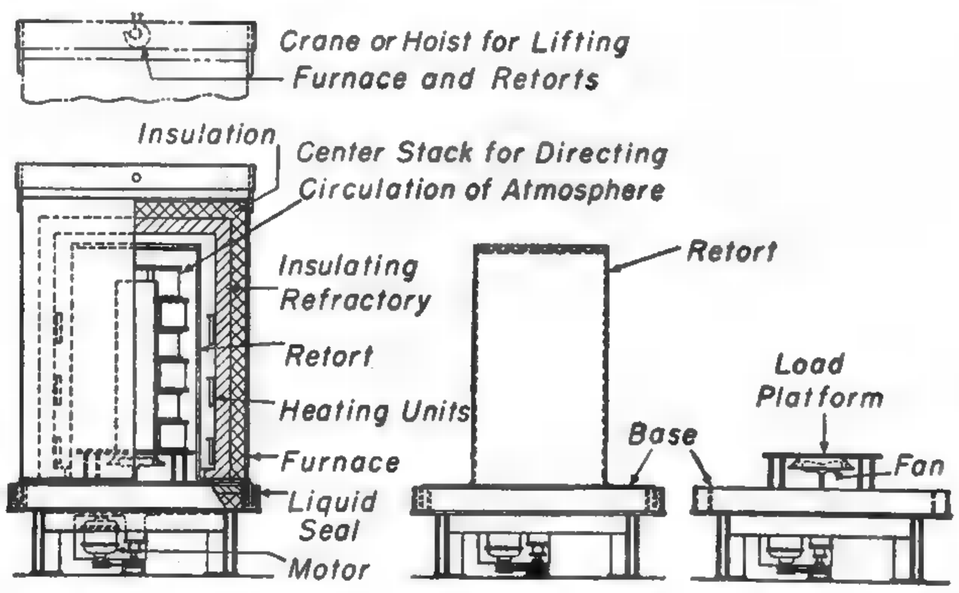

Fig. 5 Typical cylindrical bell furnace

Bell furnaces are used for the annealing of steel strip in coils, steel wire in coils, copper and brass wire and strip in coils or on spools, and miscellaneous parts loaded in baskets. These furnaces are used also for nitriding. The larger rectangular bell furnaces are used for the annealing of sheets and alloy bar stock.

Elevator Furnace (*Fig. 6*). The elevator furnace is usually rectangular but may be circular and may be provided with a fan or fans for heating by forced convection. The parts are loaded on a car, which is then elevated into the heating chamber. Where the headroom permits, the design allows a loaded car to pass under the furnace when a car is in the furnace, thereby saving the amount of floor space required for switching cars. Also, two or more furnaces may be located over the same car tracks.

Elevator furnaces are used principally for the annealing of steel castings, malleable iron castings, cast iron, steel

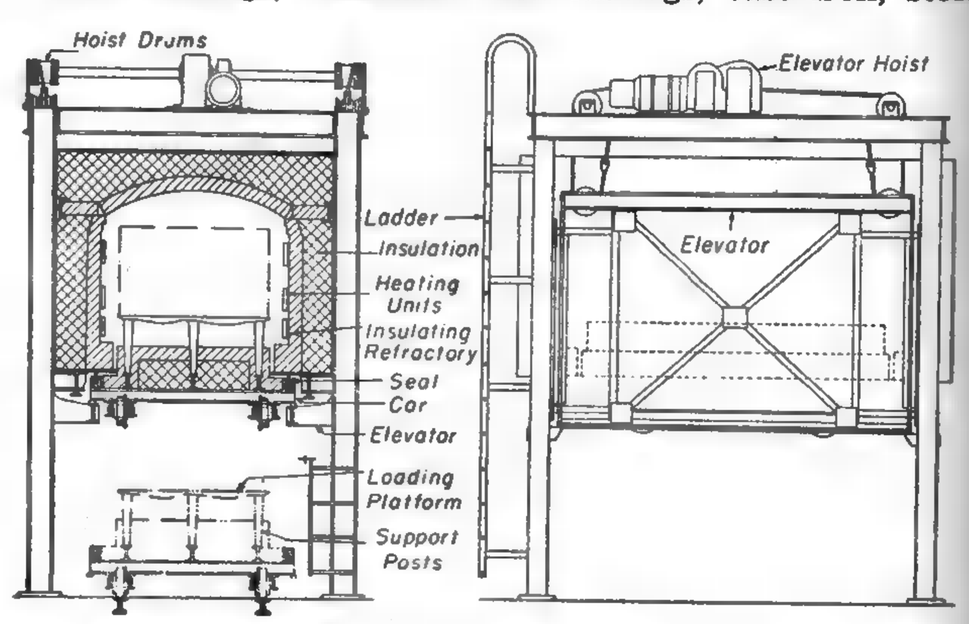

Fig. 6 Typical elevator furnace as used for annealing

bar stock, steel tubes, steel sheets and flat punchings; for the heat treating of aluminum alloys and magnesium alloys; and for pack carburizing.

When used for the heat treating of aluminum alloys, the elevator furnace is located over a tank employed for quenching parts in water. The parts to be treated are suspended from a loading rack, and the rack and charge are elevated into the heating chamber. When the work has been heated and the charge is ready to be quenched, the bottom door is moved quickly to one side and the charge is lowered rapidly into the quench tank. With this arrangement the shortest possible interval elapses between the

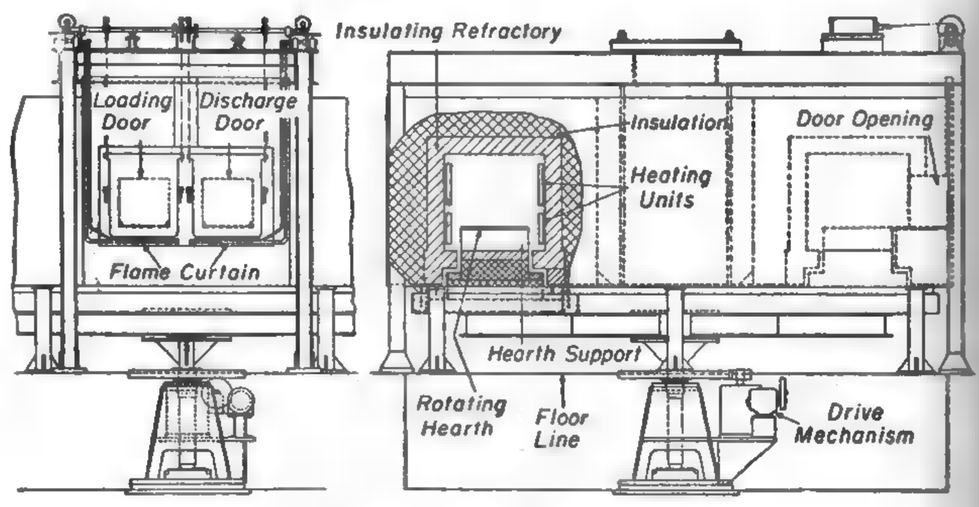

Fig. 7 Typical rotary hearth furnace

time when the work leaves the heating chamber and the time when it enters the quenching medium.

Rotary Hearth Furnace (*Fig. 7*). This type of furnace has a hearth in the shape of a doughnut; the hearth is rotated and sand or liquid steels, or both, are provided between the rotating table and the stationary part of the furnace. In small furnaces the rotating hearth may be supported from a central point and rotated within the heating chamber.

The parts are charged and discharged at one central place through the same door or adjacent doors. The furnace may have fans for heating by forced convection.

Rotary hearth furnaces are particularly suitable for heating parts that are to be handled individually. Typical applications are the heating of gears, shells, cylinders, and other parts that are fixture-quenched or individually han-

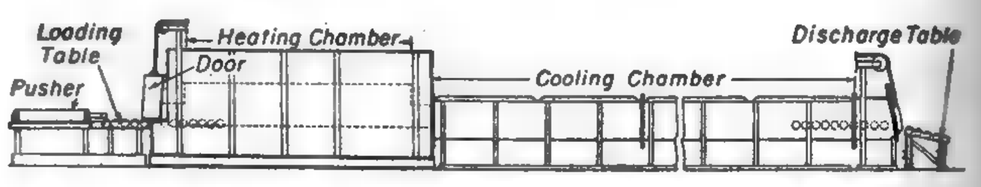

Fig. 8 Typical pusher furnace with heating and cooling chambers

ded; the heating of smaller parts loaded in lightweight trays; pack carburizing; and the heating of aluminum alloys for forging.

Pusher Furnace (*Fig. 8*). The work is pushed through this type of the furnace, one piece against another, where the parts are of such shape and size as to permit handling in this manner; or the parts are loaded on trays or stools that are pushed through the furnace, from one predetermined position to another. The furnace may be provided with a cooling chamber.

Pusher furnaces are used for the hardening and tempering of parts that may be pushed one against another—shells, cylinders, pins and the like. Other applications in-

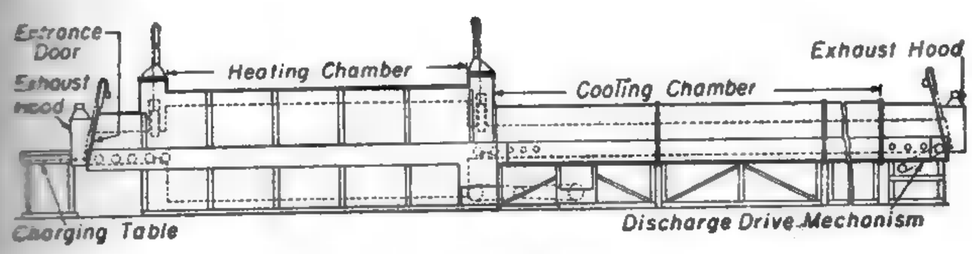

Fig. 9 Typical roller hearth furnace, with heating and cooling chambers, as used for bright annealing and furnace brazing.

clude the annealing of castings and forgings and pack carburizing, where the parts are loaded in trays.

Roller Hearth Furnace (*Fig. 9*). In this type of continuous furnace, the conveyer consists of driven rolls made of heat-resistant alloy. The ends of the rolls extend through the walls of the furnace to suitable bearings and are driven through sprockets and chain.

The parts to be heated are either loaded directly on the roll table (for tubes, bars, large sprockets and the like) or loaded in trays or on rails.

The charging and discharging, the transfer of the work rapidly from one section of the furnace to another, and the return of the trays to the front of the furnace, may all be done automatically.

The furnace may be provided with a cooling chamber, quenching tank, or fans for heating by forced convection, all depending on the application.

The roller hearth furnace is a high-production continuous furnace that is inexpensive to operate and maintain.

This furnace is widely used for: furnace brazing; bright annealing of ferrous and nonferrous products, such as tubes, stampings, drawn parts, and strip; normalizing, annealing, hardening and tempering of steel bar stock; annealing of malleable iron castings, small steel and iron castings and forgings; annealing and solution heat treating of aluminum alloy bar stock and structural shapes;

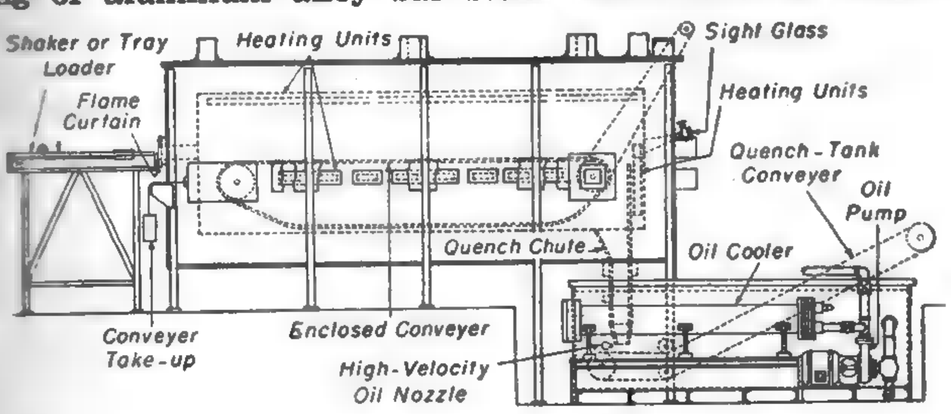

Fig. 10 Typical belt conveyer furnace for hardening

sintering of pressed parts made of metal powder; hardening and tempering of miscellaneous steel parts that are loaded directly on the roll table or on trays.

Belt Conveyer Furnace for Hardening (*Fig. 10*). This furnace has a conveyer, usually made of an assembly of cast alloy links. The furnace is used for the hardening of steel parts that may be dumped from the conveyer into the quenching tank. A discharge chute is provided for connection between furnace and quenching medium.

The furnace is usually equipped with a loading mechanism (shaker or tray loader) but parts may be loaded by hand. A suitable quenching tank is also part of the equipment.

Belt conveyer furnaces are widely used for the hardening of such parts as bolts, screw-machine products, bearing races, business-machine parts, small gears and forgings.

Shaker Hearth Furnace (*Fig. 11*). This furnace is of the continuous type for hardening small parts made of carbon and alloy steels. The parts are loaded on the hearth at the front of the furnace and are conveyed along the hearth by means of its reciprocating shaker motion, until they fall

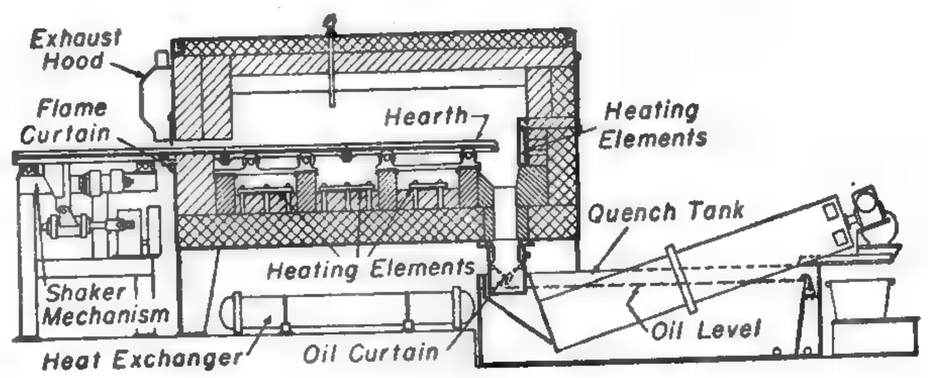

Fig. 11 Shaker hearth furnace

off the discharge end of the hearth, down the quench chute and into the quenching liquid.

Mesh-Belt Conveyer Furnace (*Fig. 12*). This furnace is usually provided with heating and cooling chambers and has a conveyer made of woven wire. The parts are loaded directly on the conveyer, which returns under the furnace.

The mesh-belt conveyer furnace is used principally for furnace brazing, bright annealing and sintering.

Tower Furnace. This type of furnace, used for the continuous heating and cooling of strip, consists of one or more vertical heating chambers and may be equipped with one or more vertical cooling chambers. Each chamber has supporting drums at top and bottom.

Catenary Furnace (*Fig. 13*). This furnace consists of heating and cooling chambers for the continuous annealing of strip in a protective atmosphere. Rolls located outside

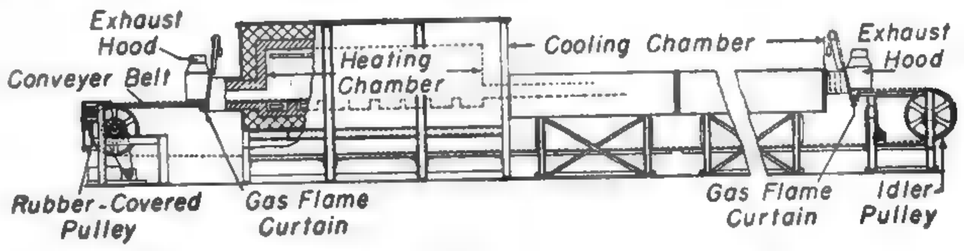

Fig. 12 Typical mesh-belt conveyer furnace with heating and cooling chambers

the heating chamber support the strip so that it hangs in a catenary having no contact with supports in the heating chamber.

Oil Bath (*Fig. 14*). The oil bath consists of a steel tank suitably insulated and equipped with immersion heaters. The oil bath is used for the tempering of steel parts.

Lead Hardening Pot Furnace (*Fig. 15*). This furnace consists of a heating chamber that contains an alloy crucible. The parts to be heated are immersed in molten lead. This furnace is used for localized heating of steel parts.

Salt Bath Furnaces. In a salt bath, the heat is transferred from the source to the work pieces by convection through the liquid bath. Since this convection is very rapid and the bath has a high heat capacity, the rate of heating the work is limited in practice only by the ability of the work to conduct the heat. For example, the rate of heating steel between 1500 and 1750 F is four to six times

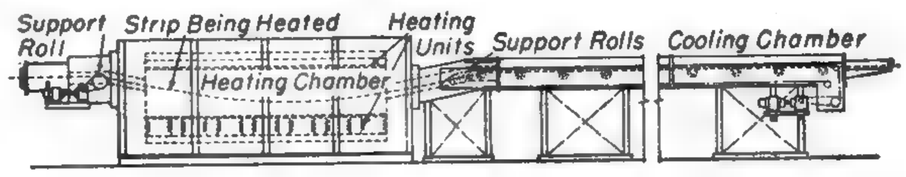

Fig. 13 Typical catenary furnace with heating and cooling chambers

faster in a salt bath than in a furnace that depends on radiation for heating the work. When cold metal is immersed in a liquid salt bath, a layer of frozen salt is formed instantly and encases the entire piece. This is because the melting point of the salt compounds used is always only a few hundred degrees (200 to 600 F) below the operating temperature of the bath. This characteris-

tic serves to preheat the work, and when the layer of frozen salt is melted (usually within 1 min) the piece is heated to the bath temperature by conduction. As a result, salt bath furnaces are designed to operate with considerably faster time cycles. See page 283 for specific

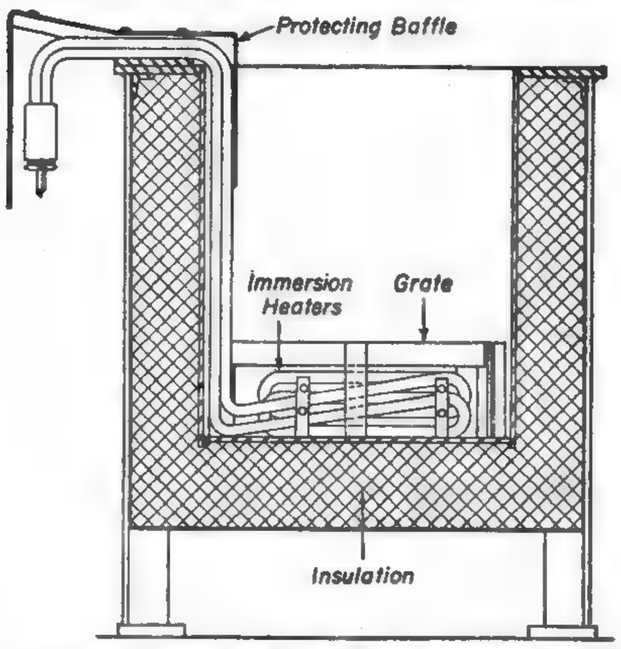

Fig. 14 Typical oil bath heated by immersion heaters

data regarding types of salts and operating techniques recommended for various heat treating applications.

There are three types of electrically heated salt bath furnaces; namely, the externally heated type, the immersion heating-element type and the immersed-electrode type.

Externally Heated Type (*Fig. 15*). The resistance heating elements that are mounted on the walls of this type of furnace, radiate heat to the outside surface of the pot.

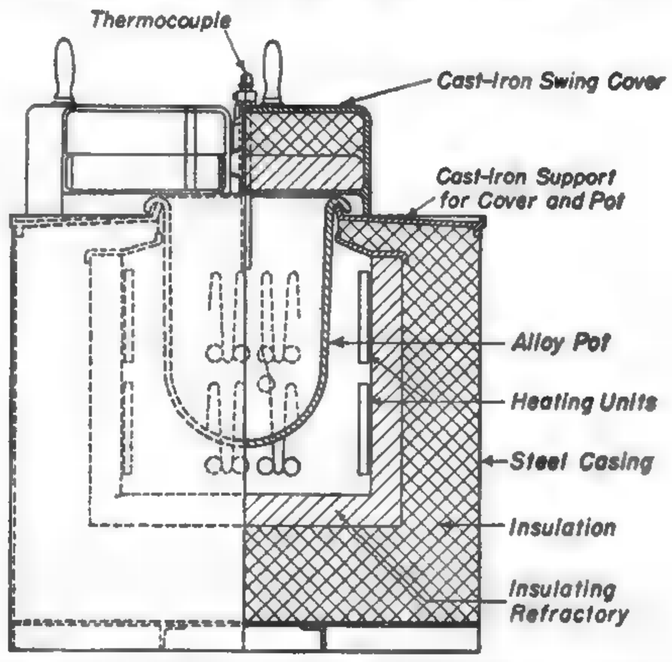

Fig. 15 Typical pot furnace with external heating for lead and salt bath hardening

The pot must be made of metal—usually of a heat-resistant alloy—in order to conduct the heat efficiently from the heating chamber to the salt bath. A temperature gradient of several hundred degrees must be maintained between the heating elements and the bath so that the energy will be transmitted through the wall of the pot. Therefore, externally heated salt bath furnaces are limited to a maximum operating temperature of approximately 1650 F. These furnaces are used for tempering, neutral hardening, cyanide hardening, and carburizing.

Immersion Heating-Element Type. This type of furnace is heated by electric immersion heaters that consist of a resistance wire embedded in refractory insulation, all

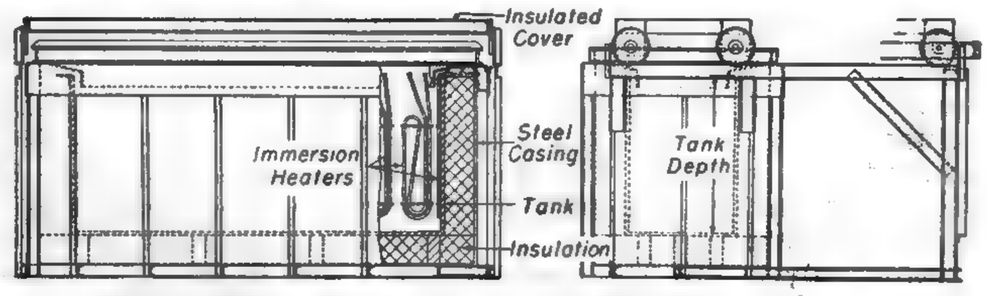

Fig. 16 Typical salt bath heated by immersion heaters

within an outer metallic sheath. Here again, a temperature gradient exists between the heating element and the outer sheath in contact with the bath. These immersion heaters are used for bath temperatures up to 1100 F. The pots are usually made of steel and suitable insulation is placed between the walls of the pot and outer casing. This type of furnace is used for the tempering and coloring of steel parts, the heat treating of aluminum alloys and interrupted quenching of steel parts in connection with austempering and martempering treatments (Fig. 14 and 16).

Immersed-Electrode Type. This type of furnace—probably the oldest electric heat treating furnace in commercial use—was introduced about 1906. Though all salts are good insulators in the solid state, they become fairly good conductors when melted. This electrical characteristic is utilized in the operating principle of the electrode type of furnace. Ordinary shop voltage, such as 220 or 440 v, from an alternating-current source, is reduced to a low voltage (5 to 25 v) by means of a transformer adjacent to the furnace. This low voltage is impressed on the electrodes immersed in the salt bath, causing an alternating current of

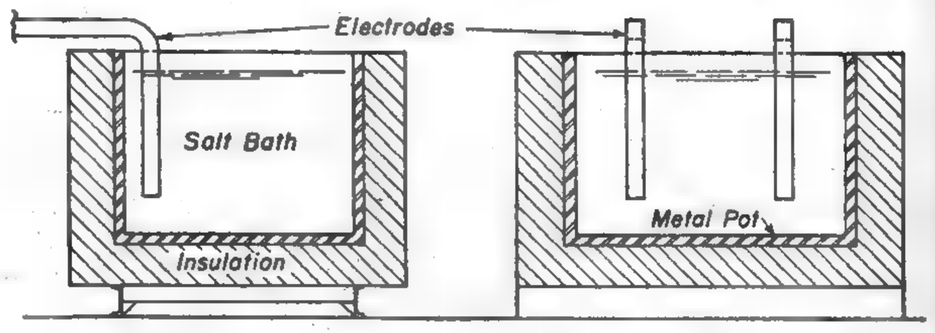

Fig. 17 Immersed-electrode type of furnace with suspended electrodes widely spaced

rather high amperage to flow through the liquid salt. The salt is heated by its own resistance to this flow of current. Direct current cannot be used because it would electrolyze and decompose the bath. The electrode salt bath furnace consists of a thermally insulated container made either of metal or refractory and usually called the "pot", with immersed electrodes to heat the salt bath internally. The operating temperature is limited only by the heat resistance and chemical resistance of the materials used for the electrodes and pot. This type of furnace is used for virtually all heat treating operations that involve operating temperatures from 325 to 2400 F, such as the following: tempering of steel parts; isothermal or interrupted quenching; heat treating of aluminum alloys; annealing of carbon and alloy steels, copper alloys, stainless steels, aluminum alloys and silver; neutral hardening of all types of steels, including martempering and austempering; carburizing and cyanide hardening; hardening of high speed steel tools; nitriding of high speed steel tools; brazing of

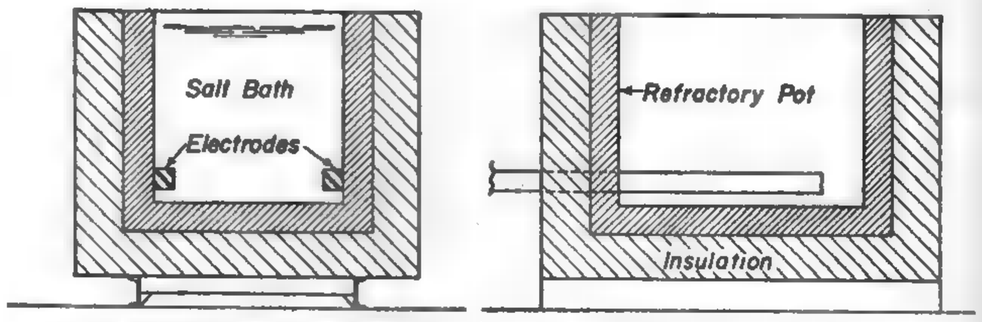

Fig. 18 Immersed-electrode type of furnace with submerged electrodes

steel, copper and aluminum assemblies using silver, brass, aluminum or copper brazing solders; heating for forging; descaling of stainless and alloy steel wire, shapes, forgings and castings.

Electrode-type furnaces now in use are of three general designs characterized by (1) suspended and widely spaced electrodes, (2) submerged electrodes, and (3) suspended and closely spaced electrodes.

In the earliest type of immersed-electrode furnace, electrodes were located on opposite sides of the bath and were suspended in it from the top. The pot or container for the salt was made of refractory. The path of current from one electrode to the other must pass through the charge, a circumstance that may lead to serious difficulties. Since the

metal charge is always a better conductor of electricity than the bath, the current density will rise abnormally in the area where the current enters and leaves the work pieces. Overheating and partial melting may result, while the temperature of the bath itself remains unaltered.

The defect in this design is overcome in an electrode type of furnace in which the pot is of metal and has the electrodes arranged along one of its walls, as shown in Fig. 19. The current passes from one electrode to the pot wall, through the pot, and then across a gap of liquid salt back to another electrode. Thus the current is confined to the electrode area and cannot enter the metal charge.

In the submerged-electrode design, a refractory pot is used and the electrodes penetrate through the pot wall at or near the bottom of the bath, as shown in Fig 18. If the charge is not too deep, the path of the current is confined to the area between electrodes. The electrodes are usually water-cooled in order to freeze and seal any leaks from the bath. Since all the heat is generated at the bottom of the bath, thermal circulation is effected by virtue of the difference in temperature between the bottom and top of

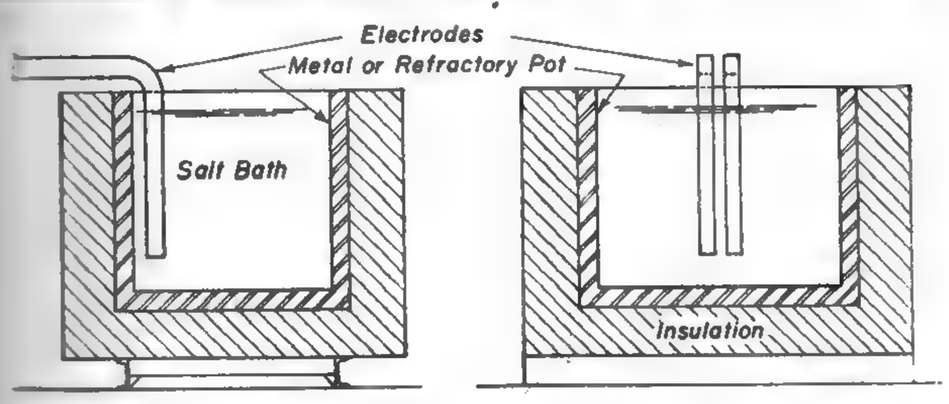

Fig. 19 Immersed-electrode type of furnace with closely spaced electrodes

the bath. The hot salt at the bottom is less dense than the colder salt at the top and naturally rises to be displaced by the colder and denser salt. The advantage of this design is primarily in the reduction in the area of the exposed surface of the bath. It is difficult, if not impossible, to replace the electrodes when the furnace is in operation. The heavy sludge that forms in most salt baths and collects at the bottom, may also present difficulties. The conductivity of this sludge varies greatly from that of the salt and if such sludge accumulates in the area traversed by the current, the power input can be affected greatly. If the bath should freeze for any reason, such as an interruption of power or failure of electrical control, the furnace could

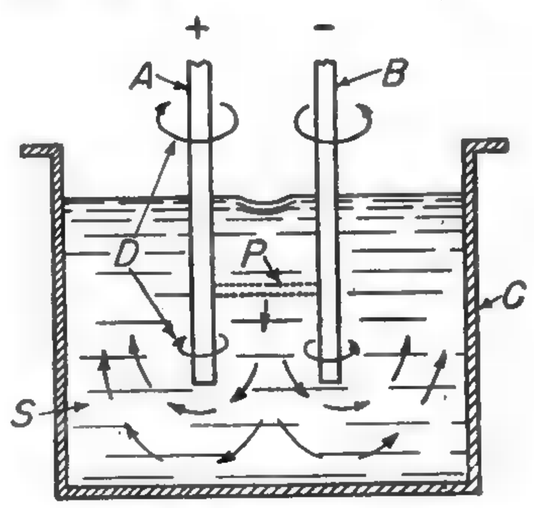

Fig. 20 Theory of electromagnetic circulation in immersed-electrode type of salt bath furnace

not be started again because of the inaccessibility of the bottom electrodes. Therefore, in this type of furnace it is necessary to anticipate such an occurrence and to insert a resistance coil from the top, to restart a solidified bath.

The third type of immersed-electrode furnace in prevalent use, has suspended and closely spaced electrodes, as shown in Fig. 19. The pot is made either of metal or refractory, whichever lends itself better to a particular operation. The main distinguishing feature of this design is that the electromagnetic field created by the current in the electrodes is utilized to circulate the liquid salt. So that these electromagnetic forces can be used to best advantage, the electrodes are grouped in pairs along the pot wall and are placed relatively close together. The gap between the electrodes is only from 1 to 2 in. so the current is confined to the electrode area and cannot be short-circuited through the charge with consequent overheating, as in furnaces that have the electrodes more widely separated.

With the electrodes arranged thus along one side of the bath, the heating zone is kept distinct from the working space. The electromagnetic circulation causes the liquid salt to be drawn into the gap between the electrodes and sucked downward, or opposite to the direction of flow that might be obtained by thermal convection. This electromagnetic circulation removes the heat as fast as it is generated between the electrodes, and ensures uniform temperature throughout the bath.

Figure 20 explains the theory of this electromagnetic circulation. Any conductor that carries current, when placed in a magnetic field, tends to move at right angles to the direction of the magnetic field and at right angles to the direction of the current. Applying this rule to the salt bath, electrodes *A* and *B* are immersed vertically and close together in a molten salt *S*, and a current of high magnitude, 3000 amp for example, is passed between them. Each electrode is surrounded by approximately circular lines of force *D*. Current of high density flows between the electrodes at all points from the surface of the bath to the ends of the electrodes. If a current element *P* is considered, midway between the two electrodes, and some distance down from the surface, and the current is traveling at any instant from *A* to *B*, then with the resultant electromagnetic field between the two electrodes extending outward from the plane of the figure at the point *P*, the con-

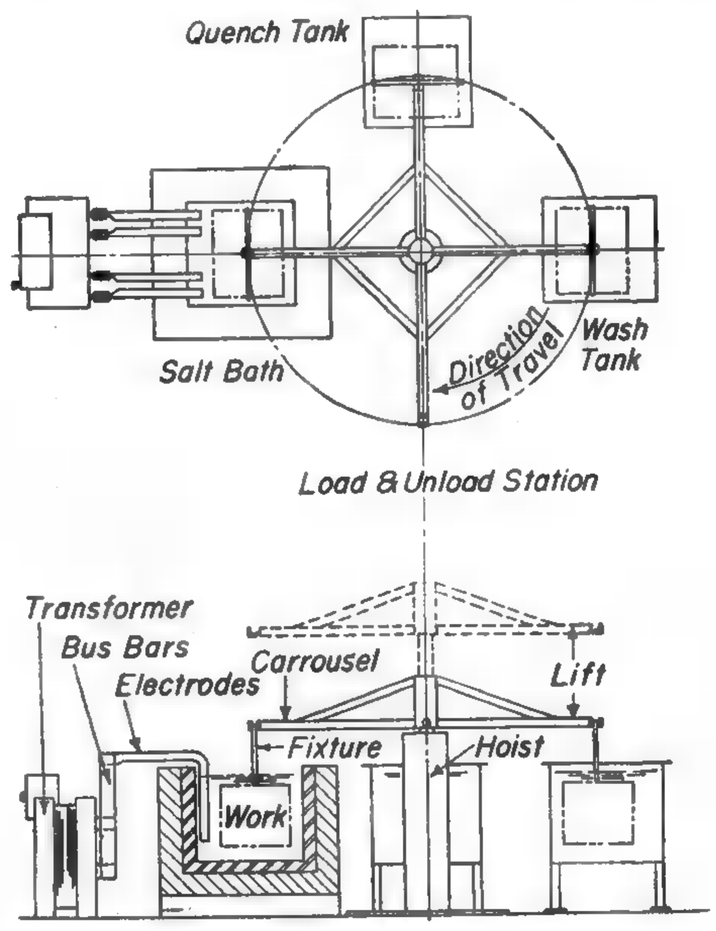

Fig. 21 Carrousel type of mechanism applied to immersed-electrode type of salt bath furnace

ductor, or element of the liquid salt that is carrying the current, will be forced downward between the electrodes in the direction of the arrow. This is according to the well-known electromotive laws of Maxwell. If the direction of current is reversed, the direction of the magnetic field also reverses, and the direction of movement is still downward.

Automatic control of temperature for salt baths is provided by means of the usual apparatus; that is, a thermocouple, pyrometric controller and magnetic contactor.

Electrodes are made of various metals such as iron, chromium-iron or nickel-chromium-iron alloys, depending on the temperature and chemical nature of the bath in which they are used. Pots for low-temperature baths to be operated at 1300 F or less, are usually made of welded steel plate. For the higher temperatures, up to 2400 F, refractory pots, made of preformed and prefired ceramic shapes, are commonly used. This is invariably good practice for neutral salts, but where carburizing baths are involved, plain welded steel pots are ordinarily used in the temper-

ature range from 1500 to 1750 F. In spite of the poor "refractory" properties of steel, these pots give long service when employed with such carburizing baths, because the ebullition of carbon monoxide gas (formed in the bath when the sodium cyanide decomposes) protects the steel from severe oxidation, which would otherwise occur.

The salt for a particular application is determined primarily by the highest temperature to which it will be heated and by whether or not a chemical reaction is desired on the surface of the metal being treated. Mixtures of nitrates and nitrites are generally used for temperatures below 1100 F. Chlorides of barium, sodium and potassium are used for the medium-temperature range from 1200 to 1750 F, and barium chloride is most commonly used for the high-temperature range from 1750 to 2400 F. Rectifiers such as borax, silicon carbide, organic cyanides, silica and carbon, are used as additions to the baths for controlling the "neutrality" of the solutions so that decarburization, pitting and other surface reactions may be inhibited. Salts that contain from 8 to 35% sodium cyanide, along with chlorides and carbonates, are used for carburizing and case hardening. The decomposition of the cyanide evolves carbon monoxide and nitrogen, which react with the surface of the steel to produce the carburized case.

The connected load of a furnace is determined by the following factors:

1 Power required to heat the charge and fixtures
2 Heat lost from the furnace
  (*a*) from bath surface
  (*b*) through sides, bottom and cover
  (*c*) by electrodes
  (*d*) by transformer

The heat lost from the surface of the bath is the largest factor in the total loss. Therefore, the designer of the furnace should try to keep the exposed area of the bath as small as possible.

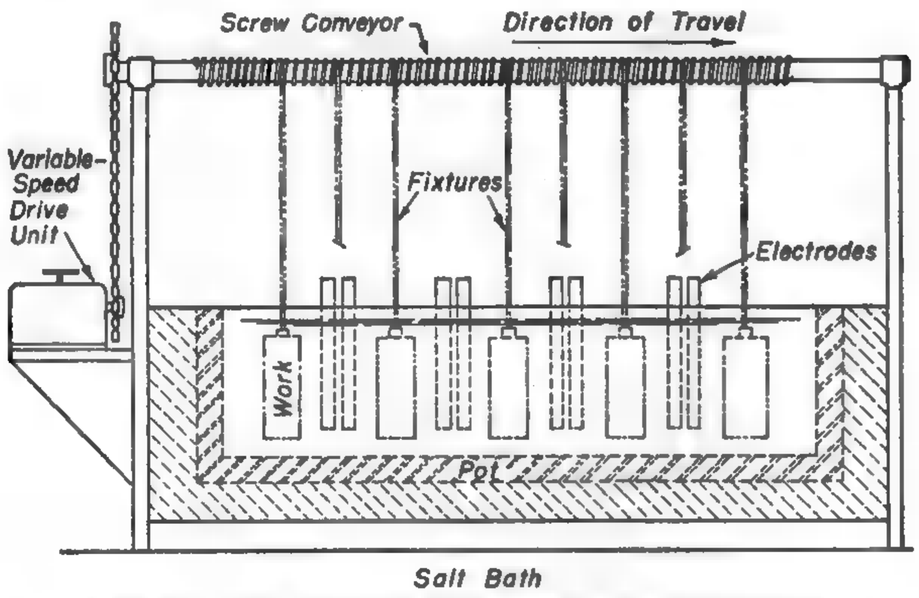

Fig. 22 Salt bath equipped with screw conveyer mechanism

The ingenuity used in devising a method for arranging the work on fixtures or supporting it in the bath, can have an important bearing on the surface area required and therefore on the efficiency of operation. Small parts, such as pins, rivets, studs, nuts and bolts, are heated in baskets made either of wire mesh or of perforated metal. Larger pieces require fixtures to support the work—in many instances simply a piece of wire passing through a hole in the work piece and attached or hooked to a supporting rod above the bath. Other fixtures, either weldments or castings, resemble trees and the pieces are hung on the "limbs". The choice of material from which to construct the basket or fixture depends on the temperature required in the bath and on whether the fixture is to be quenched.

The immersed-electrode type of furnace permits the design of any size or shape of bath, and because of its internal heating principle, ensures very long life for the pot. These factors, plus the ability to generate virtually any desired power within the bath, make it feasible to mechanize such furnaces so that work material may be sent through continuously on conveyers. One commonly used mechanized design is the "carrousel" type (Fig. 21), wherein the work pieces, suspended from fixtures, are rotated by a device located in the center of a circle that has two or more salt baths equally spaced around its periphery. The work pieces are moved progressively from one bath to the next (including quenching or washing stations if desired) for the cycle of treatment and then, after complete processing, are returned, for unloading, to the same point where they were loaded.

Another design, known as the "screw conveyer", comprises a motor-driven worm located directly over the salt bath (Fig. 22). The fixture or basket containing the work, is hung on this revolving screw, which moves the work through the bath at any desired speed, thus controlling the time-temperature cycle. In some instances the work is removed manually from the screw conveyer, but this operation also lends itself to mechanization.

The "jack rabbit" design (Fig. 23) provides perhaps the most flexible means of mechanizing a series of heat treating operations involving one or more salt bath furnaces and then quenching, washing and drying.

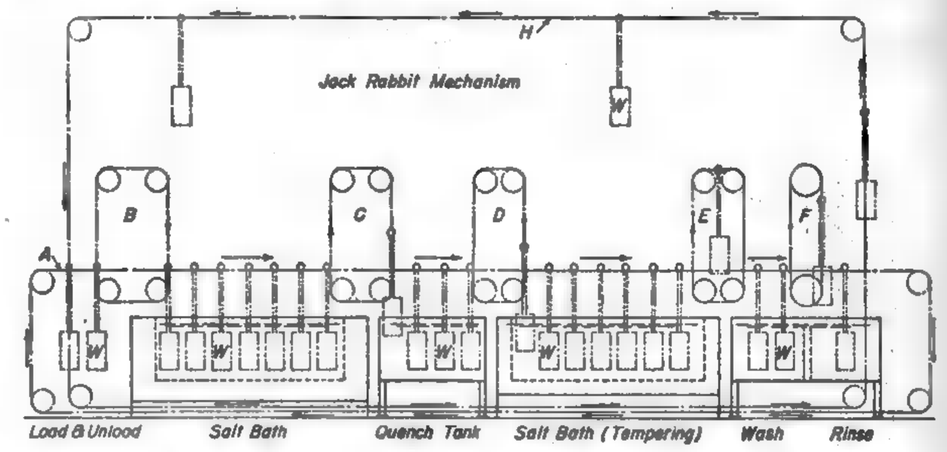

Fig. 23 Jack rabbit type of mechanism applied to a series of salt bath heat treating operations

Horizontal racks, holding the work-laden fixtures *W*, rest on two constantly moving conveyer chains *A*, on the top of the furnaces but away from the heat of the bath. Chains *A* return beneath the furnaces. When the racks of fixtures approach the entry or exit of any operation, vertical chain transfer mechanisms, *B*, *C*, *D*, *E*, *F* and *G*, actuated by limit switches, either lower or raise the fixture as required and transfer the work rapidly to the next bath. These transfer stations consist of two matched chains and are motor-driven. The separate pair of return chains *H*, powered by the main drive that also runs conveyer *A*, picks up the racks after the washing operation and conveys the work overhead, back to the starting end of the unit, where the operator unloads and reloads the fixtures.

Atmosphere for Resistance Furnace.* When this type of furnace is used for the heating of metal parts, protective atmosphere is ordinarily required in the heating and cooling chambers to protect the surface of the parts.

In almost all these procedures for heating, it is necessary to prevent oxidation of the metal. There may be other requirements also, such as preventing the removal of carbon, adding carbon, or eliminating discoloration from sulfur.

Most metals can be bright annealed without decarburization. Carbon steels, alloy steels and high speed steels can be hardened without decarburization or scaling.

Such materials as stainless steel and high-zinc brass are not strictly bright annealed in the usual production furnace unless the material being annealed is such that the furnace atmosphere can be maintained at high purity and the time at temperature is relatively short.

Before selecting the type of atmosphere equipment for a given application, a study should be made of all the atmosphere requirements for nearby furnaces. One centralized atmosphere equipment will usually entail lower first cost, lower cost of maintenance and less supervision.

Typical atmosphere equipments are:

Atmosphere Gas Converter (Fig. 24). This is an equipment for the re-forming of the available city or natural gas (or tanked butane or propane). The air and gas (in proper proportion for the application) are mixed, compressed and then fed into the combustion chamber. The composition of the output gas can be varied, within limits, by changing the air:gas ratio. The output gas contains H_2, CO, N_2, CO_2 and water vapor.

* See also the article on page 294.

This gas is suitable for the bright annealing of low carbon steels, for furnace brazing where decarburization is not a factor, and for sintering.

Additional purification of this gas may be necessary, such as removal of sulfur (if present), removal of water vapor and of CO_2.

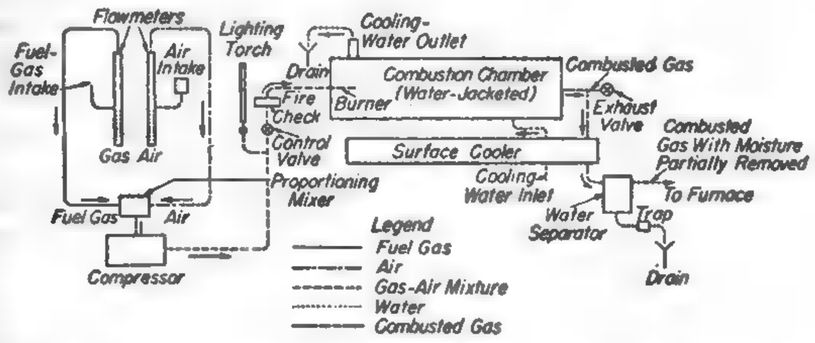

Fig. 24 Flow diagram of a typical atmosphere gas converter

Nondecarburizing Atmospheres (*Fig. 25*). To be nondecarburizing, the protective gas atmosphere must be free from CO_2 and water vapor. Such an atmosphere may be provided by passing air or products of combustion (that is, combustion of a controlled mixture of air and gas) over hot charcoal, or by combining air with a gas high in methane and heating to the range between 1900 and 2000 F. The resultant gas is CO and N_2.

Another means of providing a dry gas free from CO_2, is the use of a chemical CO_2-remover and a dryer, which may be an activated alumina dryer, or a combination of a refrigerated gas cooler and activated alumina dryer. The products of combustion (that is, combustion of air and gas under controlled conditions) are passed through an absorbing tower where the gas comes in contact with the circulated liquid absorbent. The CO_2 is absorbed by the liquid and the remaining gas passes on to the dryer where the moisture is removed. The CO_2-laden absorbent is heated to drive off the CO_2 and the liquid is recirculated.

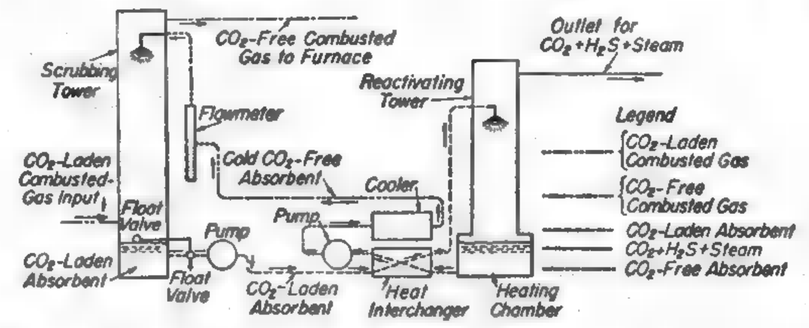

Fig. 25 Typical flow diagram of equipment for removing CO_2

In another type of equipment for producing a gas very low in CO_2 and water vapor, the air:gas ratio is low. Since the amount of heat generated at the low ratio is not sufficient to maintain the temperature required in the combustion chamber, some auxiliary heating is used. This auxiliary heating may be obtained by preheating the air-gas

Table I. Principal Applications of Electric Furnaces

Process	Material	Type of Furnace	Fig. No.	Approx Energy Consumption, lb net per kwhr[a]
Annealing and heat treating	Aluminum and aluminum alloys	Box	1	Aluminum, 8 to 14
		Pit	3	
		Car	.	
	sheets	Elevator	6	Aluminum alloys, 6 to 12
	forgings	Rotary hearth	7

		Lead pot	15	.....
		Salt bath	15	.....
		Salt bath	16	.....
		Salt bath	17 to 23	.....

(a) These are approximate figures. The energy consumption for a given application will vary, depending on production, type and size of furnace, efficiency of loading and the time-temperature cycle.

mixture or by surrounding the combustion retort with a heated chamber.

The type of equipment selected to produce a nondecarburizing atmosphere will depend on the application and the quantity of gas atmosphere required.

Ammonia Dissociator. The ammonia dissociator consists of an electrically heated chamber containing a coil of heat-resistant alloy tubing. While being passed through this coil, the anhydrous ammonia is heated and dissociated, giving a resultant gas that consists of 75% H_2 and 25% N_2. This atmosphere is used for the bright annealing of high-carbon and chromium (including stainless) steels, and as a source of hydrogen for atomic hydrogen welding and for chemical processes.

The dissociated ammonia may be mixed with air and burned to obtain a mixture that is low in hydrogen and high in nitrogen.

Temperature Control. The temperature is controlled by means of a thermocouple, working in conjunction with a standard instrument for control of temperature and a control panel. The methods of control that are used, are discussed in the article on page 174 of this Handbook.

Selection and Application of Electric Resistance Furnaces. *Selection of Heat Source.* In selecting the type of furnace and source of heat (electricity, gas, oil or coal) to use for a given application, a thorough analysis should be made of the over-all costs involved.

Some of the major factors that should be covered in the analysis of costs are: (1) heat source, (2) subsequent operations (such as cleaning, or machining), (3) transportation of parts to and from the furnace, (4) floor space, (5) labor and supervision, (6) maintenance, (7) working conditions, (8) continuity of service, and (9) acceptability of products.

Selection of Type and Size of Furnace. The differences among types of furnaces are largely differences in the handling of material and the method of applying the heat, by radiation or forced convection.

Too frequently the selection of the correct size and type of furnace is limited by a few parts of special size or a few parts that require a different heating cycle. In such instances it is well to consider a separate furnace for these few parts, or to send them to a commercial heat treating company and then to select the type and size of furnace best adapted to the requirements of the production items.

The size of furnace selected for a given application and production will be governed by the efficiency of loading (pounds per square foot, per cubic foot, and the like), the temperature gradient permissible, the weight of conveyer, trays, and other fixtures that must be heated, and the shape and size of parts to be heated.

As an example, when a belt conveyer furnace (Fig. 10) is used for the hardening of bolts, or a similar product, at approximately 1500 F, the production will be approximately 25 lb net per hr per sq ft of belt in the heating chamber. For a production of 1000 lb net per hr, the furnace should have a belt with loading area of approximately 40 sq ft in the heating chamber.

When the same type of furnace is used for hardening lightweight parts (such as typewriter parts), the production may be less than 15 lb net per hr per sq ft.

Another example is the annealing of brass stampings at approximately 1100 F in a mesh-belt conveyer furnace (Fig. 12). When annealing to reasonably constant grain size, the production may be 25 to 30 lb net per sq ft of conveyer in the heating chamber. However, if grain size is not very important and a temperature gradient can be used, production may reach 50 lb net per hr per sq ft.

When steel stampings are bright annealed (at 1650 F) between drawing operations, in a roller hearth furnace (Fig. 9) where the parts are loaded on lightweight trays, the production may vary from 40 to 80 lb gross per hr per sq ft of hearth in the heating chamber, depending on the uniformity of anneal desired. The net production will depend on the ratio of net weight to gross weight.

The principal applications of electric furnaces are summarized in Table I, on the preceding page.

Induction Heating

BY THE SUBCOMMITTEE ON INDUCTION HEATING*

THE discussion of this subject will be confined to the heating of materials by electromagnetic induction.

In recent years, the heating of metals by induction has gained such widespread acceptance and importance that it merits careful consideration in the following applications: (1) heating for hot working as in forming and forging; (2) heating for hardening or other changes in physical properties; (3) heating for joining metals by fusion, as in soldering, brazing or welding; (4) heating for sintering, for shrink fitting and for special effects. The melting of metals in induction furnaces is not discussed here; for information on this subject, see "The Induction Furnace Process of Steel Melting", page 332.

Although possibly the greatest number of applications have been made in processes mentioned in items 3 and 4, undoubtedly the greatest amount of power has been consumed in processes listed as items 1 and 2. Certainly the greatest technological developments have occurred in the processes of heating for hardening. The scope of such development has been described in detail in technical articles and scientific literature.

Heating for selective hardening (that is, localized heat treatment) has assumed major importance although a number of successful applications exist in which continuous through-hardening and tempering are carried out by induction; for instance, the heat treatment of long bars and tubes.

The principal requirements for such types of induction heating depend on the operation of the following equipment: (1) a source of alternating or pulsating current, (2) a device for transferring energy to the work piece, (3) precise methods for control of the operation, that is, rate of energy input, duration of input, and rate of cooling.

The available sources for alternating current can be classified under these commercial types:

1 *Motor-generator sets*
Frequencies: 60; 1000; 3000; and 10,000 c. A few higher steps are possible.
Capacities: a to several thousand kilowatts

2 *Vacuum-tube oscillators*
Frequencies: 200,000 to 5,000,000 c
Frequencies most used: 450,000 c and higher
(Frequencies to 15,000,000 c or more are possible.)
Capacities: 5 to several hundred kilowatts

3 *Mercury-arc converters*
Frequencies: 400 to 1500 c
(Frequencies to 3000 c may be possible.)
Capacities: 300 to several thousand kilowatts

4 *Spark-gap oscillators*
Frequencies: 20,000 to 300,000 c
Capacities: 2 to 40 kw

In application, the first problem is the choice of frequency. The following essential factors should be considered:

1 Material (ferrous and nonferrous)
2 Size (diameter or section) of the work piece
3 Depth of section to be affected by heating
4 Result desired (forging, hardening, tempering, brazing, or other processes)
5 Properties of the work piece (magnetic, electrical, thermal and such)
6 Closeness of electrical coupling (the necessary width of insulating gap between work piece and inductor)
7 Final cost of work

* The members of this subcommittee are G. C. Riegel, *Chairman* (Caterpillar Tractor Co.), Frank T. Chesnut (Ajax Electrothermic Corporation), J. P. Jordan (General Electric Company), H. E. Somes (Drummond, Mich.), A. O. Wood (The Ohio Crankshaft Company).

The high-frequency converters in the motor-generator range of frequencies are capable of having current conducted at some distance from the source. In one instance 600 kw of 3000-c power was conducted a distance of 1000 ft by use of coaxial cable.

Heating for Forging, Upsetting and Hot Coining. The rapid heating of bar surfaces for localized hardening, undoubtedly suggested and gave impetus to heating for hot working. Many large forging plants that were built during World War II depended entirely on induction heating for supplying hammers and headers.

The recommended heating times for bringing various carbon steel billets to a uniform forging temperature of approximately 2200 F are shown in Fig. 1.

If the applied power is kept at the average level, as was the practice for the curves shown, the temperature gradient in the charge piece is low, the load factor on the generator approaches a maximum and the equipment can be of the simplest design.

The heating times shown can be shortened appreciably if the power density is kept at a high level, holding the surface of the charge at the maximum temperature while the heat soaks inward. In equipment adapted to this

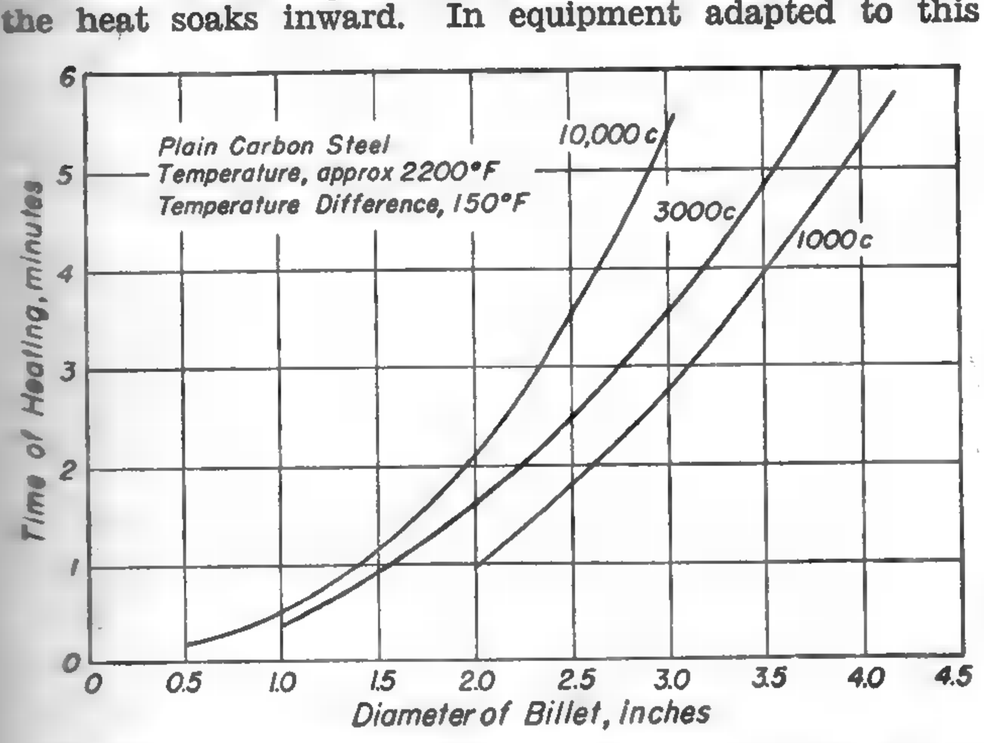

Fig. 1 Recommended time for induction heating of carbon steel billets for forging

practice, the power plant and the controls would be somewhat more elaborate than those adequate for obtaining the conditions illustrated in Fig. 1. However, the heating time would be the shortest attainable.

When several heaters, drawing average power, are connected in parallel, virtually full power is drawn from the feed lines at all times, thus enabling heated billets to be supplied to the forging equipment at the same rate as billets heated singly at a faster heating rate.

As is evident from Fig. 1, the time of heating will depend not only on the diameter of the piece being heated, but also on the frequency. Figure 2 shows the *minimum* frequency required for satisfactorily heating carbon steel bars of various diameters to forging temperature.

In general, if a lower frequency can be used, the power density can be maintained at a higher level than when a higher frequency is used, and heating time can therefore be shortened. As shown in Table I, for stock sizes less than ½ in. in diam, frequencies higher than those obtained from motor generators are needed; for stock from ½ to 1 in. in diam, a frequency of 10,000 cycles is usually employed; for 1 to 2 in., 3000 cycles; and for more than 2 in., 1000 cycles. Figure 3 shows how inductor efficiency varies with frequency and bar size.

In heating for forging, 5 to 6 lb of steel per kwhr (energy measured at the generator terminals) is usually obtained. However, the over-all efficiency of the motor-generator set should be considered in computing total power requirements.

Although the first costs and energy costs of induction heating equipment are usually higher than for conventional forging furnaces, the expense is offset by distinct advantages, such as: lower loss from scale formed (a saving equivalent in some instances to the energy cost), better die life, less forging flash, and less metal lost in machining.

The induction heating unit requires much less floor space and heating can be almost as rapid as desired, limited only by the time required for the surface and center of the billet to reach a satisfactory forging temperature.

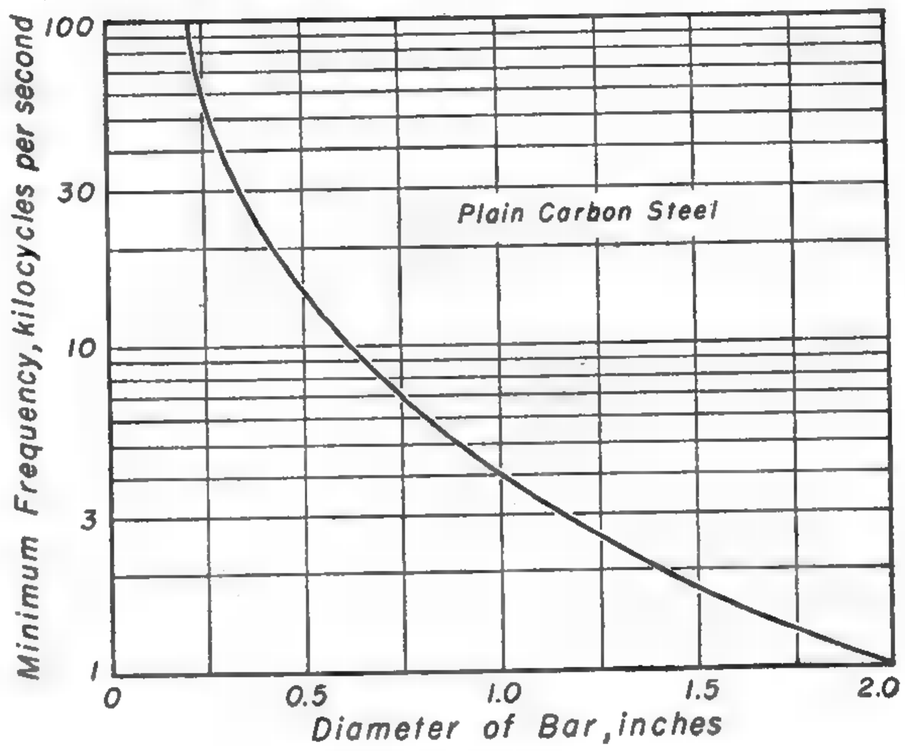

Fig. 2 Minimum frequency to heat various diameters of plain carbon steel bars to forging temperature. All diameter-frequency combinations lying to the right of the curve are satisfactory.

Higher rates of production, uniform temperature for forging, improved working conditions, lower maintenance costs, and flexibility, are difficult to evaluate on the basis of pounds of forgings produced, but the total may result in large over-all savings.

In Table I are shown the frequencies and types of equipment recommended for various applications of induction heating. Melting has been included for comparison.

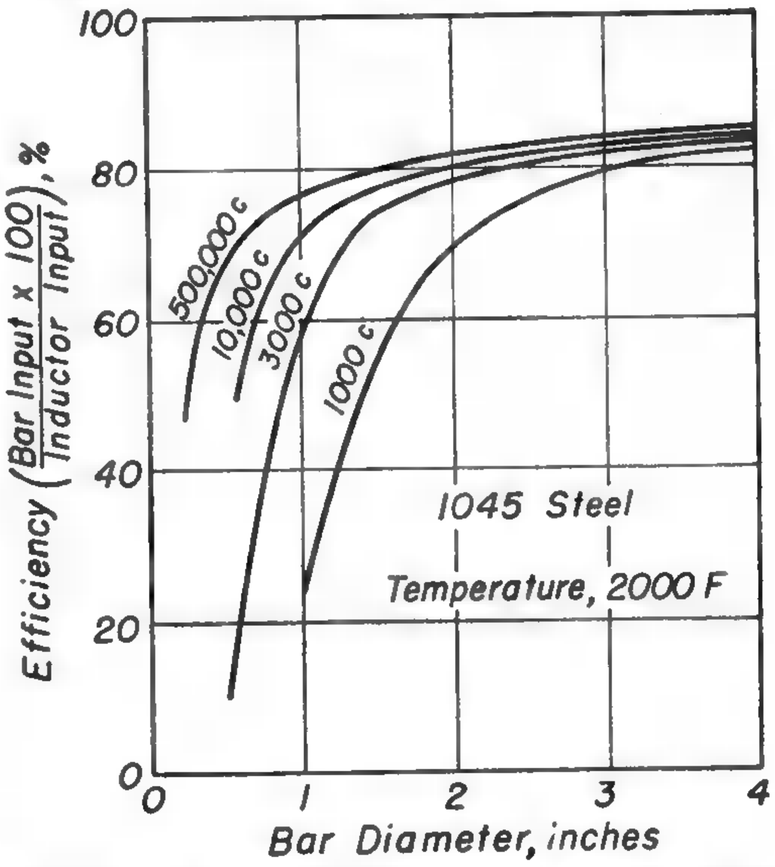

Fig. 3 Calculated variation of inductor efficiency with frequency and bar diameter for a constant air gap of 0.56 in.

Heating for Hardening, for Tempering and for Stress Relieving. As a broad generalization, it may be said that the instantaneous heating effect of an inductor varies inversely as the square root of the frequency. Thus, 10 kc heats instantly seven times deeper than 500 kc. Irregular contours are more readily followed by higher frequencies.

In obtaining desirable results, due care must be given to (1) the chemical composition of the work piece, (2) the metallographic structure of the work piece, (3) the final grain size and structure required, (4) control of stress, desirable and otherwise, (5) freedom from cracking, and (6) surface conditions of the work piece.

To illustrate, the chemical composition determines the thermal properties while the work piece is being heated. Conductivity is very high in most copper alloys, and relatively low in cast iron. Resistivity is relatively high in nickel alloys and low in aluminum alloys. The rate of solution of carbon is slow in high-chromium steels and rapid in sorbitic carbon steel.

Malleable iron is difficult to harden without a preliminary heating to bring necessary carbon into solution. Spheroidal carbon is slow to redissolve. "As-cast" structures are slower to respond to hardening than wrought structures.

A coarse-grained steel is more susceptible to cracking than a fine-grained steel. Grains excessively coarsened in heating will crack readily in severe quenching. In general, the finest grained martensite is the toughest structure in fully hardened steel.

A surface put in tension by hardening may quickly fail in service under bending loads. Residual stresses may prove sufficiently unfavorable to impair the integrity of the work piece. Beneficial stresses may make the work piece more resistant to wear and impart over-all toughness—for example, to a surface under compression opposing shearing stress. A prior slow stress-relieving of hardened parts is advisable to avoid cracking while reheating by induction. Refer to "Induction Heating", ASM, 1946. See also the article on page 243 in this Handbook.

Many parts are tempered selectively by induction heating, but low power inputs and much longer time is necessary than in heating for hardening. Stress relieving of welded joints (for example, in pipe or cumbersome assemblies) can be carried out conveniently by this method, and usually with frequencies in the lower end of the range.

If a work piece is heated too long or attains too high a temperature in air, it may scale or decarburize and thus defeat the purpose of induction hardening. Manifestly, a work piece initially decarburized will not harden by induction beyond the carbon limitation of the surface. Great care must be taken to insure obtaining the proper composition *at the surface.*

Slight seams and other surface imperfections are very injurious in drastic heating and hardening. They become "stress-raisers" which induce overheating, burning and cracking.

The shape of the work piece often determines the feasibility or desirability of induction heating or hardening.

Even more important than the ability to heat a work piece for hardening, is the ability to abstract the heat uniformly in quenching. Spotty surface hardening may result from improper jet impingement or steam pockets.

In general, the insulating gap between the inductor and the work piece should be as small as practicable, thus promoting efficiency and speed of heating. Coupling can be so remote that heating will be scarcely noticeable.

Considering over-all cost, the choice of frequency, type of equipment, and method of applying the heating and cooling often depend on other factors more important than the initial cost, the ratio of power input to cost, or the efficiency of the heat transfer. A minimum frequency might be a limiting factor; shape of the work piece might be another; type of material, another. The range of sizes and shapes to be hardened might indicate a compromise.

A comparison of the affected depth and hardened depth for the various prior structures when using power of 3000, 10,000 or 500,000 c, is shown in Table II for given power densities based on the maximum inductor input during the heating cycle. The values shown are for the minimum time of heating that will give a satisfactory microstructure for SAE 1045 steel.

Materials That Can Be Hardened by Induction. Plain carbon steel (0.15% C or more), constructional alloy steel, hardenable stainless steel, plain and alloyed cast steels, plain and alloyed cast iron, pearlitic and malleable iron.

Quenching Methods. Water, oil, air, gas, or self-quench.

Advantages of Induction Heating. Although the initial cost of installing appliances for induction heating may be several times greater than the cost of conventional methods for accomplishing a similar result, yet the advantages and economies may easily offset the first cost. Certainly, when selective hardening or continuous hardening, as by

Table I. Power Source and Frequency for Various Applications of Induction Heating[a]

(b) The depth below the surface where the hardness has decreased to Rockwell C 50

(c) Determinations made with solid single-turn inductor, 0.060-in. air-gap and SAE 1045 steel

scanning, may be applied to a part, induction heating should be given consideration. These special advantages are available from induction heating for hardening: (1) rapid processing, (2) clean operations, (3) little or no scaling or decarburization, (4) attainment of maximum hardness, (5) less noisy operation, (6) freedom from radiation of heat and hazards of hot handling, (7) easy reproducibility of hardness pattern and dimensions, (8) lower cost per piece, (9) low resultant distortion, (10) reduced floor space, (11) use of less costly material for same part, (12) location of heating equipment in production line and synchronization with the line.

Heating for Soldering, Brazing or Welding. Brazing and soldering present many suitable applications for induction heating. Because of the ease of control and the high rate of output, many highly mechanized devices have been employed for such purposes.

Continuous soldering or brazing, on a progressive belt or feeding mechanism, can be combined with the continuous flow of power through an inductor coil, or the power may be interrupted intermittently as the work pieces appear in the inductor loop. For soldering, sufficient time must be allowed in the heating period to permit liquation and capillarity to operate, which usually requires from 3 to 4 sec. By this means, less waste of solder results and no unnecessary heat is generated in the work piece.

In some instances, under sufficiently high temperature and under suitable fluxes or atmosphere, complete fusion may be obtained without the use of filler material.

Heating for Sintering. Induction heating has gained wide acceptance in sintering of pressed metal powder compacts. The compacts are placed within a muffle of graphite or high-melting material. The muffle is heated by induction; the compacts are heated by conduction and radiation. In some instances, the compacts have electrical conductivity high enough to absorb energy directly from the inductor, and the muffle may be omitted. Special atmospheres can be provided as required.

Heating for Shrink-Fitting. Annular pieces, such as rings and cylinders, are particularly suitable for induction heating operations. A simple inductor can be placed inside or outside such a piece, or a transformer core may be linked through the piece, thus heating the work quickly. When the ring is heated, it expands and can be placed around a prepared base piece and shrunk to fit. Ring gears for engine starters, tires for railroad car wheels, and cylinder muffles are commonly assembled thus.

Since differential heating is not required, low-frequency current from a commercial circuit may be used.

When the ring or cylinder has shrunk on, it may be removed by differential induction heating before the base piece is heated. This, however, requires higher input of power and generally much higher frequency. Hardening and shrink-fitting are often accomplished simultaneously.

Salt Baths

BY THE SUBCOMMITTEE ON SALT BATHS*

TECHNOLOGICAL improvements made since 1937, in both furnace equipment and bath composition, are largely responsible for the present widespread commercial use of salt baths for virtually all heat treating operations. The term "salt bath" means a bath compounded by melting one or more chemical salts to form a liquid medium for immersion of the material to be treated. The chemical nature of such baths varies according to the temperature at which they are to be used.

Salt baths possess certain inherent characteristics that have a discernible and beneficial effect on the work material being treated in them. When a cold piece of metal is immersed in the salt bath, a "cocoon" of frozen salt is immediately formed, encasing the entire piece. This layer of frozen salt acts as a temporary insulator, preventing temperature shock and too sudden heating of the work. After this layer has melted, which usually occurs in a minute or less, the piece is heated rapidly to the temperature of the bath. The rate of heating is limited only by the conductivity of the metal itself and by the ability of the furnace to supply energy at a rate fast enough to maintain the bath temperature. The rate of heating in salt baths is

* The members of this subcommittee are William Adam, Jr., *Chairman* (Ajax Electric Company, Inc.), W. E. Bancroft (Pratt & Whitney Aircraft), Stewart M. DePoy (Delco Products Division, General Motors Corporation), R. I. Hahn (Rochester Products Division, General Motors Corporation), R. S. Komarnitsky (Standard Steel Spring Company), Henry Orth (Stewart-Warner Corporation), E. S. Rowland (The Timken Roller Bearing Company), W. A. Schlegel (The Carpenter Steel Company), A. P. Seasholtz (Seasholtz Metallurgical Service), J. F. Snider (Goodyear Aircraft Corporation) and P. T. Stroup (Aluminum Company of America).

considerably faster than in furnaces heated by radiation or gaseous convection, because the charge is heated by conduction only. For most work, time cycles can be employed that are from one-fourth to one-sixth as long as those normally used for heating the same objects in furnaces of the atmosphere type.

Since the immersed parts are not in contact with the atmosphere during the heating cycle, the problem of avoiding scaling or decarburization is simplified. However, it is important to prevent secondary chemical reactions in the bath itself, because of possible deleterious effects on the metal being treated. When the part is withdrawn from the bath, a film of liquid salt adheres to it. This serves to protect the surface during transfer from one bath to another or to the quench.

Another inherent feature of salt baths is the buoyancy caused by the bath. Although less dense than any of the metals, so they readily sink in it, the bath nevertheless "supports" the charge somewhat. In effect, the metal weighs appreciably less when immersed than it did previously; thus there is less tendency to distort or warp. All material treated in salt baths must be hung on fixtures and wires or placed in baskets or trays. The degree of ingenuity used in this preliminary arranging can have an important bearing on the cost of the entire operation.

For problems involving partial or selective heating, the salt bath offers special advantages. Because of the rapid rate of heating, only the portion of metal that is immersed, is heated, with a rather sharp line between the heated and unimmersed portions.

The salt bath processes described in this article are the following: carburizing, cyanide hardening, neutral hardening, austempering, martempering, cycle annealing, heat treating high speed steel tools, annealing, brazing, heat treating aluminum and beryllium-copper alloys, descaling alloy steels, removing sand from castings, cleaning steel parts, tempering steel parts, coloring, removing enamel, heating for forming and forging, and cleaning molds.

Salts. Table I presents typical compositions of baths used for various heat treating operations. The designations listed in the first column of this table are used throughout the present article to identify the various types of salt mixtures.

All salts should be stored in closed containers in a dry place to prevent absorption of moisture. The advice of salt manufacturers should be followed in regard to correct operation and maintenance of salt mixtures. Low-temperature salts L-1, L-2 and L-3 should never be permitted to come in contact with cyanide baths, such as L-4 and C-1 to 10, since the mixture is explosive.

Equipment.* Table II presents the various available types of salt bath furnaces, together with the ranges of temperature in which they operate.

Steel pots, either welded, pressed or cast, are generally used in all furnaces for temperatures up to 1000 F. Above this temperature it is necessary to use cast heat-resisting alloy pots for externally heated furnaces, whether fuel-heated or electric. Ceramic or refractory pots, employed only with the immersed-electrode type of furnace, offer special economic advantages when operated with neutral salt baths in the temperature range from 1500 to 2400 F, because these relatively cheap ceramic pots last from two to five years.

Table II. Types of Furnaces for Salt Baths

Type of Furnace	Temperature Range, deg Fahr
Externally heated, gas or oil	350 to 1650
Externally heated, electric	350 to 1650
Internally heated, gas immersion tube	350 to 750
Internally heated, electric resistance element	350 to 1000
Internally heated, electric immersed electrode	350 to 2400

It is not necessary to hood furnaces operating with nitrate baths at temperatures up to 1000 F, but since all other baths that are operated above 1000 F fume more or less, it is good practice to provide a fume-exhaust system or a hood, and sometimes both.

Baskets, racks and fixtures for holding the metal to be treated, are made of steel for low-temperature operations, and of heat-resisting alloys for medium and high temperatures. Welded structures made of rolled shapes last longer than castings. This equipment, as well as tongs used in handling, should be made of solid material, to avoid the possibility of water or oil from the quench being carried into the salt bath, where it could readily cause serious spattering or eruptions. For the same reason, all equipment and the parts to be treated should be completely dry before being placed in the bath.

For best results, all salt bath furnaces should be provided with automatic temperature control. For operations at low and medium temperature, bimetal thermocouples are satisfactory. However, for high temperatures (2000 F and above) pyrometers of the radiation type are preferred. These may be equipped with a closed-end target tube made either of ceramic or of heat-resistant metal. The tube is immersed in the bath and the lens of the pyrometer is focused on the bottom of the tube.

* Either of the two materials marked by an asterisk in this line, or any mixture of the two materials, may appear in the percentage shown under the one material.

(a) These designations are used to identify the salt mixtures throughout the present article.

(b) This material is hygroscopic and should be added to molten salt with great care.

(c) The materials should not be operated above 1100 F in a fuel-heated pot.

Liquid Carburizing.* Liquid carburizing is a method of impregnating steel surfaces with carbon and small amounts of nitrogen to improve the strength and resistance to wear. As distinguished from plain cyanide-chloride mixtures, liquid carburizing baths are used for production of deep cases of high carbon, low nitrogen content. In composition these baths differ by the presence of alkaline earth metals (Ba, Ca, Sr), which function as catalysts to increase the rate of absorption of carbon. The presence of nitrogen in amounts produced by liquid carburizing baths is beneficial in improving the wearing properties of the case.

The economical operating range of liquid carburizing baths is from 1550 to 1750 F. Below this range such baths produce shallow, high-nitrogen, low-carbon cases comparable with those obtained in plain cyanide baths. Operations above 1750 F are not economical because of the rapid increase of cost for maintaining equipment, the necessity for preheating the work material, and the problem of selecting a suitable steel.

Baths compounded to operate within the range from 1550 to 1650 F belong to the "accelerated" or "activated" type. Operating with cyanide content of 17 to 23% and cyanate limit of 1% max, they produce carbon-nitrogen cases economically, as deep as 0.030 in.

"Deep-case" baths are characterized by lower cyanide content (7½ to 12%), presence of two catalysts, and ordinarily a higher content of catalyst. Operating within a range from 1600 to 1750 F, with cyanate limitation of 0.3%, the baths produce economically cases up to 0.250 in. deep. Nitrogen content diminishes at higher temperatures.

Though most of the carburizing baths contain sodium cyanide as the active element, a proprietary bath of calcium cyanide has been used successfully for many years. This bath gives good metallurgical results for medium case depths of 0.035 in. or less, and it is noteworthy that the percentage of calcium cyanide in the bath to produce such case depths is approximately 0.5%, or a small fraction of the percentage of sodium cyanide required to give comparable results in the other types of baths. The most serious drawback of the calcium cyanide type of bath is the necessity for using approximately 70% calcium chloride. This highly hygroscopic salt requires special precautions to avoid rusting of the finished work and also adds materially to the costs of furnace maintenance.

Liquid carburizing offers the following advantages: freedom from distortion; absence of "oxygenation" of case (often present in pack carburizing); close control of depth and characteristics of case; economy and flexibility of operation (since several batches of steel may be carburized simultaneously, each to a different case depth); and adaptability to mechanization and mass production.

Liquid carburizing baths are simple to operate if certain precautions are observed:

1 Formation of a carbonaceous cover is inherent in liquid carburizing baths. If this cover is inadequate, a natural flake graphite of high purity (1% SiO_2 max) should be used, or artificial graphite powder that contains not more than 2% ash.
2 In the bath a thick sludge forms, consisting of carbonates that have a high content of metal (reduced iron oxide from work, fixtures and pot; nickel and chromium from electrodes and thermocouple tubes; copper and other impurities). This sludge should be removed periodically by scraping the bottom of the pot with suitable tools.
3 For selective carburizing, high-density cyanide copper plating should be used on the surfaces not to be carburized. Copper-base paints are also frequently used to inhibit carburizing.
4 A nonsaponifiable oil should be used for quenching; otherwise drag-out salt may cause formation of soap and gumming.
5 Hot-spray washing with emulsion-type cleaners should be used to remove salt from the steel pieces and fixtures. To remove salt from deep recesses, the steel may be dipped for 2 to 10 sec in a 10% solution of inhibited hydrochloric acid, and then washed thoroughly in water and immersed in warm oil or a hot alkaline bath containing 4 oz of soda ash per gallon. In order to prevent the evolution of HCN gas that would result from the reaction between sodium cyanide and hydrochloric acid, the salt remaining on the work should be removed as thoroughly as possible before the steel is dipped in the solution of hydrochloric acid.

Two general types of furnaces are available for liquid carburizing: in one, the salt-filled pot is heated externally; in the other, the salt bath is heated by immersed electrodes. See page 275 for a description of batch and continuous salt bath furnaces.

Cyanide Hardening. Cyanide hardening produces a thin hard case on steel surfaces heated in molten cyanide salts and subsequently quenched. This case is caused by the absorption of both carbon and nitrogen from the salt. The presence of nitrogen in the case imparts greater hardness than is found in surfaces that contain additional carbon only. *See* page 694, in the CASE HARDENING SECTION, for a discussion of the chemistry of cyanide baths.

This method of heat treatment is used for the case hardening of finished or semifinished parts that require a case depth up to 0.008 in., and is widely used for all types of carbon and alloy steel parts. Cases deeper than 0.008 in. cannot be obtained economically with plain cyanide-chloride-carbonate salts. (*See* Liquid Carburizing, above, for cyanide baths used for deeper cases.)

The salts used for cyanide hardening are mixtures of sodium cyanide, sodium chloride and sodium carbonate. The sodium cyanide content, determined by operating conditions, varies from 15 to 30%; salt C-4 is typical.

Temperatures used in cyanide hardening range from 1300 to 1550 F. The temperature used depends on the material being treated, as well as on the core hardness desired. In general, parts are cyanided at temperatures just above the Ac_3 point, because at this temperature the penetration of carbon is more rapid and optimum mechanical properties are developed in the core when the metal is quenched.

The time cycle for cyaniding varies from a few minutes to approximately one hour. For most applications a time longer than one hour proves uneconomical, since the increase in case with increase in time is very slight. Usually the type and thickness of the case can be varied by varying the temperature, the cyanide concentration of the bath, and the time at temperature. High temperature and high concentrations of cyanide produce cases with high carbon and lower nitrogen content, while low temperature and low concentrations of cyanide produce cases with lower carbon and higher nitrogen content.

All cyanide mixtures are extremely toxic and great care should be taken lest these salts enter the human body. All parts being treated in molten cyanide baths should be clean and dry. Nitrates and nitrites, as well as other oxidizing agents, react explosively with cyanide; therefore it is imperative that all salts containing these materials be kept separate from cyanide mixtures.

In general, the same rules are followed for the maintenance and operation of cyaniding equipment as for any other salt bath equipment.

The maintenance of a correct cyanide concentration in the bath is extremely important. For the average case hardening application, a cyanide content from 20 to 30% has proved most economical. The optimum cyanide concentration for any particular application is governed by the specifications to be met. A periodic analysis should be made for sodium cyanide content, and salt of the proper cyanide content should be added in an amount sufficient to restore the predetermined concentration of the bath. Where drag-out is at a minimum, it will usually be found necessary to replenish with 96 to 98% sodium cyanide. Where drag-out is at a maximum, replenishing with a 45% cyanide salt will be sufficient. In most applications it will be necessary to use both a 45% salt and 96 to 98% sodium cyanide for replenishing the baths.

Neutral Hardening. The object of hardening carbon and alloy steel parts in a neutral salt bath is to develop a desired set of mechanical properties with no deleterious effect on the surface, such as scaling, decarburizing and pitting. Heating in a salt bath, followed by a water, oil or salt bath quench, can be used for the neutral hardening of all grades of carbon and alloy steels. The process is now in common use for gears, shafts, springs, screw-machine products, forgings, tools, dies and many other parts. However, this procedure may not prove economical for parts designed in such a way that they cannot be removed from the bath without excessive drag-out of salt.

Both fuel-heated and electric pot types of furnaces are used. However, the immersed-electrode type of furnace is generally preferred for neutral hardening, because the cost of maintenance is low. Pots externally heated by gas or

* For information concerning the chemistry of liquid carburizing and for data on the effect of duration of carburizing on the case depth, the reader may refer to page 692, in the CASE HARDENING SECTION.

oil must be made of heat-resisting alloys. Such pots can be produced only in relatively small sizes and the scale from them contaminates the bath. On the other hand, the immersed-electrode furnace ordinarily employs a refractory pot, built to any desired size or shape. These refractory pots have a long life, measured in years, and do not contaminate the bath. Neutral hardening is frequently obtained without the use of rectifiers in the bath.

Salts I-1, I-2, I-3 and I-4 are in common use for neutral hardening. Sometimes small amounts of sodium cyanide, silicon carbide or borax are added as a rectifier in order to avoid decarburization. It is important that the neutral salts should be stored in airtight containers, so that the moisture content before use will not exceed 0.5% by weight. Otherwise, an appreciable percentage of hydrochloric acid will be formed in the bath, not only affecting the work metal but also causing premature failure of electrodes and other metal parts in contact with the bath.

For neutral hardening, the bath should be free from sulfides, sulfates, oxides and carbonates and should contain no fluorides, especially where a refractory pot is used. The bath should never be overheated, since this may cause secondary reactions that will break down the solution.

A powdered graphite cover may be used on top of the bath to reduce both loss of heat and the amount of oxides forming in the bath. However, unless care is taken in removing the parts, this cover may introduce a cleaning problem.

A quick check that can be used to determine whether a bath is satisfactory, is to heat treat a high-carbon steel rod in the bath and to measure the hardness on the Rockwell 15-N and Rockwell C scales. If both scales check the same hardness, the bath can be considered satisfactory for most applications. A more accurate method is to take turnings, approximately 0.005 in. deep, off the surface of the rod and to determine the carbon content of the turnings. If the carbon content is the same as that of the bar before heat treating, the bath is neutral. Also the bar can be cut into sections and examined under the microscope to determine whether the surface has the same carbon content as the core.

Austempering, Martempering and Cyclic Annealing. Isothermal transformation diagrams, "S-curves", for certain commercial steels have been used as the basis for the interrupted quenching methods known as austempering, martempering and cyclic annealing. The quenching techniques employed in these heat treating processes are described in the article "The Quenching Process", page 620.

Quenching-bath temperatures and holding times are selected on the basis of the transformation diagram for the steel being treated. It is always necessary that means be provided, in the quenching bath, for cooling rapidly enough to remove heat from the piece at the desired rate, as determined by hardenability and mass, and to keep the temperature of the bath constant.

The quenching bath may he heated internally by gas or electricity. For dissipation of heat during quenching, a jacketed tank is often used. The bath is cooled by circulation of air at low pressure through the jacket, or by a spray of water against the outer surface of the quenching tank. Maximum speed of quenching is obtained by one or a combination of the following: an agitator that has a motorized propeller, a pump that forces salt against the work pieces at high pressure, or compressed air forced through the bath.

The salt that has proved most effective is a mixture of nitrates and nitrites that melts at approximately 290 F and has a working range from 350 to 1100 F, such as type L-1 in Table I.

Austempering involves quenching from the austenitizing temperature to a selected temperature above the M_s point and below the knee of the S-curve. The work material is held until transformation is complete, and then is cooled to room temperature.

Martempering consists in quenching to a temperature just above the martensite transformation range, and holding at this temperature long enough to equalize the temperature throughout the section (but not long enough to cause transformation to bainite); then cooling in air to room temperature.

Austempering and martempering offer special advantages where it is important to eliminate quench cracking and excessive distortion, which can readily occur during quenching in water or oil.

In any of the above procedures, it is important to select a steel with sufficient hardenability to ensure that the cooling rate of the quenching bath is greater than the critical cooling rate of the steel. Often the interrupted quench fails because of the selection of ■ steel with insufficient hardenability.

Mechanized salt bath furnaces are in operation for heat treating various sizes and shapes of steel forgings and castings. Generally these units consist of a neutral salt bath for austenitizing, and low-temperature salts for the quenching medium and for tempering if necessary. Both heating and quenching salts are water-soluble and are easily cleaned off after heat treating. *Caution.* Parts heated in a cyanide bath should never be quenched directly in the low-temperature nitrite-nitrate salts. Parts that have been liquid-carburized in cyanide baths should be transferred to a neutral salt bath before being placed in the low-temperature quenching bath.

In the hardening of steel, the formation of the softer structures should be avoided at the higher subcritical temperatures. In cyclic annealing, these soft constituents are formed intentionally by allowing transformation of austenite to take place at or above the knee of the S-curve. If a piece remains in the bath long enough to permit complete transformation, it may be cooled further at any rate desired.

Cyclic annealing in salt baths consists in heating the work pieces in a neutral salt to austenitizing temperature, then transferring them to another neutral bath and subsequently holding at a constant temperature until transformation has been completed. This process is practicable for annealing high-carbon and alloy steels when saving time is important. Salt baths also permit better control during annealing than the long-cycle, furnace-cooling process, and promote uniformity, more consistent results and a minimum of decarburization.

Heat Treating High Speed Steel Tools. Molten salts of various compositions are well adapted to all the operations in the complete heat treatment of high speed steel parts.

The critical operation in the hardening of high speed steel has always been the high-temperature heating. For salt baths to meet the requirements of this operation successfully, two major developments have been necessary.

1 The selection of a salt or mixture which will remain fluid and operable at the operating temperature, and which can be kept inert to the steel surface and can be washed easily from the treated work.
2 The design and construction of pot-type furnaces to hold the salt and serve reasonably long with a minimum of maintenance, at the extremely high temperatures involved (2200 to 2400 F).

The three chemical reactions possible in a salt bath at high temperatures are oxidation, carburization and decarburization. Most salts operable in the high-temperature range have little tendency either to oxidize or to carburize; in fact, they protect the steel from oxidation by blanketing it against contact with the air. The main problem then is decarburization.

The modern high-temperature baths are basically anhydrous barium chloride ($BaCl_2$) such as H-1 and H-2, contained in ceramic pots and heated by electrical resistance between two or more metal electrodes immersed in the molten salt. When freshly melted, this salt is inert to high speed steel surfaces and possesses the other characteristics necessary for operation at high temperature. After some use, however, the bath may become decarburizing because of accumulation of soluble and insoluble metallic oxides. When this occurs, deoxidation (rectification) may be accomplished by one of the following methods:

Silica. The periodic addition of sufficient silica (SiO_2) to the bath, in any desired manner, will keep the harmful oxide content down to a safe working level. The silica combines with the oxides to form silicates, which settle to the bottom of the pot in the form of a heavy viscous sludge that can and must be removed frequently. Addition of too much silica can be harmful to electrode life and safe operation of the furnace. Usually satisfactory additions of make-up salt contain between ½ and 5% of silica by weight.

Graphite Rod. A reasonably pure graphite rod, approximately 2 in. in diam, reduces the oxides in the bath to pure metal, which adheres to the rod. The exact method of using a graphite rod varies

somewhat, depending on the construction of the furnace. In some furnaces the rod is placed in special recesses in the pot walls and is submerged completely; in others, the rod is held by some clamping device above the top of the bath and is immersed vertically. In any type of furnace the rod should be withdrawn periodically, cooled to room temperature, and scraped to remove picked-up metal globules. This method is slower and less effective than the use of silica, but has the advantages of producing very little sludge, of being harmless to electrode life, and of maintaining higher fluidity in the bath.

Combination Method. A graphite rod used alone in straight barium chloride may not always be sufficient to prevent decarburization completely. In such instances very small amounts of silica may be added regularly to supplement the action of the graphite rod. This arrangement may prove to be the most generally acceptable method of rectification, since it combines the features of a minimum amount of sludge and bath viscosity with the excellent deoxidation characteristics of silica.

As a check on the decarburizing tendency of the high-temperature bath, test specimens should frequently be hardened by quenching in oil. A file-soft surface indicates a need for more rectification. This test may be supplemented by chemical analysis.

The soluble barium oxide (BaO) content (alkalinity) of the bath is considered the most active decarburizing agent and should be kept less than 3% by adequate rectification. For determining the content of BaO a 5-g sample from the bath may be dissolved in water and then filtered. The filtrate is titrated with N/10 hydrochloric acid, using a phenolphthalein indicator. The percentage of BaO can then be calculated:

$$\frac{\text{cu cm N/10 HCl} \times 0.00765}{5} \times 100 = \%\ \text{BaO}$$

The insoluble metallic oxides (of iron, chromium, nickel and such) have a slighter decarburizing effect and in general are kept automatically at less than the safe maximum of about 5%, by rectification based on the above test for BaO.

One of the most desirable features in the use of salt baths for hardening high speed steel is the fact that the work pieces can be supported, so that a minimum of distorting stress is applied, both while the material is in the bath and while it is being transported from one bath to another. This fact alone tends to reduce greatly the amount of distortion that occurs otherwise in heating tools of delicate shape to the very high temperatures required.

During salt bath operations small tools may be handled conveniently in baskets. For best results, it is recommended that the baskets be equipped with some means of separating individual pieces to avoid packing them together in a tight mass. Long slender parts, which may not need to be hardened throughout their length, may be supported by fixtures of the screw or clamp type, so that the work pieces hang vertically in the bath. Other types of work material may be wired, either singly or in groups, and suspended from long-handled hooks that can be laid across the top of the furnace. Since they must go through the high-temperature bath continuously, some fixtures for high production are made of heat-resisting alloys, although usually cheaper material, such as plain iron wire or low-carbon steel, is satisfactory for holding the work pieces.

In the hardening of high speed steel, several baths are used in sequence. The salts in these baths should be so related that among other factors, the carry-over from one to another will not be harmful. If there is doubt concerning possible reactions caused by carry-over, correct information should be obtained from the manufacturers of salts.

The bottom of the pot that contains the bath should be scraped periodically with a long-handled, perforated ladle to remove sludge. Dry powdered salt should be added as needed to maintain the bath level. When rectifiers are used, the removal of sludge will be necessary more frequently than otherwise.

All salt baths should be kept molten as much of the time as possible. During nights and week ends, the temperature is set down to a point just above the melting temperature of the salt and the pot is covered. Very little input of heat will be required to hold the baths in this condition.

Preheating. Either salt I-1, I-2, or I-3 may be used. Rectification is usually unnecessary where a ceramic pot is used. The operating temperature is usually between 1500 and 1600 F.

High-Temperature Heating. Either salt H-1* or H-2* may be used in a ceramic pot heated by internal electrodes made of 28% Cr iron, pure nickel, or a high-nickel alloy.

Electrodes that contain nickel will have the longest life but will cost more than the iron-chromium alloy and will cause nickel to be deposited either in or on the surface layers of the work pieces. If the silica content of the bath is held to a very low value and deoxidation is accomplished by a graphite rod, this tendency to coat the work with nickel may be minimized but whether it can be eliminated altogether is doubtful.

The hardening temperature depends on the grade of steel being treated. It is recommended that the control instrument be set about 25 to 40 degrees *lower* than in radiant furnaces to get equivalent results, because the charge will actually come closer to the control temperature in salt baths than in gaseous atmospheres. The steel is usually brought just to the operating temperature and not soaked. It is generally agreed that the temperature of the charge will become equalized with the salt temperature before the bath comes back to the control point. Therefore it is customary to consider that when the control instrument throws off the power, the steel is at the operating temperature and ready to be quenched.

Quenching. Moderately small pieces might be hardened successfully by quenching in oil or by cooling in still air from the high temperature, but a molten salt bath is recommended for parts of all sizes for three reasons: (1) to ensure that cooling through high temperature ranges is sufficiently rapid, (2) to equalize the temperature throughout the part before cooling further (principle similar to martempering), and (3) to wash off the $BaCl_2$, which is less easily dissolved in water than are most quenching salts.

Salt L-4 or a modification thereof is ordinarily used for quenching. The use of cyanide is largely a matter of preference. The presence of cyanide results in easier washing and somewhat greater fluidity at low temperatures. It also produces a file-hard carbon-nitride case about 0.002 to 0.003 in. deep on the surface of the material. This case-forming characteristic of cyanide is sometimes considered good insurance that any soft surface caused by decarburization at the high temperature, will be counteracted in a quenching bath that contains cyanide; others doubt the desirability of such cases, especially on unground tools.

Quenching baths should be operated below 1200 F, with 1250 F as an absolute maximum. The maintenance of correct temperature is complicated by the fact that most suitable salts when fresh have a melting point not lower than 1000 F, and this melting point rises when $BaCl_2$ is introduced. Consequently, the tendency is to keep increasing the temperature to keep the bath fluid. In baths that contain cyanide, high temperature may cause a crust to form on the surface, from reaction of the cyanide with $BaCl_2$. The remedy is *not* to raise the temperature further in an attempt to melt the crust, but rather to bail out salt and lower the temperature to 1150 F, keeping the bath fluid at this temperature by frequent additions of fresh salt.

All quenching baths accumulate considerable sludge of $BaCl_2$ in the bottom. Unless this sludge is removed frequently, it will become caked and difficult to scoop out.

The time required for holding the steel in the quench is usually about the same as during the high-temperature cycle. It is recommended that pieces of normal size be cooled to room temperature from the quench by hanging in still air.

All work-holding devices that enter the quenching bath, should be washed thoroughly and dried before being put back into the preheating bath.

Tempering. Either salt L-2 or salt L-5 may be used.

Tempering temperatures may vary between 1000 and 1200 F, depending on the hardness desired. The duration of tempering depends on the temperature and the results desired, but in general should be about 1½ to 2 hr total time for each tempering operation. After having been tempered, the work should be air-cooled to room temperature before the salt is washed off in water. If calcium chloride ($CaCl_2$) is present in the salt, special precautions

* Rectified in a suitable manner

should be taken to guard against subsequent rusting. The first washing should be followed by a short pickling treatment in an inhibited mineral acid or 10% acetic acid, plus one or two more rinsing operations with a final dip in an alkaline cleaning solution.

"Nitriding". This operation may be performed in any one of a variety of mixtures that contain fairly large percentages of cyanide. Salt C-10 is commonly used.

These "nitriding" baths are usually not very effective until they have aged by standing molten for a period of time to permit the formation of at least 5% cyanate. The bath should be operable at this stage and the cyanate content should be kept at more than 5% during operation, by periodic bailing out and additions of fresh NaCN or salt mixture. Occasionally it may be necessary to remove excess carbonate salts by cooling the bath to just above the melting point (about 850 F) and scooping the precipitate out of the bottom.

The "nitriding" operation is usually performed on finished or nearly finished tools. The usual temperature for the operation is 1000 to 1050 F and the duration of immersion may vary from 10 min to 1½ hr, depending on the type of tool and the results desired. The main purpose of this treatment is to produce an extremely hard, wear-resistant case on the ground surface, but it must be understood that this may cause some brittleness in tools of small size or delicate shape.

Annealing. As a means of heating both steel and nonferrous alloys for annealing operations, the salt bath is steadily widening its field of usefulness, principally because of the rapid rate of heating and the preservation of the surface of the metal. The principal application in this field lies at present in the stress relieving or process annealing operation, in which the metal or alloy is recrystallized after cold work and is thus softened for further cold forming or finishing operations. In the wire industry, salt bath annealing is used for softening low-carbon, high-carbon, high-alloy and stainless steels between passes, and is currently employed in heating austenitic stainless steels for the final softening quench. In the nonferrous field, salt baths have the following typical uses: the annealing of sterling silver at various stages in the forming operations, in order to soften it for further processing; and the annealing of aluminum alloy wire and shapes, as well as cupro-nickel condenser tubing and the like.

The salt bath method of process annealing has these advantages: elimination of all atmosphere and of the accompanying problems of oxide, pitting, decarburization and the like; almost no alteration of the surface condition; uniform heating of all parts of the charge; a very rapid rate of heating in comparison with other methods, and consequent reduction in floor space required for a given installation. Disadvantages include the rinse necessary to remove adhering salt; the maintenance of electrodes, pot and salt in a suitable condition for operation; and the need for a continuous flow of material at all times to ensure economical operation.

The newer installations for salt baths are entirely of the internally heated, immersed-electrode type, having metal pots for low-temperature service, and refractory pots for high-temperature service. In the annealing of wire, the tightly bound coils are strung on a horizontal bar, if the annealing temperature is low and the gage of wire heavy. If there is danger of sagging into an oval shape, a condition known as "horsecollaring", the coils are strung on a saddle fixture that supports the upper half. For handling partially formed articles, trays made of coarse wire mesh or special fixtures are employed. Immediately after removal from the furnace, material is immersed in a strong stream of hot water, which rapidly dissolves the adhering salt. Light pickling is generally necessary before the next drawing or cold forming operation.

The actual cycle employed in process annealing depends on the material being handled, the amount of prior cold working and the amount of softening required for subsequent processing. In annealing practice for steel, the carbon and engineering alloy grades are heated to a temperature just below the transformation range and are removed from the salt bath as soon as the entire charge has reached temperature. Temperatures range from 1250 to 1325 F, depending on the gage of the wire and the duration of heating (from 30 to 40 min in typical installations, depending on the weight and tightness of the coil). From four to six 250-lb coils are annealed in a batch and handled together through the subsequent rinsing, pickling and liming operations in preparation for further drawing.

The intermediate grades of stainless steel are treated in the same temperature range, but are generally held at temperature for time intervals up to 30 min before removal from the bath; for example, type 430 stainless steel is heated to 1325 F and held 30 min before discharge, while type 416 is held 10 min at 1275 F. The austenitic stainless steels and certain nickel alloys are process annealed at about 1850 F; austenitic stainless steels may be quenched finally from 2100 F after being heated in such a bath. The temperatures and time periods that are used in the stress relieving of nonferrous alloys cannot be stated precisely since they depend largely on composition, amount of prior cold work, and the next operation to be performed. Sterling silver, for example, is completely softened at 1225 F; the total heating cycle for tableware and other small articles does not exceed 10 min. For other operations, however, temperatures ranging from 700 to 900 F are used satisfactorily.

The carbon and engineering alloy steels are usually heated in a molten salt mixture composed of equal parts of Na_2CO_3 and KCl. The same salt may be used as successfully if the intermediate grades of stainless steel are processed through the same installation. This salt does not break down rapidly and requires no rectification. The bath should be sludged regularly and the pot should be drained and cleaned about twice yearly in continuous operation. The H-2 salt mixture is used for the high-temperature treatment of austenitic stainless steels and nickel alloys. The low-temperature carbonate-chloride mixture is widely used in the annealing of most nonferrous alloys.

Brazing Steel and Copper Assemblies. The molten salt bath may be used as a medium for joining steel or copper metals by nonferrous brazing, simply by dipping the assembly into the bath. This process is recommended only for brazing assemblies that can be washed readily, after the brazing operation, in order to remove the traces of solidified salt adhering to the joint area. The process is satisfactory for brazing with almost any bonding agent, such as silver solder, bronze, brass or copper, but is not satisfactory for low-temperature solders that flow below 900 F. Although all the bonding agents mentioned above may be used, silver and copper alloys have proved most satisfactory and efficient when a salt bath is employed as the heating medium.

During the operation, the assemblies to be brazed should be fitted tightly together with not more than 0.004-in. clearance and with a shim of brazing metal between the parts. A wire of small diameter may be wound around the outside of the joint, instead of the shim between the parts. During the melting, the wire is drawn into the joint by capillary action. It is important that the assembly remain in correct alignment while heating; this sometimes requires special fixtures.

The dip brazing in the salt bath is accomplished in seconds rather than the minutes required by other processes; hence a rather small furnace will produce a large output. Moreover, no cooling chamber is required after the brazing cycle, because the work material is either cooled in the air or quenched directly from the brazing temperature, thus reducing requirements for floor space to a minimum.

If the assembly is large or long and brazing is required only on one end, the salt bath has the definite advantage of local heating, making it unnecessary to heat more than the section to be brazed. This feature accounts for the present general use of salt baths for brazing the return bends on heat exchangers. Each end of such a unit may have 20 to 100 joints, which are brazed simultaneously, in one minute or less, by immersing the end of the assembled unit in the bath.

The operation of the process is relatively simple. Because of the high temperatures necessary for copper brazing, salt furnaces that have internal electrodes are recommended; the preferred salt is H-2. When the carbon

rod is used as a rectifier (*see* section on Heat Treating High Speed Steel Tools, page 286) the salt is rendered nondecarburizing for an indefinite period. The temperature should be controlled closely, according to the size of the assembly and the parent metal used.

A temperature of 2050 F is recommended for the copper brazing of steel. After heating long enough to "flow" the copper, it is advisable to quench the assembly in another salt bath (L-4 or L-5 salts) operating at 1000 to 1150 F. Occasionally this quenching bath is used for preheating also. By selecting the proper transformation temperature and time in the quench, it is possible to anneal the parent metal to any desired pearlitic structure isothermally.

The same process may be employed for all other bonding metals, except that the "flow" temperature will vary according to the metal used. When brass is used as the bonding metal, very close temperature controls must be employed. The zinc in brass may oxidize at a temperature slightly above the melting point. This results in a bond of low quality; furthermore the zinc oxide contaminates the bath. For brazing the metals that melt at lower temperatures, salts I-1, I-2 and I-3 are recommended.

Another interesting use for salt baths is in the simultaneous carburizing and brazing of a steel assembly. An activated carburizing bath, such as salt C-5, is used and operated at about 1675 F. When the brazing material—usually Muntz metal (60% Cu, 40% Zn)—is assembled at the joints, the steel assembly is immersed in the bath and left there for the time required in order to produce the desired depth of case. During this time, the brass melts and enters the joints. The assembly is then removed and quenched in water. By this method, brazing and carburizing are accomplished in a single operation.

Brazing Aluminum and Aluminum Alloys. For dip brazing, aluminum or aluminum alloy parts are assembled on a suitable rack, when the filler material is in place, and are then dipped into a molten salt bath held at the correct temperature to melt the filler material and cause it to flow into the joints. The process is peculiarly adapted to the joining of thin-gage aluminum or aluminum alloy assemblies, including aircraft heat exchangers, thin tubing, radiators and similar assemblies that permit complete drainage of the molten flux after brazing.

The advantage in dip brazing lies in the fact that many joints, particularly line-contact joints such as exist in heat exchangers, can be made in one operation. The chief disadvantage is the drag-out of flux. Parts to be dip-brazed should be designed so that alignment during brazing is obtained by the fit of the parts rather than by holding the pieces in jigs or fixtures.

It is important that the flux be held in a container that will not cause contamination. Certain ceramic linings have been found suitable and nickel pots are satisfactory, but a service life of about six months is all that can be expected from the nickel.

The flux may be heated either externally by gas or internally by immersed electrodes. Control of temperature within 5 F of the brazing temperature, is essential. The bath should be large enough so that the chilling effect from immersing the parts to be brazed, does not decrease the temperature too much. Increased speed and smoother joints are obtained if the parts are preheated to the range between 900 and 1000 F before they are dipped into the molten flux. This preheating, usually a separate operation, prevents local freezing, distortion, inconsistent joining and entrapment of flux in small openings. In some installations the work is preheated directly over the salt bath and is then lowered into the molten bath at the proper temperature, as shown in Table III.

The assembled parts are dipped from 30 sec to 3 min, depending on the shape and thickness.

The flux bath consists of a mixture of chlorides and fluorides having suitable melting point, density and fluxing characteristics. Two fluxes are now available as No. 34 and No. 53 brazing fluxes.

Addition of flux, to replace drag-out or to increase the depth, will introduce moisture. A coil or piece of aluminum sheet dipped into a freshly melted bath of flux, will eliminate the moisture before the brazing operation. As long as moisture is present, hydrogen, evolved by reaction of the water with aluminum, will ignite on the surface, producing small flames. The source of this moisture is water chemically combined in the flux constituents, and unless the bath is dehydrated, the moisture will attack the aluminum parts. During the period when a dip-brazing bath is in use, metallic impurities may enter the bath, making periodic cleaning necessary. For this purpose aluminum sheet is dipped into the bath at intervals determined by the appearance of discoloration on the work material during brazing. Since a certain amount of flux is lost by drag-out, partial purification results from the continuous addition of flux to the bath.

Table III. Brazing Temperatures for Some Aluminum Products

Brazing Material	Temperature, deg Fahr
2 S	1160 to 1185
3 S	1160 to 1185
No. 1 Brazing sheet	1160 to 1185
No. 2 Brazing sheet	1160 to 1185
53 S	1060 to 1090
61 S	1060 to 1090
No. 11 Brazing sheet	1090 to 1140
No. 12 Brazing sheet	1090 to 1140
No. 21 Brazing sheet	1090 to 1120
No. 22 Brazing sheet	1090 to 1120

Often the filler material for the assembly is supplied by special brazing sheet. A thin coating of filler metal is bonded to one or both surfaces of the sheet in the mill. Parts formed from this sheet can be joined to coated or uncoated sheet by dip brazing. The sheet is available as an alloy that cannot be heat treated (No. 1, 2, 11 or 12 brazing sheet) and also as an alloy that can be heat treated (No. 21 or 22 brazing sheet). The heat treatment may be accomplished directly by quenching from the dip brazing bath or, if the design is such that direct quenching will result in breakage or distortion, the heat treatment may be conducted as a separate subsequent operation.

After the brazing operation, it is always essential that the joints be properly cleaned in order to remove flux residue that might cause corrosion during subsequent exposure to moist environments. The first step in cleaning is immersion in water—preferably boiling—which will remove the major portion of the flux. Then the work is dipped into concentrated nitric acid for 5 to 15 min, depending on the design, drainage and accessibility of the parts of the assembly. The acid is removed by a rinse in hot water. An alternative cleaning method is to dip the work material for 5 to 10 min in a solution of 10% nitric acid plus 0.25% hydrofluoric acid at room temperature and then to rinse with water. Brazed parts with thin sections, 0.010 in. and lighter, and also parts where maximum resistance to corrosion is important, should be immersed in hot water and then dipped in a solution of 10% nitric acid and 10% sodium dichromate for 5 to 10 min, before a final rinse in hot water.

Heat Treatment of Aluminum and Beryllium-Copper Alloys. Salt baths are employed as the heating medium in the solution heat treatment of certain aluminum alloys, and are also used extensively in the precipitation or aging treatment of beryllium-copper alloys. These baths heat the alloys rapidly and uniformly.

The use of salt baths is more desirable for the heat treatment of wrought products than for castings, since castings are generally irregular in shape and have relatively rough surfaces that greatly increase losses of salt through drag-out. Also, removal of salt from the surface of a casting is difficult and sometimes impossible; hence severely corrosive conditions may result.

Because of the more rapid heating and the consequently short cycles used in a salt bath, clad aluminum objects can be heat treated with a minimum of diffusion of the pure aluminum coating into the base alloy; thus such work retains its resistance to corrosion. The complete immersion of the parts prevents bare aluminum alloy from blistering as it sometimes does in air-convection furnaces.

When parts such as stampings and extruded and formed shapes are treated in salt baths, distortion is noticeably less, because of the uniform heating and the possibility of quenching the parts individually. A further advantage is

that salt baths permit parts that have widely varying gages to be treated simultaneously.

Because of the widely varied shapes and sizes of aluminum aircraft parts to be heat treated, and because most of these parts are given further forming operations after solution heat treatment, the use of elaborate fixtures is not practical. Ordinarily, parts are suspended individually or on small racks and are handled manually.

Small beryllium-copper parts, hardened in salt, are commonly held in steel fixtures, particularly if they are formed parts and if dimensional stability is of prime importance.

Aluminum. Time-temperature cycles for the solution heat treatment of aluminum in salt baths depend on the alloy and gage. The range from 880 to 980 F includes satisfactory temperatures for virtually all the wrought alloys heat treated in salt baths. Time cycles range from 10 min to 1 hr, depending on the gage. The time in the bath may be considered the time "at temperature" under normal operating conditions.

The salt generally used is sodium nitrate (L-3). However, if the salt bath is to be used for both annealing and heat treatment, a mixture of sodium nitrate and potassium nitrate (L-2) is used, because it has a lower freezing point. Commercial grades of these salts are suitable for heat treating baths. The addition of about ½ oz of sodium dichromate or potassium dichromate per 100 lb of nitrate, is recommended for inhibiting corrosion from residual salt. After continued use of the salt bath, the heat treated material may show evidence of etching or corrosive attack, when removed from the quench water; this is a warning that more dichromate should be added. An alternative method is to check the nitrate bath and add potassium dichromate so that the pH of a 1% solution never exceeds 7.5. Care must be taken to ensure that the potassium dichromate is thoroughly dry before it is added.

Several fatal and disastrous explosions* have occurred during the heat treatment of aluminum alloys in nitrate baths, while relatively few explosions have been reported in the use of nitrate baths for ferrous products, probably because lower temperatures are used for ferrous products. Since nitrate salts are highly oxidizing, special precautions must be taken to prevent any reducing salts, such as cyanide, from being added by mistake, with explosive results. A bath of nitrates should never be used at temperatures above 1100 F, because of the possibility of violent reactions. The reaction with iron may start at a temperature as low as 1100 F and is vigorous at 1600 F. This danger from iron pots is caused particularly by local overheating, which sometimes results when sludge or sediment accumulates at the bottom of the pots and the heating is applied externally through the bottom. This kind of attack is less serious when the pots are made of certain alloy steels.

Aluminum is reported to react vigorously with the nitrate at 1500 F and in some instances as low as 1350 F. Under no circumstances should magnesium-base alloys ever be heat treated in nitrate, nor should aluminum alloys that contain more than a few per cent of magnesium, be heat treated in this manner.

Beryllium Copper. Precipitation hardening of beryllium copper is accomplished between 600 and 700 F. Time periods may range from 1 to 3 hr at 600 F, to as low as 15 min at 700 F. Salts used in these treatments are nitrate-nitrite mixtures (L-1).

The temperature of the bath and the duration of immersion must be controlled carefully. At the higher temperatures, control becomes more critical. After the heating cycle, parts are quenched in water to remove salts and allow handling, but not for any metallurgical reason other than to control definitely the length of the heating cycle.

Cleaning and Descaling Processes. Sodium hydride, a strong reducing agent, is employed in this process to reduce metallic oxides, such as annealing scale and mill scale, thereby expediting the cleaning of metals and alloys during the processing and fabrication into finished articles. When the reducing reaction stops, there is no further action; consequently there is no attack on the base metal. All metals and alloys are amenable to this treatment except those that react with fused caustic soda or that have physical characteristics which are affected adversely by the temperature of the bath (700 F plus or minus 20 F). Materials that react slowly with fused caustic soda, may be treated during short cycles if satisfactory results are obtainable. The scale produced in oxidizing atmospheres is reduced quite readily; on the other hand, it is reported that the scale produced on some high-chromium irons in highly reducing atmospheres is sometimes difficult to remove. Most oxides that form scale are reduced to the metal. Oxides of metals that form acid radicals are only partially reduced, but the action is sufficient to produce entirely satisfactory results.

Fused caustic soda is used as a carrier bath for the sodium hydride. The concentration of sodium hydride is kept within the range of 1.5 to 2% by weight and is produced "in place" by metallic sodium and hydrogen reacting in open-bottom chambers partially immersed in the bath. These chambers, called "generators", are arranged where convenient on the sides or ends of the carbon steel tank that contains the descaling liquid. Sodium bricks, weighing either 2½ or 5 lb, are fed at regular intervals to the generators into which hydrogen or dissociated anhydrous liquid ammonia is introduced near the bottom, at a rate adjusted to the rate of adding sodium.

No pitting occurs during descaling and it is not possible to overtreat the work material. Pickling losses are eliminated since there is no attack on the metal in the descaling bath. The working temperature (700 F) is below the transformation range of most steels, which makes treatment possible without changing the structure of alloys.

The process has been used commercially to descale the following metals and alloys:

SAE and AISI steels	Chromium-nickel stainless steels	Inconel
Carbon steels	High speed tool steels	Silver
Cast iron and steel	Silicon steels	Copper
Chromium stainless steels	Nickel	Stellite

Sodium hydride descaling baths are also being applied to iron castings, since this type of bath readily removes any sand entrapped in recesses or adhering to the surface. Installations have been made for cleaning steel stampings, such as the frames for automobile windows and autobody trim. Here the function is not descaling, but rather the rapid and effective removal of surface dirt or stain caused by previous manufacturing operations.

Sodium and hydrogen react directly to form sodium hydride, as shown by the following equation: $2Na + H_2 = 2NaH$. Theoretically, each pound of sodium requires 7.8 cu ft of hydrogen. When dissociated ammonia is employed as the source of hydrogen, approximately 12 to 15 cu ft of the dissociated gas is required (75% H_2 and 25% N_2 by volume). The sodium hydride that is formed, is dissolved in the fused caustic carrier bath and emerges from the bottom of the generator. The sodium hydride is then distributed uniformly throughout the bath by the convection currents, without auxiliary means. Since the sodium hydride bath is quiescent and does not give off irritating fumes or vapors, hooding is unnecessary.

Reactions between sodium hydride and scale are illustrated in the following equations:

$$4NaH + Fe_3O_4 = 3Fe + 4NaOH \quad (1)$$
$$NaH + CuO = Cu + NaOH \quad (2)$$
$$NaH + Cr_2O_3 = 2CrO + NaOH \quad (3)$$

Complete reduction is shown by equations (1) and (2) while partial reduction is shown by equation (3). The sodium hydride reduces the scale in all these examples to the metal or lower oxide, simultaneously forming caustic soda. Since the carrier bath is caustic soda, no undesirable materials are made that necessitate replacing the bath.

A typical treating cycle consists of the following steps: sodium hydride treatment, water quench, water rinse, acid dip and water rinse.

Work to be processed is placed in baskets or on suitable racks; careful arrangement is unnecessary provided the bath has free access to and from the surfaces that require treatment. Optimum duration of treating may be established readily by experiment and usually ranges from 8 to 20 min for large batch operations.

When the scale has been reduced completely, the work

* For a discussion of Safety Precautions in the Use of Salt Baths, the reader may refer to the February 1947 issue of *Metal Progress*.

is removed from the bath, is allowed to drain and, while still hot, is immersed in water. A large portion of the reduced material is dispelled during this operation.

A high-pressure water hose is used in rinsing away loosely adhering material and washing off any caustic soda that remains.

A short dip in acid produces bright surfaces, such as are required for drawing, rolling and forming operations. This dip may be eliminated when parts are cleaned before inspection, machining and the application of hot dip coatings.

A high-pressure water hose is used in rinsing away smut and acid that remain after the brightening dip. A clean bright surface is obtained by this operation.

Other salt-bath processes that do not employ sodium hydride as the active element are now in commercial use for descaling, cleaning, and preparing the surface of metals. In one of these processes, the bath consists essentially of sodium hydroxide. When a direct current is passed through this bath, oxidation is effected at the positive pole and reduction at the negative pole. The metal to be processed becomes one pole of the electrical circuit, and the tank becomes the other. By means of a reversing switch, the polarity of the work material can be changed from positive to negative. The timing and sequence of oxidation and reduction depend on what material is being processed and what kind of surface is desired.

Another bath, for descaling stainless and alloy steels, as well as nonferrous metals, consists essentially of caustic soda. No sodium hydride is used, but a still undisclosed addition is made, and the bath is operated at 900 to 1000 F, instead of at 700 F as in the sodium hydride process.

Miscellaneous Applications. In addition to the foregoing applications, salt baths are used for various other purposes.

Tempering Carbon and Alloy Steel Parts. For this application a bath composed of nitrates and nitrites is usually employed, such as L-1 or L-2. The eutectic mixture has a melting point of 275 F, and the useful operating range of the bath is from 300 to 1100 F.

Coloring Steel Parts. When nitrate baths, with or without the addition of manganese dioxide, are used in the temperature range from 600 to 1000 F, they impart the characteristic blue colors to prefinished parts. The time of immersion varies with the temperature and with the size of the pieces, but rarely exceeds 6 min. Care must be taken not to leave the metal in the bath longer than necessary to produce the blue color desired. Otherwise the color will be destroyed, changing to black.

Removing Enamel. The formed steel shapes from defective enamelware, can be recovered for re-enameling. This is accomplished by immersing the pieces in a molten bath of sodium hydroxide, kept at a temperature of approximately 900 F. The enamel is removed in a matter of minutes by the reaction of the caustic soda. However, the removed enamel does not dissolve in the caustic bath. Instead, the bath is allowed to remain quiescent for a period, during which the suspended enamel settles to the bottom, where a pan is provided to collect it.

Heating for Forming and Forging. The use of salt baths for heating steel shapes before forming or forging, is of recent origin and the true merits of the practice have not yet been clearly established. During World War II certain salt baths were used successfully for heating selectively the ends of high-explosive shells, for the nosing or closing-in operation. The selectively heated portion of the hollow forging was then subjected to combined upsetting and forming operations by dies in a press. Salt baths are also used occasionally for certain forming operations. The problem presented by the accumulation of salt in the dies, must be solved before the salt bath can be utilized for any forging application.

Cleaning Metal Molds. Another recent innovation is the use of a nitrate bath in the temperature range from 600 to 800 F, for removing residual rubber, carbon black and lubricants from rubber molds, both cast iron and aluminum. The molds to be processed are simply immersed in the bath from 10 to 30 min and then quenched in water.

Lead Baths

By R. B. Schenck*

THE various liquid heating mediums employed in the heat treatment of steel fall into three general classes: metals, salts and oils. Of all the metals, lead is the only one that has proved suitable as a commercial bath material. Lead is used for this purpose in its commercially pure form, without the addition of other metals. The salt bath materials are usually mixtures of two or more different salts and cover a wide range of composition. The oils are limited to low-temperature applications well below the melting point of lead and will not be discussed here.

Lead has little, if any, application in the heat treatment of nonferrous metals and alloys, many of which are actively attacked by molten lead.

Properties of Lead

Melting point, deg Fahr	621
Heat to raise metal from 60 F to melting point, Btu per lb	18
Latent heat of fusion, Btu per lb	11.3
Mean specific heat, liquid state	0.034
Boiling point, deg Fahr	3170
Unit weight, solid, lb per cu in	0.41
Unit weight, liquid, lb per cu in	0.37

Comparative Properties of Lead and Salts.* *General Comparison.* In comparing the properties of lead with those of the commercial salt bath materials, there are certain marked characteristics which differentiate the two. Lead is higher in specific gravity, higher in thermal conductivity, higher in electrical conductivity, lower in specific heat and lower in latent heat of fusion. The melting point of lead is lower than that of any of the salts used for hardening, but higher than that of most of the tempering salts. Lead has a total working temperature range of about 650 to 1700 F. The salts, as a class, have a range of approximately 350 to 2400 F. Lead oxidizes readily but is otherwise stable and has no appreciable chemical action on the metals with which it comes in contact. Many of the salts tend to decompose and some have various chemical effects on the metals. Lead does not adhere unless the stock is impure or oxidized, but the salts cover the work metal with a film of bath material. Lead is not hygroscopic, whereas the salts all possess this property to a greater or lesser degree. Lead has a much higher heating rate than any of the commercial salt bath materials.

Specific Gravity. Steel sinks in all of the salts, but floats on lead unless immersed by suitable fixtures. The specific gravity of molten lead is approximately 10, while that of the salts is about 2.

Thermal Conductivity. The high thermal conductivity of lead is one of its most valuable properties, tending toward rapid heating, high output, uniform temperature throughout the bath, and high thermal efficiency.

Electrical Conductivity. Because of its high electrical conductivity, lead does not lend itself to internal resistance heating by immersed electrodes. The salts, however, are readily heated by this method, which offers greatly increased pot life and improved temperature control as advantages over external heating. Both metal and ceramic pots are used in electrode heating.

Specific Heat. Because of its low specific heat, the thermal capacity of lead is less than that of most of the salts even on the basis of volume. Low thermal capacity results in greater temperature drops where cold stock is intro-

*For information concerning the use of salt baths in heat treating operations, see the article on page 283.

duced, and decreases thermal stability. Low thermal capacity also tends to reduce time and fuel in bringing a cold pot up to temperature; also it probably increases thermal efficiency in batch operation, and maintains a greater average temperature differential between the pot and the source of heat.

Latent Heat of Fusion. The low latent heat of fusion of lead tends to cause the formation of heavier layers of solidified bath material when cold stock is placed in the pot. Independent of melting point and other considerations, these layers actually form more extensively in all salt baths, as a result of the much lower thermal conductivity of the salts. On the basis of volume, the number of heat units involved is less for lead than for most of the salts; consequently, less time and fuel are required in bringing a cold pot up to temperature.

Melting Point. The melting point of a bath material not only determines the minimum temperature of operation, but also has a pronounced effect on the heating rate when cold stock is charged. The solidified layer of bath material that forms on cold stock, in lead and salt baths, must be completely melted before the temperature of the stock can rise above the melting point of the bath. The lower the melting point, the less will be the weight of frozen material formed. The greater the difference between the melting point and the bath temperature, the more rapidly this layer will be removed. Heat conductivity plays an important part in this connection, with the result that, for the same temperature differential, the frozen layer melts much more rapidly in lead than in salt baths. Therefore, lead can be used satisfactorily at temperatures closer to the melting point, and the heating rate is less adversely affected at higher temperatures. Other factors being equal, a bath operating at 1500 F with a melting point of 700 F will heat more rapidly than one operating at the same temperature with a melting point of 1300 F. In some instances where intricate parts would otherwise be inclined to warp or crack in hardening, the retardation of heating because of the solidified layer is distinctly advantageous. Preheating the stock to temperatures below the melting point will decrease the amount of frozen material, and temperatures above the melting point will, of course, eliminate the solidified layer.

Temperature Range. The wide temperature range of lead, approximately 650 to 1700 F, makes the lead bath available for the majority of hardening and tempering operations. The lower limit depends primarily on the melting point; the upper limit is determined by the ability of the pots to stand up and the ability of the coverings to give adequate protection against oxidation.

Some of the salt mixtures are used as high as 2400 F for the hardening of high speed steel, and others are employed for tempering as low as 350 F. All intermediate ranges can be covered by selecting proper salt mixtures.

Oxidation and Decomposition. Molten lead is readily oxidized by the air at all temperatures and must be protected by a suitable covering to prevent excessive formation of dross. Lead oxide is sufficiently insoluble in molten lead to preclude any appreciable contamination of the bath as a whole. Aside from this tendency to oxidize, lead is inherently stable in composition when used as a bath material, and seems to be free from any tendency to pit or decarburize the work metal.

Many of the salts tend to oxidize or decompose after continued use, and require the addition of so-called "rectifiers" to prevent changes in the properties of the bath, sometimes resulting in troublesome sludge deposits and pitting and decarburization of the work material.

Rusting of the Stock. Lead leaves no corrosive agent on the stock after heat treatment. Certain salts, especially the chlorides, rust steel very readily in the presence of moisture, so that cleaning with hot water or hot sal soda solution is frequently necessary to remove all the salt.

Chemical Action on Pots. Lead seems to have no appreciable chemical action on the commercial pot materials, but some of the salts are troublesome in this respect. The nitrates and nitrites attack metals violently when slightly overheated, and the cyanides are detrimental to chromium-nickel alloy pots if permitted to enter the combustion chamber. Most of the other commercial salt mixtures normally have little chemical action on the pots and, in comparison with lead, the shorter life frequently obtained is probably more the result of local overheating from external firing than of any other cause. Local overheating is much more prevalent with salts because of their lower heat conductivity. Sludge formation may also be a contributing factor of considerable importance.

Adherence to the Stock. The tendency of lead to oxidize is a troublesome feature, resulting in loss of lead and dirty stock. Suitable coverings must be used, but at low temperatures even the best coverings may be inadequate and special means are often required to clean the work. Above 850 F, however, lead can be well protected and the bad effects of oxidation kept to a minimum.

Salts cover the stock with a continuous film of the bath material, resulting in large mechanical losses, but because of the solubility of these materials in water, the work is easily cleaned. The adhering film of salt may be an advantage where it is important to have a fine finish, since this film effectively prevents oxidation by the air when the metal is removed from the bath. The thickness of the film and, consequently, the mechanical loss, depend largely on the fluidity of the bath.

Affinity for Water. The fact that lead does not absorb water is a decided advantage. Some of the salts are objectionable in this respect and require careful handling in order to avoid dangerous explosions when they are added to a molten bath. All the salt bath materials have more or less affinity for water and should be shipped and stored in airtight containers.

Heating Rate. The heating rate, or time required to bring a piece of steel of a given size up to the temperature of the bath, depends mainly on heat conductivity and melting point. Lead so greatly excels in heat conductivity that, for any temperature within its range of operation, few other bath materials approach it in rate of heating.

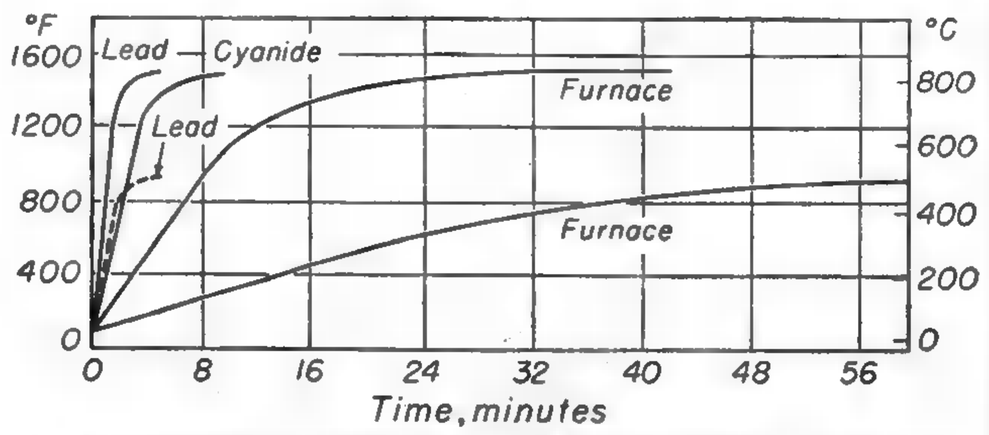

Fig. 1 Comparative heating rates of steel in different mediums

Figure 1 shows the comparative heating rates of steel in a lead bath, a cyanide bath, and an oven furnace. The test piece consisted of a cylinder of low-carbon steel with a stem on one end bored to admit a thermocouple. All the units tested were of sufficient size to prevent more than slight temperature drops when the cold test piece was introduced. The lead and cyanide baths were of exactly the same size. The baths and furnace were constant in temperature and remained nearly so, without firing, throughout the duration of the test. By analysis at the time the test was performed the cyanide mixture showed a composition of approximately 14% NaCN, 14% NaCl, and 72% Na_2CO_3. The extremely rapid rate obtained in lead is clearly shown. It is also interesting to note that lead heats to the required temperature in the same time at 900 and 1500 F, while the oven furnace takes longer to heat to the lower temperature.

Quality of Lead Used. The grade of lead purchased for baths is not of great importance. Ordinary pig lead seems to answer every requirement. Special grades, claimed to be superior for lead pot work and marketed at a higher price, apparently give no better results than the regular commercial pig. Tin is to be avoided since, even in small percentages, it tends to cause lead to stick to the work. Tin contamination is sometimes encountered in lead which has been refined from dross. Sulfur also is claimed to be an objectionable impurity.

Pot Materials. In general, there are three classes of pot materials: cast iron, steel, and the special alloys.

Cast Iron. Cast-iron pots, if properly made, usually give good service at temperatures below 1300 F. At higher temperatures, cast iron has not been found satisfactory, except in small units operated at low output. The composition of such pots ranges from ordinary gray iron to the so-called "alloy iron", made with additions of steel scrap and containing small quantities of alloying elements.

Steel (Cast and Pressed). Cast steel is used for all temperatures throughout the range of lead. Below 1300 F it gives excellent results. At higher temperatures the life depends largely on the conditions of service. The chemical composition varies considerably, and within certain limits is of much less importance than freedom from porosity.

Pressed steel pots are also successfully used throughout the temperature range of lead. Their advantage lies in light weight and freedom from porosity. Unfortunately they do not possess the flexibility of design attainable with cast steel and, on account of die cost, are confined for the most part to standardized shapes and sizes.

Special Alloys (Cast and Pressed). Most of the special alloys come under three general classifications: high nickel-chromium, low nickel-chromium, and chromium. These materials are all much higher in price than steel and, to prove economical, must give correspondingly longer service. They are always used at temperatures above 1300 F, since they cannot compete with cast iron and steel in the tempering range.

Special alloy pots are usually cast, although certain compositions are obtainable in pressed form. As with cast steel, the composition of a cast alloy pot is often of less importance than its freedom from porosity. The advantages and the limitations of design of the pressed steel pot apply in greater degree to the pressed alloy pot.

Pot Design. An important factor in obtaining efficient service is the design of the pots. Sharp corners and abrupt changes of section should be avoided wherever possible. Large radii in corners below the lead level are especially important. Thickness of section is a much disputed point. As a rule, the cast special alloys do not require such heavy bottoms and sidewalls as cast steel. Extremely thin sections tend to cause failure because of bulging followed by cracking; thick sections often fail to give service in proportion to their greater cost, especially when operated at high temperatures and high output. In other words, the life of a pot is not directly proportional to its thickness, except possibly within narrow limits. Probably the premature failure of thick pots often results from the greater temperature difference between the inner and outer surfaces. Pressed pots, either of steel or of special alloy, are necessarily of quite uniform section throughout.

Furnace Design. Lead baths are generally fuel-heated with either oil or gas. Also in use are electrically heated units, in which the heat is applied by means of resistors surrounding the pot. The principal advantages of electric heat consist of exceptionally long pot life and cleanliness. Electric heat is especially well adapted for use in the machine shop. The following discussion, however, is confined to fuel-heated baths. The design of the furnace, and especially of the refractory setting which supports the pot and forms the combustion chamber, should receive the most careful consideration. Proper location of burners and vents, adequate combustion space, correct vent area, length of flame travel, location of splash brick, and height of combustion chamber are all items which, if neglected, may result in unsatisfactory and costly operation. For information on fuel-heated and electrically heated furnaces see the articles on pages 267 and 273 of this Handbook.

Lead Bath Coverings. As previously stated, molten lead is readily oxidized by the air at all temperatures and must be covered with some suitable material in order to avoid excessive lead loss and dirty stock.

Solid Coverings. Wood charcoal, corncob charcoal, charred nut shells, charred leather, coal coke and petroleum coke are some of the materials which have been used as pot coverings. One of the best coverings is hardwood charcoal, size No. 3, also used in the manufacture of carburizing compounds, but this covering is not always the most economical. In determining the most suitable covering, a great deal depends on the nature of the work and the temperature of the operation. In hardening transmission gears, the best covering obtainable is generally none too good; but in hardening axle shafts later to be tempered in lead, a covering of coal coke or the cheapest grade of charcoal screenings will answer the purpose.

The action of the carbonaceous coverings is both chemical and mechanical. Their efficiency depends, to a great extent, on the rapidity with which they burn and the temperature at which burning starts, sometimes called the "kindling temperature". The chemical action is caused by the reducing effect of carbon monoxide gas generated by the combustion of the covering. Below the kindling temperature no carbon monoxide is formed and the protective effect becomes entirely mechanical. Coal coke has such a high kindling temperature that it is virtually useless in the tempering range, although it makes an excellent covering for some classes of work at the higher temperatures. Wood charcoal has a much lower kindling temperature, somewhere in the neighborhood of 850 F, and will protect the lead much less effectively at 800 than at 900 F in spite of the fact that the tendency of lead to oxidize increases rapidly with temperature. The size of the covering, which must also be considered, depends largely on the nature of the job. Sizes much larger than No. 3 charcoal are generally unsatisfactory.

Depending on the nature of the work, the kind of covering employed and the temperature of operation, the bath must be skimmed more or less frequently. The coverings burn to an ash, which collects rapidly and interferes with the action of the carbon monoxide gas. Moreover, the protective effect is never perfect and a certain amount of oxide will always form, even under the best conditions. This ash and oxide must be removed and replaced with new material every so often or trouble will result.

At temperatures below the kindling point of the covering, the problem of cleaning the stock often becomes serious. This difficulty has been overcome by dipping the stock into molten caustic soda immediately after its removal from the lead, and then quenching in water. The result is perfectly clean work and a large saving in lead. The caustic soda pot is held at a temperature slightly below that of the lead. Sodium nitrate has been successfully used for the same purpose.

Liquid Coverings. Molten salts of suitable composition make effective coverings, but are generally more expensive than solid coverings. Cyanide mixtures are very efficient but their cost for large production is prohibitive. Mixtures of NaCl, Na_2CO_3 and K_2CO_3 have been used successfully on small units. Salt coverings have the advantage of producing exceptionally clean work and keeping the lead loss extremely low. The salt consumption, however, is usually a source of considerable expense. Many salts, other than those mentioned above, have been tried without success. Caustic soda causes a gradual oxidation of the lead; sodium nitrate is still worse in this respect. Most of the mixtures of chlorides and carbonates tend to decompose and form infusible products which are very undesirable.

A decided objection to the use of salt covering on large pots is the great amount of heat radiated from the surface of the bath, resulting in bad working conditions for the operators and lowering thermal efficiency. The solid coverings have a marked blanketing effect; the salts have almost none.

Pot Failures. With properly designed and operated units, pot failures result from three general causes: porosity, cracking and oxidation. Cast iron almost always fails by cracking. Cast steel usually fails from porosity and from oxidation, as a secondary effect, when blowholes open up as the metal scales away. Failures with cast steel pots are seldom caused by cracks. Cast alloy pots usually fail from cracking, and in many cases from porosity. They suffer very little from the effects of oxidation except where metal segregation occurs. Pressed steel pots nearly always fail from oxidation, and pressed alloy pots usually fail from oxidation or cracking.

Lead Poisoning. In order to insure protection from lead poisoning, all lead pot installations should be provided with suitable ventilating equipment to prevent lead and its compounds, in the form of fumes and dust, from being inhaled by the operators. Hoods should be designed to collect the products of combustion as well as the fumes and

dust arising from the surface of the bath. For further information on lead poisoning, see the article on "Industrial Poisoning by Metals", page 755.

Caution. To be immersed in a lead or salt bath with any degree of safety, material must be entirely free from moisture. When moist material is immersed in a molten bath the moisture is instantly changed into steam, thus causing a violent eruption of the bath, which may burn the operator severely.

Methods of Operation. Lead pot furnaces may be operated by either the batch or continuous method. For tempering, the former is the more satisfactory, but for hardening, both methods are successfully employed. In the batch method, the pot is filled to capacity and the work material is all removed as soon as the desired temperature is reached. It is usually necessary to shut off the burner before removing the work, but in some hardening operations, if charging and discharging are sufficiently rapid, the burner may be allowed to remain open. With the continuous method, the bath is held at the desired temperature by removing part of the work material and replacing it with cold work at stated intervals. Automatic handling of the stock has been employed in lead baths with a certain degree of success but many difficulties have been encountered which are not met in oven furnaces. Parts requiring local heating may be handled with rotary fixtures in round pots, or with chain conveyers in oblong pots.

Applications. Although at one time the lead bath had a wide range of utility, it has been largely superseded in recent years by the salt bath, the controlled atmosphere furnace, and flame and induction heating. It is still used to some extent for local hardening and tempering and for other special applications where rapid heating to a definitely controlled temperature is required.

Protective Furnace Atmospheres

By A. G. Hotchkiss* and H. M. Webber*

PROTECTIVE furnace atmospheres are usually employed to perform one or both of two important functions for the purpose of insuring better quality in metals that are heated in a furnace. These functions are prevention of oxidation, commonly recognized as bluing or scaling, and prevention of decarburization, commonly recognized as a loss of surface carbon in ferrous metals. When surface oxidation is eliminated, cleaning methods such as pickling and sandblasting are unnecessary. When decarburization is eliminated, ferrous alloys are hard at the surface instead of having a soft skin, and thus have high strength and good resistance to wear, without requiring machining or grinding to get down to the hard metal.

A wide variety of gases and mixtures of gases are used for protective furnace atmospheres. Bottled hydrogen, nitrogen, carbon dioxide, and sulfur dioxide are commonly available. Of these, hydrogen is perhaps the most widely used and will be discussed briefly below. Dissociated ammonia serves as a high-quality, low-cost substitute for hydrogen in numerous instances. Products of combustion of hydrocarbon gases, sometimes purified, sometimes reacted in a special manner, are by far the most widely used gases for protective furnace atmospheres.

Table I gives the characteristics and costs of various protective furnace atmospheres. Table II lists processes for heat treatment in which protective furnace atmospheres are advantageous and, in the right-hand column, specifies recommended atmospheres.

Typical chemical reactions that are possible among furnace-atmosphere gases, iron, carbon, and cementite (Fe_3C), at elevated temperatures, are listed in Table III. Generally the reactions proceed to the right, but equilibrium conditions vary with the temperature and with complex mixtures. Many of these reactions are included in the following text, where the use of furnace atmospheres is discussed.

Hydrogen. Because of excellent properties and ready availability, hydrogen has been a standby for furnace atmospheres for more than 40 years. It is commonly produced by the dissociation of water into hydrogen and oxygen in a battery of electrolytic cells. Although hydrogen is sometimes taken directly from holders fed by the cells, it is more commonly purchased in bottles holding 220 or 440 cu ft of hydrogen measured at atmospheric pressure and compressed to between 1800 and 2000-lb pressure. A typical composition is 99.8% H_2, 0.2% O_2, saturated with water vapor. When the gas is compressed to 2000 lb, the moisture is condensed and the dew point of the gas is lowered to about minus 30 F. This gas is highly reducing when in contact with iron and copper oxides at elevated temperatures.

The H_2O/H_2 ratios for equilibrium with iron are shown in Fig. 1. To the left of the curve the atmosphere is reducing; to the right of the curve it is oxidizing. At high temperatures the hydrogen atmosphere is reducing with relatively high amounts of moisture; at low temperatures less moisture is permissible to maintain reducing conditions. Since metals heated in a hydrogen atmosphere are generally cooled in the same protective gas, and it

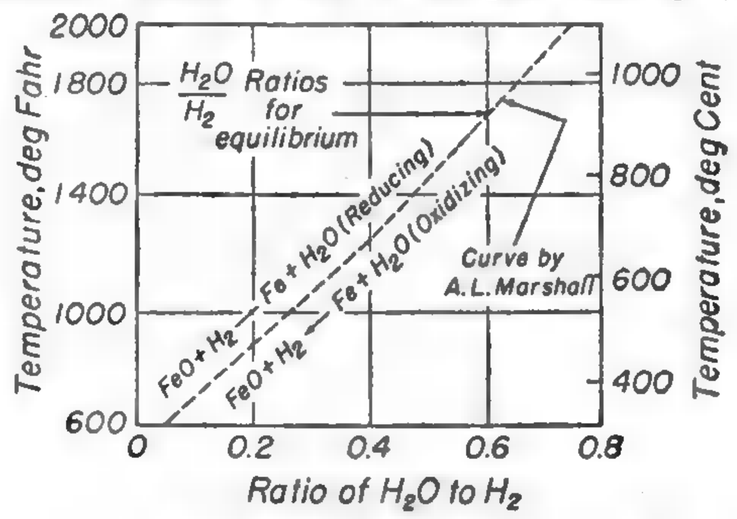

Fig. 1 Theoretical equilibrium relations among iron, iron oxide, hydrogen, and water vapor

is desired to avoid oxidation during this cooling cycle, the content of moisture must be reasonably low to avoid crossing the line into the oxidizing range during the cooling period. In practice, this offers no problem because the minimum H_2O/H_2 ratio of 0.05 at 600 F, shown at the bottom left of the chart, or 5% H_2O by volume, is considerably higher than ordinarily encountered. This explains the ease with which iron can be brought out bright from hydrogen atmospheres. However, at elevated temperatures, oxygen and water impurities in hydrogen will form selective oxides with chromium, manganese, silicon, vanadium, zinc, aluminum, beryllium, titanium and certain other metals. Accordingly, when metals containing these constituents are being treated in a furnace, it is sometimes necessary to purify the entering hydrogen.

Removal of Oxygen. Two methods are commonly used for removing oxygen from hydrogen. One of these is to pass the hydrogen over copper, heated to about 1100 to 1200 F. The copper serves as a catalyst to convert the oxygen with hydrogen into H_2O, completely removing the oxygen except for traces. The remainder can be removed by passing the hydrogen over hot ferromanganese, ferrotitanium or ferrosilicon, at 1650 to 1850 F.

In the other method for removal of oxygen, the hydrogen is passed through a palladium-catalyst purifier. This method is superior to the one using copper chips as a purifier, not only because it is less expensive but also because it is more convenient and more economical to operate. The palladium-catalyst purifier is simply a small tower that contains the catalyst, which operates effectively

(a) Costs include only materials consumed, such as power, gas and water. They do not include factors for obsolescence, installation, maintenance, and the like. The estimates have been based on the following unit costs: power, 1 cent per kwhr; natural gas, 50 cents per M cu ft; water, 5 cents per M gal; charcoal, 3 cents per lb; ammonia, 3½ to 15 cents per lb.

at room temperature. The purifier is connected in the gas line and functions much as a filter would. Like the copper-chip unit, it converts oxygen plus hydrogen into H_2O. However, it is more effective than the copper-chip unit since it removes the oxygen completely, giving purity equivalent to that obtained by the combination of the copper-chip and ferromanganese purifiers; in fact, the extremely high purity of less than one part oxygen per million parts hydrogen is claimed for this type of unit. Hydrogen delivered from the purifier contains H_2O, so if dry gas is necessary, removal of moisture is also required.

Removal of Moisture. The dew point and moisture content of gases, and the extent of moisture removal by various methods, are shown in graphic form in Fig. 2, indicating that most of the moisture can be removed by refrigeration. For example, with a dew point of 70 F and moisture content of about 2½%, refrigeration will reduce the dew point to about 40 F with a moisture content of 0.8%; thus 67% of the moisture is removed in this one step. With a higher initial dew point and the same final dew point, the ratio would be even greater.

A typical refrigerated cooler for gases consists of a condensing unit and a finned-tube evaporator.

Combusted gases, to be discussed later, are sometimes partially dried by refrigeration for batch annealing of low-carbon steel sheets or coils, to assure brightness of finish. The need for refrigeration of gases generally arises in summer, when water for cooling is warm and

Table II. Heat Treatment Processes and Furnace Atmospheres Recommended for Them

Heat Treatment	Metal to be Processed	Requirements: Metallurgical	Requirements: Surface	Temperature Range, deg Fahr	Furnace Atmospheres Recommended(a)
Annealing	Low-carbon steel		Bright	1200 to 1350	IIIA1, IA1, IA2, IIB1
	Medium-carbon or high-carbon steel	No decarburization	Bright	1200 to 1450	IIIB1, IIIB2
	Alloy steel, medium-carbon or high-carbon	No decarburization	Bright or clean	1300 to 1600	IIIB1, IIIB2
	High speed tool steel	No decarburization	Clean	1450 to 1650	IIIB1, IIIB2
	Stainless steel		Bright	1800 to 2100	IB1, IB2, IIA
	Copper		Bright	500 to 1200	IIIA2
	Copper-nickel alloy		Bright	800 to 1400	IIIA1, IA1, IA2, IIB1
	Brass		Clean	800 to 1400	IIIA2, IIIB3a
Normalizing	Low-carbon steel		Bright or clean	1600 to 1850	IIIA1, IA1, IA2, IIB1
	High-carbon alloy steel	No decarburization	Bright or clean	1500 to 2000	IIIB1
Hardening	High-carbon or carburized steel	No decarburization	Bright or clean	1400 to 1750	IIIB1, IIIB3b, IIIB3c, IVA1
	Alloy steel, medium-carbon or high-carbon	No decarburization	Bright or clean	1400 to 1750	IIIB1, IIIB3b, IIIB3c, IVA1
	High speed tool steel	No decarburization	Bright or clean	1800 to 2400	IIIB1, IIIB3b, IIIB3c, IVA1
Brazing	Low-carbon steel	Copper braze	Bright	2050	IIIA1, IA1, IA2, IIA, IIB1
	Medium-carbon or high-carbon plain or alloy steel	Copper braze, no decarburization	Bright	2050	IIIB1, IIIB3b, IIIB3c, IVA1
	Stainless steel	Copper braze	Bright	2050	IB1, IB2, IIA
	Low-carbon steel	Silver braze	Bright	1100 to 1600	IIIA1, IA1, IA2, IIB1
	High-carbon steel	Silver braze	Bright	1100 to 1600	IIIB1, IIIB3b, IIIB3c, IVA1
	Copper or brass	Silver braze	Bright or clean	1100 to 1600	IIIA2, IIIB3a
Sintering	Low-carbon ferrous metals	Sintering	Bright or clean	1800 to 2100	IIIA1, IA1, IA2, IIA, IIB1
	High-carbon ferrous metals	Sintering, no decarburization	Bright or clean	1800 to 2100	IIIB1, IIIB3b, IIIB3c, IVA1
	Stainless steel (with Ti or Cb)	Sintering	Bright or clean	2150 to 2500	IB1, IB2
	Copper, copper-lead, copper-tin, graphite	Sintering	Bright or clean	1300 to 1900	IIB1, IIIA1, IIIA2
	Tungsten	Sintering	Bright or clean	2150 to 2500	IB1, IB2, IIA
	Molybdenum	Sintering	Bright or clean	2150 to 2500	IB1, IB2
	Alnico magnets	Sintering	Bright or clean	2150 to 2500	IB1, IB2, IIA

(a) See Table I for approximate composition and cost of furnace atmospheres.

the surface cooler of the atmosphere-gas converter becomes less effective; this allows too much moisture to stay in the combusted gas. Refrigeration reduces the moisture content and establishes the proper H_2O/H_2 ratio for brightness.

When refrigeration is inadequate for certain applications, additional drying is necessary for good results. In these situations, the gas can be passed through a regenerative dryer. Such units in daily operation are known to reduce the dew point of gases to as low as minus 100 F. It is a rather common practice to dry the gas in two steps, first by refrigeration and then by adsorption, for the sake of economy both in initial cost and in operating cost.

Hydrogen from a palladium-catalyst purifier, when passed through a regenerative dryer of adequate capacity, has sufficient purity to reduce oxides of chromium; to bright anneal 18-8 stainless steel; to sinter 18-8 stainless steel compacts, Alnico, 80 Ni – 20 Cr and similar alloys.

High-purity gas is of little value if it is allowed to become contaminated in the furnace by oxygen or H_2O, or both. Air that infiltrates while the doors are open during the charging and discharging of the work, air and H_2O entrapped in the work and in the furnace lining, H_2O and CO_2 from flame curtains and such, are all sources of these impurities. To be sure of maintaining the high purity of the hydrogen surrounding the work material the most certain and successful method is to enclose the material in a well-sealed metal retort or box that has a pipe inlet for the purified hydrogen and a small outlet to allow circulation of the pure gas. A modification of this method sometimes used successfully is to have a metal retort running throughout the heating and cooling chambers, with well-sealed furnace ends through which the charge travels. In this manner, strands of nickel-chromium wire and strip are bright annealed, and trayloads of Alnico compacts are sintered.

Table III. Typical Reactions of Furnace Atmospheres With Ferrous Metals

Reaction	Effects when proceeding to the right
$CO_2 + Fe \rightleftarrows FeO + CO$	Oxidizing
$H_2O + Fe \rightleftarrows FeO + H_2$	Oxidizing
$H_2 + CO_2 \rightleftarrows CO + H_2O$	(Water gas reaction)
$CO_2 + Fe_3C \rightleftarrows 3Fe + 2CO$	Decarburizing
$H_2O + C \rightleftarrows CO + H_2$	Decarburizing
$CH_4 + 3CO_2 \rightleftarrows 4CO + 2H_2O$	Decarburizing

Dissociated Ammonia. Dissociated ammonia, a well-known high-purity gas mixture that is sometimes used as a low-cost substitute for hydrogen, is obtained by cracking anhydrous ammonia (NH_3) at about 1650 F over a catalyst. The chemical composition of dissociated ammonia is 75% H_2, 25% N_2, with traces of NH_3 as an impurity. The dew point is about minus 60 F.

Because of the relatively high purity of dissociated ammonia it has a wide field of application. There are few alloys for which it cannot be used successfully as a furnace atmosphere. In general, it is employed for the same applications as pure hydrogen. Exceptions are those where unwanted nitriding might take place, because of the nitrogen in dissociated ammonia, as in the sintering of compacts made of stainless steel powders that contain small percentages of titanium and columbium; in the sintering of compacts made of molybdenum powders; and in other heat treatments involving molybdenum.

One pound of liquid ammonia gives about 45 cu ft of dissociated ammonia gas, consisting of about 33.7 cu ft H_2 and 11.3 cu ft N_2. Thus 22.2 lb of liquid ammonia is required to produce 1000 cu ft dissociated ammonia. Dissociated ammonia can be burned with air to reduce cost and inflammability. When dissociated ammonia is given this treatment, the hydrogen content can be controlled within a range of 24 to 1%, leaving 76 to 99% of nitrogen, saturated with H_2O.

Combusted Gas. The most common gas used for furnace atmospheres is combusted gas, resulting from the partial or complete combustion of hydrocarbon fuel gases with air in atmosphere-gas converters. Industry has used such atmospheres for years, and the characteristics and advantages of them are now well known.

Coke-oven, natural and propane gases are commonly employed for burning in atmosphere-gas converters. The chemical composition of the gas product depends on the

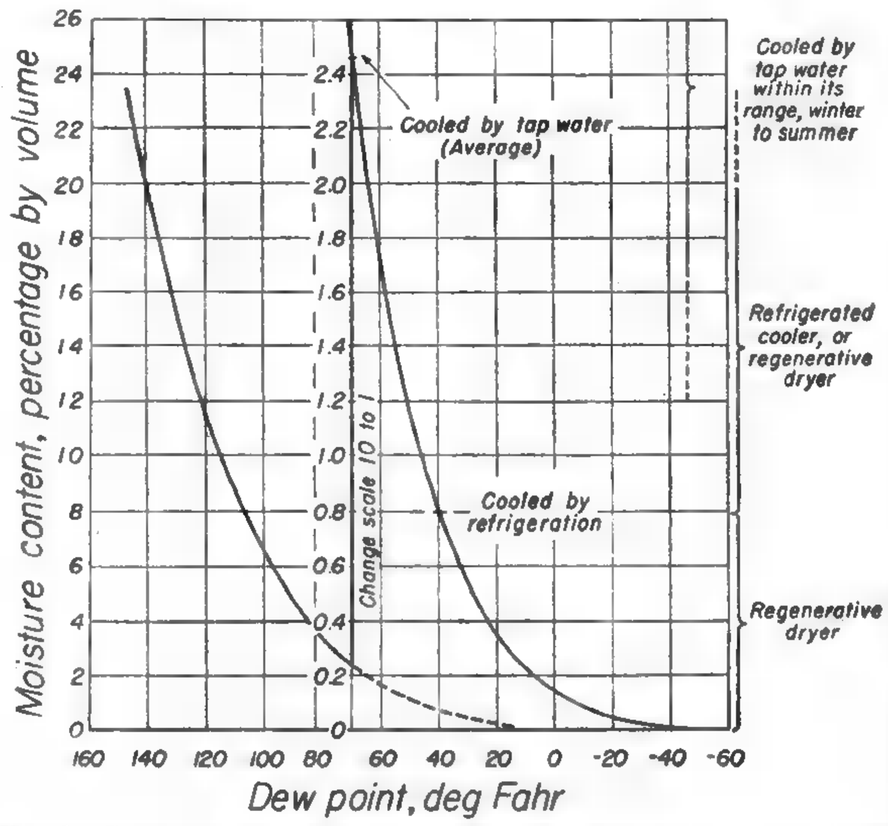

Fig. 2 Curves showing relation between dew point and moisture content of gases and the extent of moisture removal by various methods

ratio of input air to gas, as indicated in Fig. 3. For example, a 6–to–1 ratio of air to gas (at *A*), when natural gas is burned, gives approximately 5% CO_2, 10% CO, 14% H_2, 1.5% CH_4 (methane), and 69.5% N_2. The gas is saturated with H_2O at a dew point approximately 10 F above the temperature of the cooling water used in the surface cooler. This mixture (at *A*) is commonly used for various treatments of ferrous metals, such as hardening, bright annealing, furnace brazing, and sintering. When burning natural gas at almost complete combustion, or 10.25–to–1 ratio (at *C*), the composition is about 11.5% CO_2, 0.7% CO, 0.7% H_2, 0.0% CH_4, and 87.1% N_2. This gas (at *C*) has wide application in the bright annealing of copper.

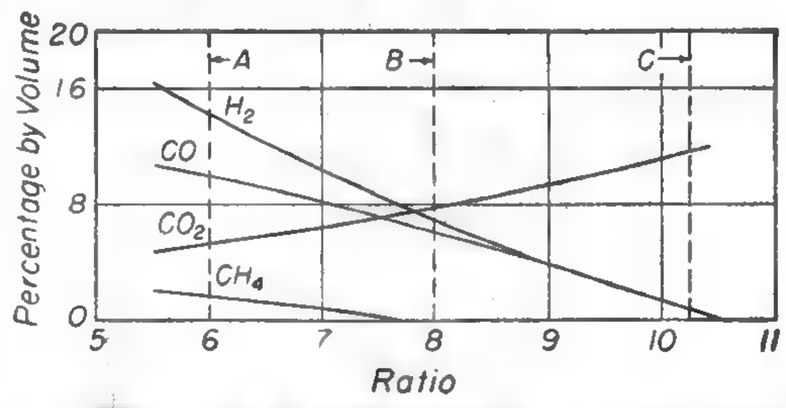

Fig. 3 Products of partial combustion of natural gas consist largely of nitrogen. The above curves show the remaining constituents for various input ratios of air to gas. *A* is the ratio commonly used for atmospheres employed in hardening, bright annealing, furnace brazing, and sintering ferrous metals; *B*, for sintering bronze compacts; *C*, for bright annealing copper.

A typical atmosphere-gas converter consists of air and gas flowmeters, a proportioning mixer, a compressor, a fire check, a burner, a combustion chamber, and a surface cooler, with condensate separator and trap.

The complexity of the combusted gas mixtures at various ratios, and the resulting effects with respect to oxidation of iron during heating and cooling, have frequently been explained by the equilibrium curves shown in Fig. 4. The H_2O/H_2 equilibrium curve at the left will be recognized as the one shown in Fig. 1. The area to the left of the curve is reducing to iron; that to the right is oxidizing. For example, when treating iron at 2000 F with the low-ratio gas mentioned above, having an assumed dew point of 70 F (2.5% H_2O), and containing 14% H_2, the H_2O/H_2 ratio is 2.5/14 or 0.18. The ratio of

0.18 is indicated on the chart by the dotted line *A–A′*. At 2000 F, *A-A′* is predominantly reducing to iron and no oxide would form. On the contrary, any oxide present (FeO) would be reduced to iron plus H_2O. However, during the cooling of the metal along the line *A–A′*, the curve is intersected at about 860 F; and at temperatures lower than 860 F the work pieces would be in the oxidizing range. Thus during slow cooling, the iron parts could be oxidized. However, many parts are relatively thin in section and cool rapidly enough so that oxidation within this range is slight. In addition, the extra effect of the CO_2/CO ratio in this complex gas should be considered. The right-hand curve in Fig. 4 is the equilibrium curve for CO_2/CO ratios with respect to iron. To the left of this curve the gas is reducing; to the right it is oxidizing. With the low-ratio gas above, containing 5% CO_2

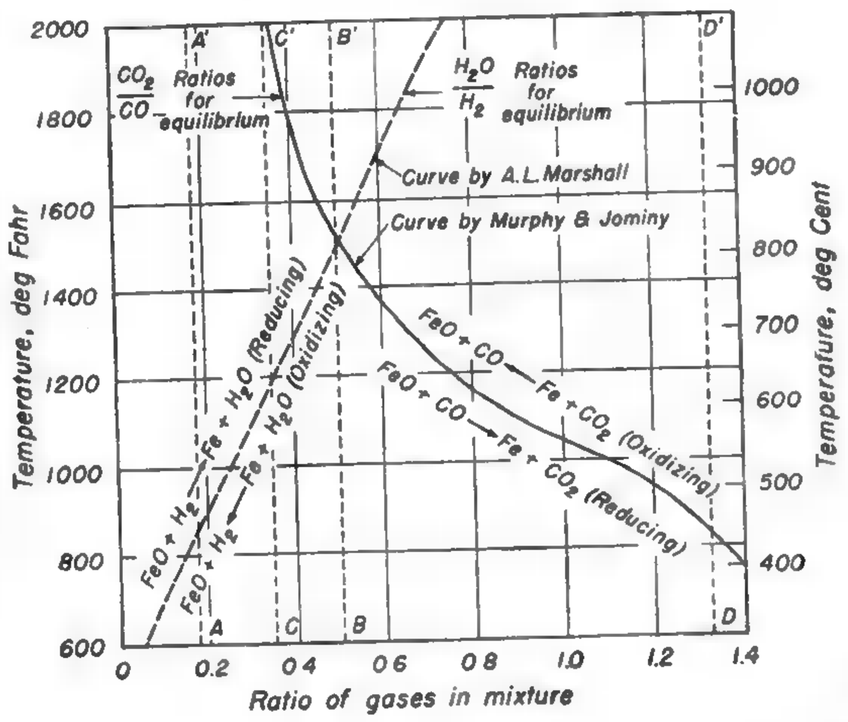

Fig. 4 Theoretical equilibrium relations among iron, iron oxide, hydrogen, and water vapor and among iron, iron oxide, carbon monoxide, and carbon dioxide

and 10% CO, the CO_2/CO ratio is 1 to 10, or 0.5; and as indicated on the chart by the dotted line *B–B′*, at 2000 F the work would be in a slightly oxidizing atmosphere with respect to CO_2/CO; but the predominantly reducing effect of the H_2O/H_2 ratio overcomes this and the net result is that the atmosphere is definitely reducing. During cooling, the work crosses the CO_2/CO curve at about 1525 F, and at any lower temperature the action is reducing. At 860 F it is predominantly reducing, and increases somewhat even below that point. Thus during the cooling cycle, this reducing effect overcomes the slightly oxidizing effect of the H_2O, and gives reasonable assurance that the work pieces will come out bright.

With the higher air-gas ratios, conditions are less favorable for iron, because the atmosphere is definitely oxidizing; an explanation will indicate why high ratios are therefore not used for iron. When an 8–to–1 ratio is assumed (at *B* in Fig. 3), and 70 F dew point, the H_2O/H_2 ratio is 2.5 to 7, or 0.35 and is indicated by the dotted line *C–C′*. This atmosphere at *C′* (at 2000 F) is not so reducing as the one at *A*; and the oxidizing effect is more pronounced after crossing the curve at about 1200 F. The CO_2/CO ratio is 8 to 6, or 1.33, indicated by dotted line *D–D′*. At 2000 F this atmosphere is so predominantly oxidizing for iron that it would overcome the slight reducing effect of the H_2O/H_2 ratio. Also, the oxidizing effect continues until the temperature drops to about 830 F, and adds to the oxidizing effect of the H_2O/H_2 ratio at less than 1200 F. Thus the work material would be thoroughly oxidized before it encountered the feeble reducing effect of the CO_2/CO ratio below 830 F. In consequence, from the standpoint of oxidation, it is impractical to treat iron parts in the 8–to–1 gas, unless the H_2O and CO_2 are removed or greatly reduced:

Removal of Sulfur. Copper-base and nickel-base alloys are subject to discoloration, embrittlement, or both, if the combusted gas contains sulfur. Coke-oven gas commonly contains sulfur, but natural gas and propane are generally free from it. Where removal of sulfur is required, it can be accomplished easily. First the combusted gas passes through a water-spray tower which removes sulfur dioxide (SO_2). Then it passes through a tower containing iron oxide on wood shavings, called "lux", which removes hydrogen sulfide (H_2S). From here the gas goes to the furnace completely free from sulfur.

A simple test can be used to detect whether sulfur is present in combusted gas. Chemically pure zinc is placed in the bottom of a beaker; then 1 to 20% solution of hydrochloric acid is poured in. One or more parts that have been treated in the furnace atmosphere suspected of contamination are then placed in the beaker, the beaker is covered with a piece of filter paper that has been soaked in lead acetate solution, and the filter paper is covered with a glass plate. If sulfur is present, the lead acetate paper will turn brown or black within a minute or so; if no sulfur is present, the color will remain unchanged.

Removal of CO_2. Combusted natural gas, partially burned at a 6–to–1 ratio, or the equivalent of such gas, is commonly used for heat treatment of iron or steel products. The highly reducing characteristic is responsible for obtaining good appearance with little or no oxidation of the work pieces. However, this gas has a strongly decarburizing effect on medium-carbon and high-carbon steels. It removes carbon from the surfaces at elevated temperatures, causing a soft skin to be present after heat treatment and thus impairing the resistance to wear and decreasing the strength. To get down to the hard metal, machining or grinding is necessary, which is costly and time-consuming. There are many instances in which such surface decarburization is not considered objectionable; but there are also numerous instances in which it is highly desirable to have the metal hard at the surface after heat treatment. Fortunately, it is possible to eliminate this decarburizing action simply by removing two constituents from the gas — H_2O and CO_2. This combusted gas, free from CO_2 and H_2O, is being used very successfully for various heat treatments on medium-carbon and high-carbon steels and carburized steels, without surface decarburization.

Because of the reducing and carbon potential requirements, low-ratio dry combusted gas, free from CO_2, is specified for short-cycle annealing, clean hardening, and furnace brazing of medium-carbon and high-carbon steels. This atmosphere consists of approximately 10.5% CO, 15.5% H_2, 1.5% CH_4, 72.5% N_2, with a dew point of minus 40 F. Other uses for this low-ratio gas are the hardening of high speed steels (in both the preheat and high-temperature furnaces); the sintering of high-carbon ferrous metals; the restoration of carbon to decarburized surfaces; and use as a carrier gas for propane or natural gas in gas-carburizing work. On the other hand, a high-ratio (9.5 to 1) dry combusted gas, free from CO_2, is required for long-cycle annealing of low-carbon, medium-carbon and high-carbon steels, and for annealing brass, in bell-type furnaces. This atmosphere is approximately 2% CO, 2% H_2, and 96% N_2, with dew point minus 40 F.

Carbon dioxide is usually removed from combusted gas by means of an absorption chemical which is reactivated by heat and recirculated to provide continuous operation. The remover of CO_2 can be supplied as a separate unit in conjunction with the atmosphere-gas converter; but a combination of the two units is available which effects economies in cost and floor space by having the combustion chamber of the converter built into the boiler of the reactivating tower of the equipment for removing CO_2. Thus heat, otherwise wasted from the combustion chamber in its water jacket, is utilized to boil the chemical to drive off the CO_2, which saves about 18 kwhr per M cu ft processed. For drying the gas, refrigerated gas coolers and driers of a regenerative type, as previously described, are commonly employed.

The need for dry combusted gas, free from CO_2, to prevent surface decarburization is graphically illustrated by Gonser[1] in Fig. 5. Steel samples containing carbon varying from 0.10 to 1.0% or higher were treated for 3 hr at 1740 F, unless otherwise noted on the chart. The furnace atmosphere was low-ratio combusted gas, with

or without purification. For two samples (11 and 12), the CO_2 was removed to 0.0%; for the other samples (10 to 1), the CO_2 was gradually increased to 5.3%. For most samples the gas was completely dry but for a few it was undried. Usually the CH_4 content was less than 1%. It will be noted that the best results were obtained with 0.0% CO_2 (curves 11 and 12); regardless of the amount of carbon in the steel, parts were slightly carburized as indicated by the weight increases, and there was no sign of decarburization. However, as soon as CO_2 was introduced, and in some instances H_2O, decarburization became evident, as indicated by loss in weight; this loss in weight increased with the increase in CO_2 and, in some samples, H_2O. This comparison shows the superiority of dry combusted gas, free from CO_2, over raw or incompletely purified combusted gas.

Figure 6 shows results of weight-change tests on SAE 1060, 1090, and 52100 steels, held for 1 and 2 hr at 1500 F in low-ratio dry combusted gas atmosphere, free from CO_2, and in low-ratio untreated combusted gas atmosphere. The samples treated in dry combusted gas, free from CO_2, showed a slight increase in weight, indicating some carburization, but the samples treated in raw combusted gas showed quite a sharp decrease in weight, indicating decarburization. The samples that were treated in the purified gas were within the generally acceptable range of weight change from minus 20 to plus 50 g per

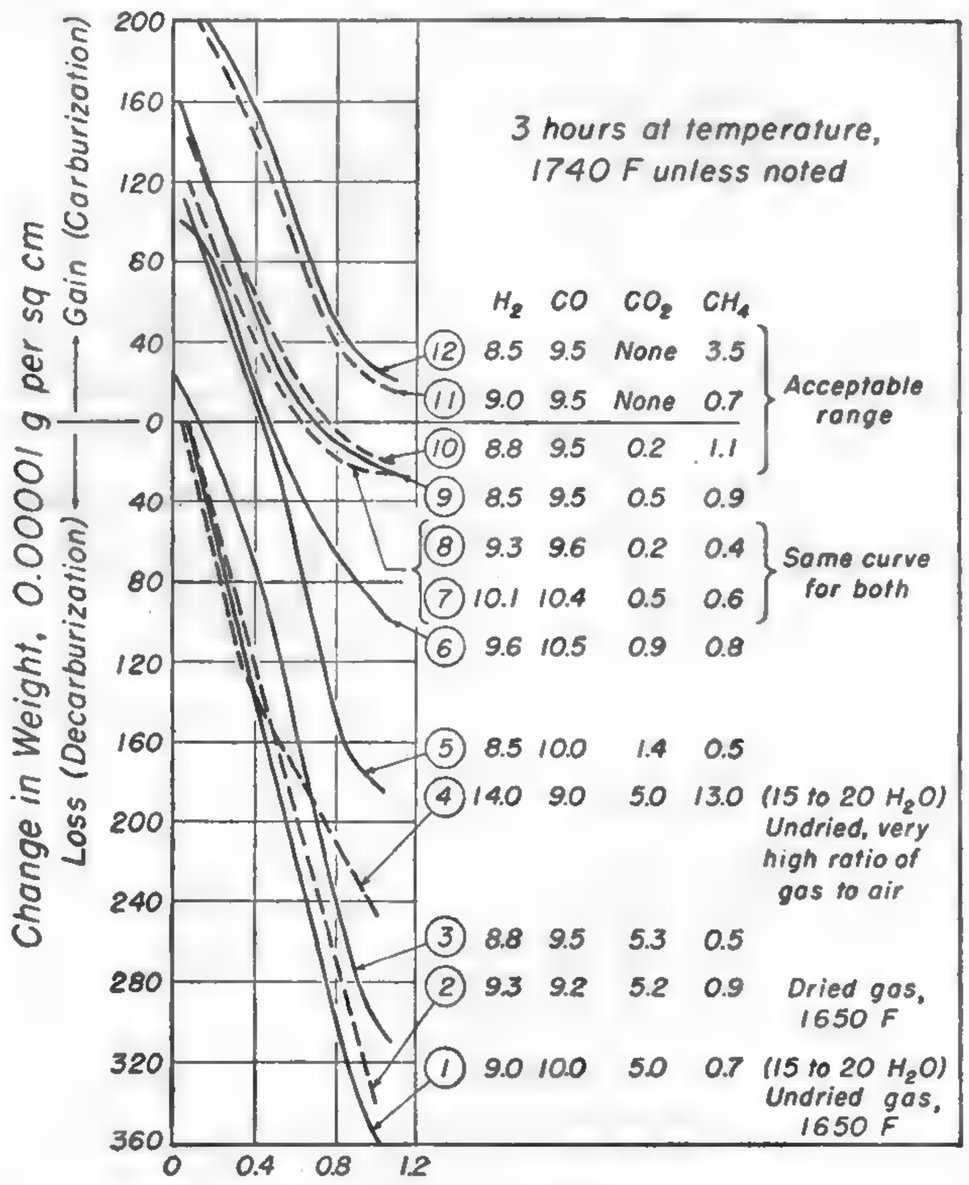

Fig. 5 Curves showing slight carburizing action of dry combusted gas, free from CO_2 but including methane (CH_4), and the increasing decarburizing action with increasing CO_2 and, in some instances, H_2O (Gonser[1])

sq cm times 100,000, as indicated by the bracket at the extreme right of Fig. 6. However, if the slight carburization on the SAE 1060 and 52100 steels should be considered objectionable, this effect can be reduced (1) by changing the combustion ratio of air to gas, or (2) by passing some moist combusted gas around the dryer to increase the dew point of the gas within the furnace.

Rockwell hardness tests on the weight-change samples, after hardening, confirm the data concerning changes in weight. Rockwell 15-N readings converted to the C scale, on samples treated in dry combusted gas, free from CO_2, were greater than the direct C readings, indicating that no decarburization, but actually carburization, had occurred. A similar comparison of samples treated in raw, partially combusted gas under the same conditions gave the reverse effect in hardness readings, indicating that decarburization of the surface had occurred.

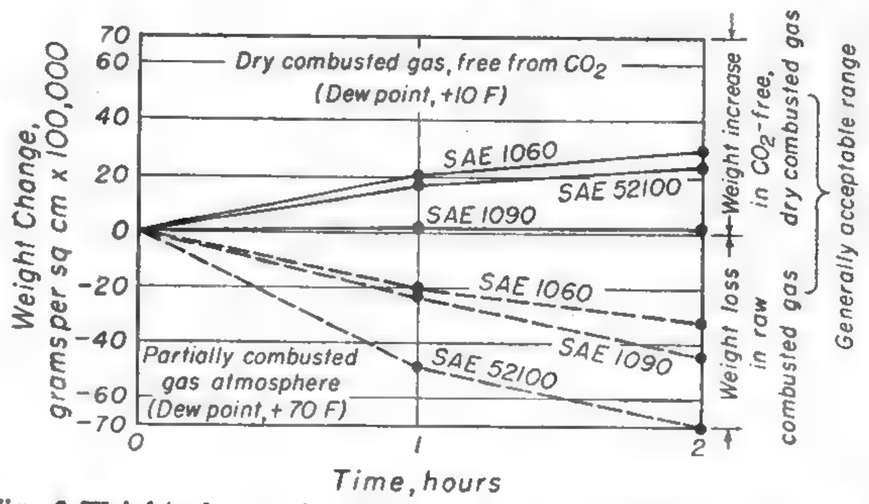

Fig. 6 Weight-change tests on samples of three different types of steel, treated in atmospheres of dry combusted gas free from CO_2, and in raw combusted gas. Slight carburization occurred in the dry combusted gas and serious decarburization in the raw combusted gas.

Charcoal-Converted Combusted Gas. Another type of equipment is available for making nondecarburizing gas, combining the production and purification stages in one unit. In this unit, products of combustion of hydrocarbon gas are passed through incandescent charcoal to convert the H_2O and CO_2 into H_2 and CO. Most of these units are operated at complete combustion, some with water removed from the products of combustion before conversion by the charcoal, and others without the water removed. The chemical composition of a typical gas from a unit with water removed is 0.0% CO_2, 20.0% CO, 3.0% H_2, 0.0% CH_4, 77.0% N_2, with a dew point of minus 20 F. The composition when all the water vapor is being converted by charcoal is approximately 0.0% CO_2, 30.0% CO, 16.0% H_2, 0.0% CH_4, 64.0% N_2, with dew point minus 15 F.

Catalyst-Converted Fuel Gas and Air. Another method of producing a nondecarburizing atmosphere is to react mixtures of air and hydrocarbon gases at very low ratios, such as 2.5-to-1 air-to-natural gas, over a heated catalyst. Just enough air is used to furnish oxygen for converting all the hydrocarbons to CO. The reaction is endothermic and gives gas with approximately the following composition: 0.0% CO_2, 19.0% CO, 38.0% H_2, 1.5% CH_4, 41.5% N_2, with a dew point of minus 10 F.

Solvent and Vapor Cleaning of Metals

By Walter R. Meyer*

THREE methods of cleaning metals contaminated with oil, grease or buffing compositions are discussed here: simple solvent cleaning, emulsifiable solvent cleaning and vapor degreasing. All these methods of cleaning are employed for degreasing metals prior to organic finishing. However, metals that are to be electroplated should be cleaned with alkaline solutions after preliminary cleaning by one of the three methods mentioned above.

Solvent Cleaning. Solvent cleaning usually employs special naphthas with flash points above 100 F, such as "Stoddard Solvent" used in the dry cleaning industry. Solvents of this type are preferred to kerosene and VM & P naphtha because there is much less residue left after evaporation of the solvent. The work material is immersed in the solvent or scrubbed with it and is usually dried with sawdust or corncob drying meal.

Chlorinated solvents are sometimes used instead of naphthas, but they are more likely to cause skin irritation and physiological harm to the operator although fire hazard is reduced or eliminated. Chlorinated solvents used most commonly are trichlorethylene and ethylene dichloride. Ethylene dichloride is a better solvent than trichlorethylene, but it is more volatile and burns weakly. Occasionally, buffing compounds containing tallow and stearic acid must be removed by simple solvent washing; cyclic hydrocarbons such as toluol and xylol are used for this purpose because of their good solvency. Proper ventilation should be provided when using these solvents because they are more noxious than naphthas.

Emulsifiable Solvent Cleaning. Naphthas and other hydrocarbon solvents are made emulsifiable by the addition of emulsifying agents. These emulsifiable solvent cleaners may be used in two ways. They may be added to water, particularly in power-spray washing machines, usually in the ratio of 1 to 5 volumes of emulsifiable cleaner to 100 volumes of water, with the operating temperature between 130 and 160 F. Aqueous emulsions of this type are used most advantageously with pressure spray or agitation. Emulsifiable solvent cleaners may also be used without dilution with water, then followed with a water rinse. This method is more effective for removal of pigmented drawing compounds and oils containing solid dirt. Occasionally different solvents, such as xylol or ethylene dichloride, may be used for specific applications. The work to be cleaned is immersed and occasionally agitated in the emulsion cleaner so that oil and grease are dissolved and each solid particle is wetted thoroughly by the cleaner. Then the work material is drained and rinsed with running water, or preferably with a pressure spray. For organic finishing, a second rinse in hot water will suffice, but for electroplating, the work is transferred from the hot water to an alkali cleaner.

Emulsion cleaning decreases the length of the time required in the alkali cleaner and insures removal of solid dirt. The best emulsifiable solvent cleaners contain emulsifiers and penetrants that neither harm alkali cleaners nor react with acid to form insoluble fatty acid films. The advantages of cleaning with emulsifiable solvent are: use at room temperature for removal of solid and organic dirt; no harmful action on active metals such as aluminum and zinc; lower toxicity than chlorinated hydrocarbons.

Vapor Degreasing. The vapor degreaser may be likened to the chemist's reflux condenser. A nonflammable solvent, such as stabilized trichlorethylene, is heated to boiling, by electricity or by steam coils, in a chamber around the top of which are cooling coils or compartments to recondense the hot vapors and to prevent escape of the solvent. The work material to be cleaned is hung in the hot vapor, which condenses on the work and washes off the grease and oil. Because the oils removed are only slightly volatile at the operating temperature of the degreaser, the hot vapor will be essentially that of clean solvent although the liquid solvent itself may be badly contaminated. The volume of solvent condensing on the work to be cleaned, and consequently the effectiveness of cleaning, is determined by the weight of the metal, the specific heat of the metal, the rise in temperature necessary to bring the work to the temperature of the solvent, and the latent heat of condensation of the solvent. For a given metal and cleaner, the amount of vapor condensed will depend on the weight of the metal to be cleaned. It is obvious, therefore, that light metal sections with heavy films of oil will be cleaned poorly, whereas heavy metals with comparatively heavy grease films may be cleaned effectively. The vapor cleaner cannot completely remove solid dirt from the surface, and frequently, though well cleaned of oil, the work may be covered by a cloud of solid dirt, which necessitates a subsequent wiping operation.

To overcome the difficulties mentioned, spray cleaning, combinations of two solvents, or a sequence of boiling liquid, cold liquid, and hot vapor may be employed. In the last-named sequence, the work material is first immersed in the boiling solvent where most of the solid dirt and oil are removed. (This cleaner soon becomes contaminated but the cleaning efficiency of the system is not seriously affected.) The work metal is transferred from this chamber to a chamber containing relatively cleaner cold solvent that is formed by the condensation of the vapor from the first cleaner. In the second chamber, the work material is cleaned of dirt that was not removed in the previous chamber; and the solvent in the second chamber is kept relatively clean by the constant condensation of the clean hot vapor and the run-off of excess condensate into the first compartment. The work material is withdrawn from the cold chamber and held above the hot compartment where the hot clean vapor condenses and removes any residue of oil not removed in the cold chamber. This sequence, although more laborious than simple vapor clean-

*President, Enthone, Inc., New Haven, Conn.

ing, makes possible the cleaning of thin, badly contaminated work pieces.

In designing vapor degreasers it is essential that sufficient heating capacity be provided; otherwise the vapor line in the cleaner will drop too low when the cold pieces are immersed, and the cleaning process will be seriously retarded. Improper height of the vapor column and poor condensing facilities permit large loss of solvent and a decrease in the amount of heat that can be applied to the boiling solvent. The equipment should be designed to meet the requirements of size and volume of work as closely as possible, because too large units allow higher ratios of solvent lost by diffusion to amount of work cleaned, and too small units permit large loss of solvent by displacement of vapor when the work material is immersed.

Vapor degreasing has several specific advantages: (1) After cleaning, the drying of the work is rapid, a feature of particular value for recessed work or where water stains might be objectionable; (2) the high temperature of operation softens the solid fats and lowers the viscosities of the oils, allowing rapid penetration and removal of material in holes or crevices (removal which would be difficult with alkaline aqueous cleaners); (3) metals such as aluminum or zinc that are attacked by many alkaline cleaners may be cleaned by vapor degreasing with almost no visible effect on the finish. The installations may be made automatic and are cleaner than alkaline cleaning methods. Vapor degreasing is particularly valuable for cleaning metals prior to lacquering, japanning, enameling, or general organic finishing; however, an alkaline cleaning that removes all traces of organic matter still remaining on the surface, should follow vapor degreasing before a metal is plated.

The disadvantages of vapor degreasing include cost of materials greater than for alkaline cleaning, difficulty in removing solid dirt, toxicity of the solvent (troublesome in poorly designed equipment), and the need for subsequent alkaline cleaning preceding plating operations.

Blast Cleaning of Metals

By Victor F. Stine*

IN the process of blast cleaning metals a metal abrasive (grit or shot) or sand, propelled by centrifugal or air force, is directed at the surface to be cleaned. The method of application varies with the requirements of the material to be cleaned. During the past 10 years, the centrifugal process has come into wide use, although there are still many applications where it is desirable and necessary to use the compressed-air method. However, with the centrifugal process, only metal abrasives can be used, since the specific gravity of sand is too low for centrifugal force to clean as efficiently as is possible with the much heavier metal abrasives.

Centrifugal Method. In this process the abrasive is thrown against the work at approximately 250 ft per sec by means of a bladed wheel, running at approximately 2200 rpm. The wheel units are capable of throwing as much as 60,000 lb (30 tons) of steel abrasive per hour, using as high as 50 hp. It is said that as much work can be cleaned by using the centrifugal method with 25 hp as can be cleaned by using 150 hp with the compressed-air method.

Three types of machines are used with the centrifugal method—barrels, tables and special cabinets. Where work can be cleaned in a barrel, by batch handling, this is the most economical way. For flat and fragile work, tables are used. For parts such as cylinder blocks, cylinder heads, bath tubs, and other large pieces, cabinets with monorails are ordinarily used for handling the work material. For cleaning steel rods, steel plates, steel sheets and the like, the flat type of conveyer is used to conduct the work pieces through the blast cabinet.

Types of Air-Pressure Blasts. Two major types of blast are used in air-pressure blasting: (1) the direct pressure type and (2) the induction type, based on either the gravity principle or the suction principle.

Direct Pressure Type. When the principle of direct pressure is applied, the full pressure of compressed air is carried all the way to the tip of the nozzle. In order to introduce the abrasive into this high-pressure line, it is necessary to provide a pressure storage tank in which a certain amount of abrasive is also under pressure. Through an orifice in the bottom of the tank, the abrasive is permitted to flow by gravity into the high-pressure abrasive line; the pressure in the tank and line are equal. In actual practice, the apparatus is often complicated by the introduction of adjustable orifices, means for shutting off the abrasive and air, and double-chamber arrangement for obtaining continuous operation.

Gravity Type. The gravity method provides an overhead abrasive storage, or other means of supplying abrasive by gravity to an induction type of gun in which air is introduced through a jet that is in definitely spaced relationship to a nozzle. The air rushing from the jet into the nozzle creates a partial vacuum in the space surrounding the gap between jet and nozzle. The abrasive introduced into this gap is sucked into the nozzle and mixed there with the compressed air, which accelerates the movement of each grain. At the nozzle tip, the air suddenly expands, pressure is transformed into velocity and the grains receive a last and quite effective shove. Although less effective than the direct pressure blast, the gravity principle is frequently used, mainly because of lower initial and maintenance costs.

Suction Type. The use of suction is similar to the use of the gravity type of blast and, though somewhat less effective, finds even more frequent application, particularly in the design of automatic equipment for treating materials easily cleaned. An air jet and a nozzle are again in definitely spaced relationship but, as distinguished from the open hopper or funnel type of mixing chamber used in the gravity type of outfit, these parts are enclosed in a body commonly called a gun. An outlet is provided at some point with an arrangement for attaching an abrasive hose or pipe line that leads to an abrasive feeding device, often many feet away. The partial vacuum inside the gun creates a strong suction in the abrasive line, sufficient to lift the abrasive entering the end of the hose or line for considerable distances. However, to lift this abrasive, energy is required that is lost from useful work; consequently this principle is the least effective of the three.

Blast from Blower. The medium of force in another method of blast cleaning is generated by a specially designed blower that blows air at approximately 30,000 fpm through a nozzle into which approximately 10 times as much abrasive is fed as when using compressed air through a standard ⅜-in. nozzle. Surfaces are cleaned by a scouring action. It is claimed that the power and maintenance costs are very low. However, the cleaning efficiency may not be so great as that of high-pressure air blasting or centrifugal blasting.

Nozzles. A small but important part of all air-pressure blast cleaning equipment, the nozzle, is subject to wear at the inlet as well as at the outlet. The wear at the inlet is of concern because the size of the inlet controls the air and power consumption.

A new ⅜-in. nozzle, for instance, permits the flow at 90-lb pressure of about 211 cu ft of free air, requiring 40.5 hp. If the nozzle is permitted to wear at the inlet to $\frac{7}{16}$ in., the air flow increases to 286 cu ft or 35½%, and the power to 54.9 hp (also 35½%). Clearly it may prove to be bad economy to use a nozzle too long, particularly in equipment using multiple nozzles. The wear at the nozzle tip is much more rapid than at the inlet because of the expansion of the air, which carries a certain amount of abrasive

* Vice President, Pangborn Corporation, Hagerstown, Md.

with it, forcing the abrasive against the nozzle walls. This explains why abrasives of lighter specific gravity will wear down a nozzle faster than the heavier abrasives. Each moving abrasive particle has a certain kinetic energy directly proportional to its weight or mass. If it were possible to fire a cork ball and a lead ball simultaneously from a double-barrel gun during a windstorm, the cork ball would be deflected from its course much more rapidly than the lead ball. Similarly, the side thrust exerted by the expanding air acts more quickly on the lighter grains than on the heavier ones.

Another reason for the rapid wear on nozzles by the lighter abrasives (such as sand or artificial abrasives) is the fact that the light abrasives travel through the nozzle faster than the heavier steel abrasives, because it is easier for the compressed air to accelerate a lighter particle than a heavier one. This higher velocity causes a larger volume of abrasive to flow in a given time, resulting in more frictional wear.

It goes without saying that granular abrasives (meaning abrasive grains that have sharp corners) wear away a nozzle more quickly than globular grains of essentially spherical shape, such as metal shot. The explanation of nozzle wear applies also to the wear of all other parts through which abrasive flows. The least wear is encountered when metal shot or grit is used. A long nozzle will give a more concentrated stream, whereas a short nozzle covers a larger area but shows a slightly higher abrasive velocity.

Recent years have brought the development of nozzles made from boron carbide, which give more than 750 hr of service using sand abrasive, and 1500 hr of service using steel abrasive.

Finishes. Almost any desired finish can be produced by using the proper abrasive or mixture of abrasives.

Types and Sizes of Blast Cleaning Equipment. There are various types and sizes of blast cleaning equipment. Proper selection among them depends on the work to be cleaned and the rate of cleaning desired.

Air Pressure. For ferrous metals the pressure used ranges from 60 to 100 lb, depending on the extent of cleaning required and the condition of the work. For nonferrous metals the pressure is from 10 to 60 lb, also depending on the nature of the work and extent of cleaning. In blast work for design or frosting effect, the air pressure is usually from 3 to 15 lb.

Health Precautions. Blast cleaning is applied both to rough castings to which core sand is adhering and to finished products (free from sand) prior to painting, dipping, and lacquering. Whether the abrasive is silica sand, steel grit or shot, the sandblaster must be protected by a helmet supplied with air, special gauntlets, apron and often special spats. The blasting equipment and the blasting room have been brought to a high degree of efficiency and include ventilation involving as many as 12 air changes per min, with cleaning and recirculation of the air that is withdrawn. The air supplied the worker (about 6 cu ft per min) should be from a separate source and must be clean, odorless, dry and free from gaseous contaminants. If taken directly from the compressed-air receiver, it is likely to be wet and malodorous.

The health risk from blast cleaning is silicosis, a disease resulting from the breathing of very fine silica particles. In past years, sandblasting improperly done has been the cause of many cases of silicosis, the effects of which can be permanently disabling and even fatal. No matter how good the equipment may be, the blaster should be X-rayed before he is employed and at least once a year thereafter. The films should be read by a physician specializing in this particular field.

Sandblasting of sand-free steel or iron castings, and shot blasting of sandy castings will both produce enough fine silica to make the air dangerous to breathe. The standard equipment with which the blaster is provided will keep him comfortable and insure his breathing good air. However, the men who blast and clean are usually unskilled workers with no conception of health risks, even if warned. It is not unusual for such men, on finishing a cleaning job, to turn off the blast, remove their helmets and blow the loose sand from the casting. Every safety director knows that such practices are wrong, but the dusty air is not unpleasant to breathe and the worker may be wholly unaware of his physical peril.

The purpose of this note is simply to emphasize that blast cleaning jobs can be done without health risks to the workmen, but that such work is safe only if the advocated precautionary measures are followed rigorously.

Tumbling, Rolling, and Barrel Burnishing

By R. W. Mitchell*

METAL PARTS, after fabrication, are often cleaned, rinsed, rolled, ball burnished and dried, all in one sequence of operations. The words "tumbling" and "rolling" are often used synonymously. There is, however, some distinction between the two processes, and the words may be used to differentiate between two operations, similar in general but differing in detail.

"Tumbling" is an operation in which the work pieces (usually castings or forgings or stampings) are rotated in a barrel, drum, or chest, together with stars, jacks, slugs, metal punchings, or some abrasive such as sandstone or granite chips, slag, silica, sand or pumice. Ordinarily in this operation the work is packed tight and the barrel is nearly filled.

"Rolling" consists in rotating a barrel containing a load of work pieces and abrasive, so that the load rolls over and over upon itself in a continuous flowing motion. Rolling may be done in either horizontal closed barrels or open tilt barrels. In open barrels the load is lighter and much more free to move within itself or to roll as the barrel rotates. Work pieces may be rolled with any one of a large number of abrasives of varying particle size, sharpness and hardness, such as ground slag, sand, silex, pumice, volcanic ash, emery, carborundum, alundum, Vienna lime, crocus, or rouge. The abrasive is generally finer in size than any used in tumbling.

Both tumbling and rolling may be done either dry or wet, depending on the results desired. The amount of "bite" to the abrasive, and the resultant cut are affected considerably by the amount of water present. The water may contain dissolved chemicals such as muriatic or oxalic acid, acid salts such as sal ammoniac, or cyanide, to aid in removal of scale.

"Ball burnishing" is a method for putting a high finish or luster on metal parts, by rolling them in a revolving barrel with polished hardened steel balls (or a modification of these) and some lubricant. In tumbling and rolling, metal is removed from the surface; in ball burnishing it is not. The continuous rolling pressure and rubbing action of the heavy load of balls flowing over the metal surfaces of the work, peens and smooths out minute surface inequalities to produce the luster characteristic of an even reflecting surface. In some instances, small parts such as buttons and rivets can act as a self-burnishing load. Surface irregularities are cold worked or flowed to a more even plane; they are not cut down. Ball burnishing can be successful only on a surface properly prepared for this final finishing operation.

Tumbling might be compared with snagging or grinding; rolling is analogous to polishing or cutting down; and

* Technical Director, Magnus Chemical Co., Garwood, N. J.

burnishing corresponds to buffing. Tumbling removes sand, "skin", scale, and fins from castings, and scale from forgings. Rolling removes flash and burrs, wire edges, pits, rough spots, scale and rust, and cuts down a metal surface to an even and uniform condition. Both processes, unfortunately, also remove corners and round off edges. Barrel burnishing puts a lustrous finish on a clean and smooth, but dull, metal surface.

Tumbling. Foundries use a "rattler" for removing sand, rough "skin" and fins from castings. Scale and rust have long been removed by tumbling metal parts in acid; the mechanical action greatly aids the pickling effect.

Modern tumbling equipment removes dust and dirt by means of exhausted air circulation and dust filters, automatically loads and discharges the work material, and then separates the work from the stars, sawdust and other materials.

Tumbling is the least expensive method of cleaning castings. It is claimed that tumbling increases the strength of castings, since the peening action during tumbling evens the surface and neutralizes residual strains. On some classes of work material this has the same effect as annealing. Liberal use of stars or jacks is essential for quick and thorough cleaning, in order to reach every pocket and corner of the castings and to produce an even finish.

Barrel Rolling Operations. Rolling, a cutting down operation, is done in open tilt barrels or in horizontal closed barrels. Depending on time and abrasive, the cut may be light or heavy. This method can be applied to objects that will form a rolling load in a slowly rotating barrel. Generally this means small parts and parts that will not entangle, nest or interlock; that are not so thin in any cross section as to become bent; and that do not require the holding of sharp edges or corners. In some instances it is possible to have a little extra metal at edges or points subject to the greatest cutting down effect, to make the barrel rolling method acceptable. Hollow or drilled pieces are not suitable if the rolling abrasive cannot readily be rinsed from them. Ordinarily this process is not used for pieces that have a dimension much greater than 6 in. An exception is long straight work, such as curtain rods, tools and handles, which can be rolled in a horizontal barrel in such a way that their long axes are always parallel.

The tilt barrel, designed for rolling small parts, has an open top and hence is readily loaded and discharged. It can be inclined at different angles for varying effect.

The rolling action increases in intensity as the axis of revolution is lowered toward the horizontal. Speed of rotation varies between 20 and 60 rpm, usually the slower the better. Speed should suit the requirements of the work material, and should never be great enough to cause the pieces to "throw" or move in any but a gentle rolling motion. The barrel should be from 40 to 50% full. An advantage of the open tilt barrel is that the operator can watch the progress of the work and avoid excessive rolling, which not only wastes time but also may damage the work material.

Types of Barrel Construction. Barrels are made of wood, rubber and most of the metals, in a number of shapes, both round and polygonal, with angle-cornered or round-cornered bases. These different shapes provide different rolling actions. The polygonal form affords more effective rolling, carrying the load farther up the side of the barrel and allowing it to roll down a steeper slope. Barrels may be left smooth inside or may be fitted with cleats, fins, steps or similar devices to effect a more complete movement of work in the load. The individual pieces in the load should not only roll over and over but should rotate in more than one plane and move back and forth slowly, in a direction parallel with the axis of the barrel.

Wooden barrels are used for rolling comparatively light articles, either wet or dry—particularly articles made of nonferrous metals such as brass and nickel silver. Wooden barrels are not suited to withstand the wear of rolling rough or heavy articles in sand or other coarse abrasives.

The metal used in construction should be such as to avoid galvanic action with the load.

Cast barrels are used for either wet or dry tumbling, or for rough work involving the use of abrasives such as coarse sand and gravel, and for finer work requiring fine pumice or emery.

Barrels made of nonferrous metal are used for tumbling articles in certain acids that would corrode iron, and for rolling high-grade brass articles, which might become discolored by rubbing against cast iron.

Sheet metal barrels are used to tumble heavy articles that have sharp corners, since these might chip a cast barrel and wear it away rapidly.

It is usual to set up the barrels with a water pipe arranged so that water will run into the open head. For washing and rinsing the work pieces in the barrel before rolling, or for rinsing them in solutions after rolling, a piece of hose connected to the water line is run to the bottom of the barrel. A running rinse then displaces the solution by overflowing.

The usual method of discharging the work pieces is by tilting the barrel so that the load slides into a sieve-topped box, which serves to separate work from jacks, balls or abrasive. When sturdy sieve caps on metal frames are used, locking tight into the head of the barrel, the barrel is lowered and run in this position for a few minutes, allowing separation of work pieces and rolling medium, the work being retained in the barrel temporarily.

Horizontal Barrels. Larger articles, or those with one long dimension, roll more evenly in horizontal barrels, which afford more uniform cutting down and polishing. In the tilt barrel such parts would roll end over end, and produce too much action on the end faces or corners. Horizontal barrels are also better suited structurally for large and heavy loads. The horizontal barrel is more generally used for "rough work"—grinding and smoothing up—and the tilt barrel for light finishing.

Horizontal barrels with the axis of the barrel a little out of line with the axis of rotation, are used to give the most effective motion to the load.

Horizontal barrels are made with one or more multiple compartments. They are usually of metal, often cast iron, although other metals may be used to meet special requirements. They may be lined with wood for rolling soft or easily discolored metals. Barrels should be designed to balance and run without jerks.

When wet work material is tumbled in closed barrels, the barrels must be vented every few hours, because finely divided metal reacts with water, forming hydrogen gas, and the frictional heat generated by the mechanical working of the load, builds up dangerously high gas pressure.

The open-ended horizontal barrel is quite different. It is able to handle large loads and has been highly developed expressly for automatic operation. These barrels are designed to be self-loading and, by means of spiral fins on the inside surface, are self-discharging when the rotation is reversed. Some have a device for separating work pieces from stars, balls or slugs, and automatically returning the tumbling agent to the barrel.

Abrasives and Duration of Rolling. The abrasives commonly used are slag, cinders, sea sand, sharp sand, or builders' sand, pumice, limestone, and granite chips, broken glass, silex, emery, alundum and carborundum. Particle size, hardness and sharpness are factors affecting the time required for rolling. Pumice is a sharp but light and soft abrasive used mostly on brass and soft metals in finish smoothing. Hard metals require hard, quick-cutting abrasives such as emery, alundum and carborundum.

To provide a more uniform action, to add weight, or to carry the abrasive with a rubbing motion into depressions or corners, an auxiliary load is often added, such as wood blocks, jacks, slugs, punchings, steel balls or steel wool.

Where the surface of the work material is soft or where a brightening action is desired rather than a cutting down action, milder or finer abrasives are used. Silica, chalk, lime, crocus, polyroth, and rouge are suitable. Leather scrap or meal, felt, and hardwood sawdust (maple, boxwood, or lignum vitae) are also used, ordinarily dry, and sometimes with fine abrasive mixed in. After an abrasive roll, sawdust is employed to scour fine abrasive from the metal surface.

Greater cutting action is obtained in the wet process. The amount of water present has a great effect on the success of the process. For maximum action, the amount should be just sufficient to make a wet paste or mud. If too dry, the abrasive will stick to and coat the work material and interior of the barrel, preventing the desired action. If too much water is present, most of the abrasive particles will go to the bottom of the load and will not work evenly through the rolling mass.

Water evaporates during rolling and must be replaced or the abrasive will pack and ball up. Chemicals may be added to the water. Dilute sulfuric or muriatic acid, or ammonium chloride aids in removing scale. In the rolling of steel, alkali and cyanide in small amounts are often added to improve color. Cream of tartar or cyanide improves the color of copper alloys. Soap solutions are not used in cutting down or polishing operations, but are applied later during the burnishing. Oil may be employed for rolling with sharp abrasives; kerosene is often used with emery.

Proper speed of the barrel should carry the load of work and abrasive up the side of the barrel to approximately three-fourths of the inside diameter. The mass should then have a slope that causes the top of the load to fall over and roll backward upon itself.

Dry rolling, using sawdust, is preferable to wet rolling for brightening screw-machine products. Fine sawdust should be used to avoid the clogging of threads and slots. The dry roll gives a better color in the allowable time and has a less injurious effect on the threads. If sufficient sawdust is used (several times the volume of the work load) to keep the screws or bolts spaced well apart and away from the barrel surface, the work material may be rolled as long as 2 hr without appreciable dulling of thread edges. This is sufficient to give a high finish. To remove any oil, the work pieces should be rolled in sawdust about 15 min; then the sawdust should be changed. It is not possible to bring the objects out entirely free from sawdust, but in some instances this is not essential.

To obtain high finishes—that is, smooth, even and bright surfaces—a long rolling is required. Coarse abrasive used at the start, is gradually broken down; consequently as rolling proceeds, the cut becomes finer and finer.

The length of time required obviously depends on the quality of surface desired, and on the condition, shape and hardness of the metal surface. The softer a metal, the faster it is cut down.

For brass and bronze castings the average duration of rolling is 10 to 15 hr; for malleable iron castings, 30 to 40 hr; for gray iron castings, 70 to 80 hr. For stampings or automatic screw-machine parts, the necessary time varies from 1 to 100 hr, depending on the quality of the stock and the extent of die marks, scoring, or rough edges, brought from the machine operations. Ordinarily when hot rolled and pickled stock is being prepared for ball burnishing, the parts are rolled for about 48 hr. Often 80 to 90% of forging scale is removed by rolling for a few hours. A much longer time would be required to remove scale entirely.

Often much time is saved and a net economy is effected by performing one wheel operation before barrel rolling and burnishing. Sprues, parting fins, or any gross surface irregularities, should always be removed by an abrasive wheel or belt. Deep scratches or score marks should also be polished out on a wheel before rolling.

Barrel Burnishing. The purpose of barrel burnishing is to develop high luster on parts otherwise unfinishable because of size or shape, or to provide this finish at a lower cost than possible with hand labor. Barrel burnishing allows the finishing of small parts in bulk. The process can replace buffing on a wheel in many instances, and may be used as a preliminary to electroplating and as a finishing process afterward.

Burnishing has no cutting or abrading action; it must avoid these. In burnishing, rubbing pressure flattens and spreads all minute surface irregularities to a perfectly even surface. This action also reduces the porosity in plated surfaces.

Burnishing will not remove visible surface irregularities, scratches or pits. It will not improve color. These conditions must be treated before the burnishing operation (*see* Barrel Rolling).

In barrel burnishing, the rubbing action that produces the burnishing may be between pieces of the work itself (self-burnishing), or between hardened steel balls (ball burnishing), or other suitable forms—cones, slugs or pins—and the work. The rubbing pressure varies with the weight and depth of the load, and is influenced by the speed of rotation. A lubricant solution prevents abrasion from metal-to-metal contact in the rubbing, prevents heating of the load, and promotes the development of the high luster that is the object of the process.

In general, about two volumes of burnishing agent (balls and the like) should be used to one volume of work material. For some work, a ratio of one to one suffices. The proper ratio is influenced by the type of barrel, by whether it is run full or only partly full, and by the form of the work objects. The weight of the burnishing mass provides most of the pressure. There must be plenty of balls to space off and surround each piece of work entirely. Hollow or recessed work requires a larger proportion of balls than solid articles. Stampings require more balls than do castings or forgings. It is better to use too many balls than too few.

Work that floats or rides on the burnishing mass is obviously under no pressure and hence does not burnish. Work cannot float on the balls if no free space is left above the burnishing load.

Burnishing Agent. Round steel balls are ordinarily the most satisfactory burnishing agent because they can be hardened and they supply best the fundamental combination of half-rubbing and half-rolling action. Pressure is a necessary factor in burnishing; however, too much pressure between ball and work might result in grooving or rubbing off metal. When excessive pressure might occur because of some resistance in the load, grooving is avoided by the natural tendency of the ball to roll. The balls need not be perfectly spherical but they must be hard, smooth, and too tough to fracture.

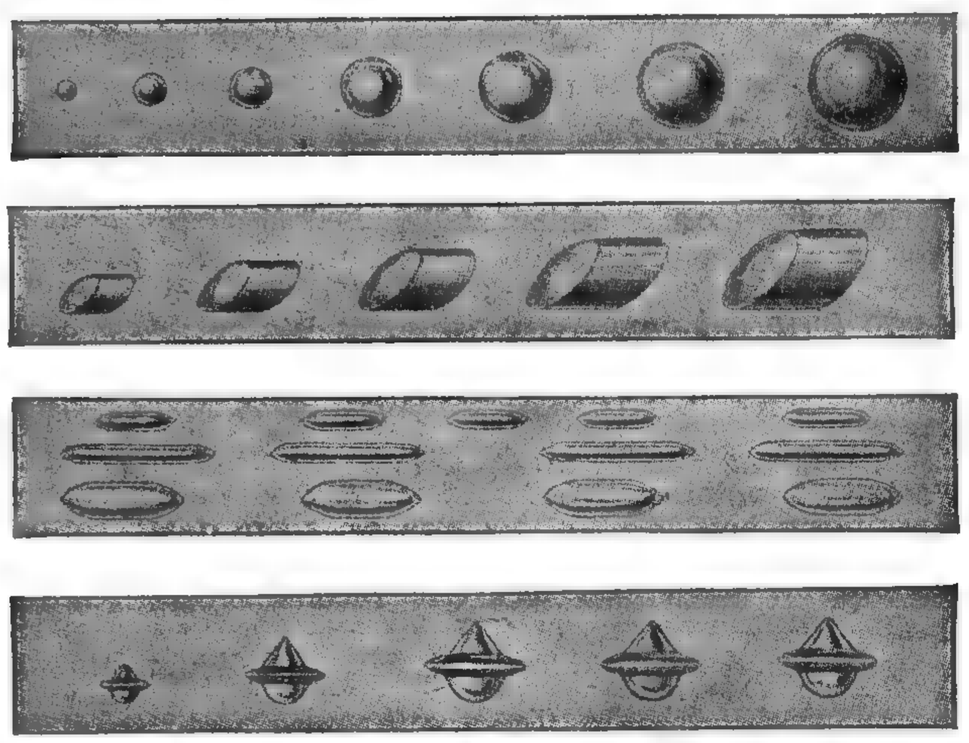

Fig. 1 Balls, slugs, pins, and ball cones for burnishing operations (Hartford Steel Ball Co.)

A ball will not burnish in corners and angles. It cannot enter an angle, slot or indentation smaller than its own diameter. In such places, or where the surface of the work material is figured, the use of other shaped pieces is required. Slugs, diagonals, burnishing steels, cones, ball cones, fin balls, pins or "oats" (Fig. 1) burnish into angles, corners or grooves not reached by balls. These forms are generally used in admixtures with balls. Too high a ratio of pins or "oats" may cause a stippling effect on flat work. "Balls" should be understood to mean either balls, some of the modified forms, or mixtures of these.

The unit size of burnishing agent is important. Small balls obviously provide more contacts with the work, but they give lighter pressure. Large balls are less expensive and less readily lost while handling. It is common practice to mix two sizes of balls.

For drilled, slotted or recessed work pieces, it is advisable to choose balls larger than the holes or slots into which they might otherwise wedge.

On soft metals small balls are necessary to avoid too much pressure in rubbing. Balls ⅛, 3/16, and ¼ in. in diam are the sizes most commonly used.

Much time and labor are expended in making the surface of burnishing balls mirror smooth, and successful burnishing depends on keeping the balls this way. Steel ordinarily rusts easily, and balls with surfaces roughened or pitted are seriously impaired. Steel does not rust when kept immersed in a solution of pH 9.5 or more. A dilute soap solution, or a dilute solution of soda or alkali will have a pH of at least 9.5; hence steel balls kept under such solutions are protected.

Balls pick up dirt or scum and become dull or even black. The dirt may have been brought in on the work pieces, or it may be an accretion of the sticky, insoluble lime soaps formed from the burnishing soap and the small amount of "hardness" usually present in water. Balls should be kept clean and bright at all times. Dirty balls are ordinarily cleaned by rolling with a warm solution of sodium cyanide, about one ounce per gallon in concentration. They may also be cleaned by rolling with metal cleaner and rinsing thoroughly afterward.

Surfaces to Be Burnished. Before the burnishing operation, the metal surface must be in proper condition to attain the final quality of finish desired. Burnishing will not remove metal or take out surface blemishes. It is absolutely impossible to secure good results without a good surface in the beginning. If the natural surface is not good, it must be prepared by rolling with abrasive.

In addition to being smooth, the work must be clean of all dirt, rust, scale or tarnish.

Burnishing will improve luster but it will not improve color. To provide good color, brass, copper, bronze and nickel silver, are often bright dipped and thoroughly rinsed before burnishing. Annealed drawn brass, or brass that has acquired an uneven color or perhaps actual tarnish from standing around or being handled, must be either bright dipped or dipped in cyanide. A dip commonly used is made by pouring 3 volumes of sulfuric acid (1.84 sp gr) into 3 volumes of water, and then adding 1 volume of nitric acid (sp gr 1.4).

A pinch of salt (sodium chloride) or about 1% of hydrochloric acid (conc) added daily, makes the dip more effective. The temperature of the dip should not rise above 95 F. Enough lampblack is usually added to bright dips to form a thin covering film on the surface.

Aluminum and particularly aluminum die castings are ordinarily dipped first into hot dilute caustic soda solution (about 3 to 4% conc) for 5 to 10 sec. Then they are rinsed, and are finally bright dipped in a solution made by mixing 3 volumes nitric acid (sp gr 1.4) and 1 volume hydrofluoric acid (48%), for use at room temperature. To find a suitable container for this solution entails some difficulty. A lead-lined vessel is recommended, painted inside with a mixture of 1 part beeswax and 4 parts paraffin. Avoid personal contact with the liquid, and do not breathe the fumes from it.

Hydrochloric acid (20 Bé or sp gr 1.16) is used for brightening steel or iron and for removing rust. Acid ammonium citrate in warm dilute solution will remove light rust without roughening a polished steel surface.

Sometimes, after a short period of burnishing, a dark scum will appear on the solution covering the load. If this occurs, the solution should be run out, the load rinsed, and fresh water and burnishing lubricant added.

The load of work pieces and balls is usually just covered with water, the burnishing lubricant is added, and the barrel is closed and set in rotation. Enough burnishing soap should be used to build and hold a heavy cushion of suds in the barrel throughout the run.

Importance of Hardness. The harder the surface of the work material, the higher the finish it will take. Many small steel parts that are finished by ball burnishing are hardened especially for this reason. It takes longer to develop luster on the hardened metal, but higher quality and more permanent results are obtainable.

Soft metals, however, can be ball burnished to a good luster. When small balls and low speeds are employed to avoid excessive pressure, even die castings can be brought to a high finish. Brass, soft nickel plate and nickel silver can be given a beautiful luster. Because die castings are soft, they must be ball burnished with a relatively small burnishing ball, at a low speed, and with more than the ordinary amount of lubrication.

A plated surface can be ball burnished as well as a solid metal. A hard plate will develop a better luster than a soft electrodeposit.

Zinc and aluminum die castings can usually be brought to a good finish in about 60 min. Sometimes overburnishing is detrimental. A 60-min burnishing period is also usually sufficient for nickel or for brass.

For steel, burnishing time varies greatly, depending on the quality of the surface, the result desired, and above all on the hardness of the steel. Burnishing may require from 15 min to 100 hr or more.

Chromium plate is harder than nickel plate and, under similar conditions, should be burnished about twice as long.

Chromium solutions have what is known as a "bright range". Occasionally parts will be dark or "burned" in some spots because of too high local current density and will be dull in other parts because of too low local current density. Ball burnishing evens up the finish by giving a more uniform brightness to such surfaces.

Speed for Burnishing. The speed of rotation depends on the nature of the work material and also on the diameter of the barrel. The smaller the diameter of the barrel, the faster the allowable speed. The faster the rotation, the more movement in the load and the greater the number of burnishing rubs. On soft metals, too great pressure may develop, causing deformation of the surface. Small or regularly shaped pieces can be run faster than large or irregularly shaped pieces. Articles with edges or sharp corners must be run slowly. If the work shows scratches, dents or peen marks, the speed must be reduced.

Racking and Work-Holding Barrel. For pieces that scratch or dent one another, or pieces with large smooth areas that must be free from rubbing marks, racking is essential. A framework is needed into which the parts can be locked by clips, or by clamping the frame together after loading. Some shapes can be slid on rods with spacers between the parts. The racks are designed to slip closely into an open-ended barrel.

Sometimes it is important to keep parts from nesting together. This can also be done on racks. On studs and other parts where only the head should be finished, threads can be protected by tightly fitting covers made of short pieces of elastic rubber tubing.

Unloading the Barrel. After the burnishing has proceeded long enough to produce the required luster, the solution is run off and the load of balls and work pieces is *thoroughly* rinsed with clean water. Any soap film left on the work material will dim the luster. On brass, or similar alloy, residual traces of soap cause rapid tarnish and change of color. The next step is to separate the balls from the work pieces and to dry the work pieces. The customary procedure is to dump the load on a riddle or sieve of mesh that will permit the balls to fall through to a tray or box. The upper box is arranged to slide on cleats. After the balls have been riddled through the screen bottom, the upper box is removed to carry the work to a sawdust or hot air drier. The bottom box can be arranged with a bottom sloping toward the front. The balls collecting there can be returned to the barrel by a portable loading machine.

Work removed from the barrel is commonly dried by tumbling or rubbing with clean dry sawdust; maple or boxwood sawdust is preferred. The work pieces are sometimes passed through a hot air drier, employed for those parts that retain sawdust; for example, split or tubular rivets, threaded or slotted screw-machine products.

Sawdust is the best drying medium where it can be used. It serves as a cushion between pieces and prevents scratching or marring. Only good hardwood sawdust is suitable and it must be dry since moist sawdust clings to the work material and is likely to leave water marks. Sawdust is kept dry by circulation through a fanning mill or by storage in a box or bin with a steam coil in the

bottom. Cob meal (ground corncobs) is an excellent alternative for sawdust.

Burnishing Lubricants. Many kinds of material have been used for burnishing solutions. Soap, soap bark, blackstrap molasses, stale beer, alkalies, alkaline cleaners, cyanide, and cream of tartar are the most important. Foremost among these is soap, at least in extent of use.

Soaps may be made neutral, acid or alkaline, depending on whether alkali base and fatty acid are present in exact chemical equivalents or not. Small percentages of free alkali, or of free fatty acid, greatly influence the properties of soap solutions. Commercial soaps often contain added filler or builder (alkaline salts or silicate), rosin, or solvents. Depending on the method of saponification, glycerine may be either removed from or left in the soap.

Soaps used in commerce vary greatly in solubility, gelling power, ability to produce lather, ease in rinsing, alkalinity and viscosity. The differences in properties are important in barrel burnishing.

High-titer soaps give the best lubrication and burnishing action. However, they may not be used where good rinsing is a controlling factor, or in a tubbing machine where their solutions would gel. Lower-titer soda soaps are best where rinsing is difficult because of the nature of the work material.

For nickel, brass or other copper alloys, or aluminum, a neutral soap is required. A small amount of borax or bicarbonate of soda (both less alkaline than soap) or of cream of tartar is used with the soap. On aluminum, use of the proper nonalkaline soap means the difference between success and complete failure.

For steel, the presence of free alkali is desirable. The use of cyanide with soap is also desirable on steel, since this combination increases the speed of burnishing and keeps the color white and free from a dull or leaden appearance.

The use of rosined soaps, or those containing silicate, should be avoided.

Where burnishing is done on a large scale, it is convenient to prepare a soap solution in a tank or barrel, and to add a measure of the liquid soap to the burnishing barrel instead of throwing in dry soap. In this way the soap gets to work as soon as the barrel is started. Where other ingredients are used with soap, this liquid soap is particularly desirable.

Enough soap or soap mixture should be added to build and maintain a heavy suds in the barrel throughout the burnishing period. To use more than this amount is wasteful. The solution should just cover the load.

Soap bark is often used for burnishing brass and other copper alloys that are sensitive to alkaline tarnishing. Soap bark and cream of tartar, or "tartar substitute", is a favorite combination.

A good formula for use on steel is made by dissolving 30 lb of high-titer burnishing soap in 50 gal of hot water, together with 15 lb of alkali (such as trisodium phosphate or soda ash) and two "eggs" of sodium cyanide. This mixture sets, becoming a soap jelly. About one quart is enough to use with the average load.

Dry burnishing is sometimes carried on where, for some particular reason, the wet method must be avoided. Dry burnishing ordinarily takes several times as long. Steel is dry burnished with cocoa butter and lime, or sometimes chip soap and rouge; nickel is burnished with leather meal and rouge; aluminum is burnished with leather meal and whiting; zinc die castings are burnished with boric acid crystals.

After brass has been burnished and rinsed thoroughly, a dilute solution of bichromate is sometimes applied to hold the color. The work is then thoroughly rinsed again and dried.

Burnishing Barrels. Widely differing designs and constructions of burnishing barrels are in common use. Barrels may be single or in tandem. They may have single, double, or triple compartments, or a single barrel may be built with a number of different pockets, each a separate sector of the barrel. In these pockets, a number of different small lots of work pieces can be run at one time without mixing. The barrel may rotate evenly about its axis or, with some designs, it may rotate eccentric to its axis, giving the load a combined rotational and oscillating movement.

Barrels are commonly made with cast shells. Articles should not be rolled against cast iron because it has a tendency to deaden color. Hence, these barrels are lined with hard maple wood. When not in use, a wood-lined barrel should be kept wet and the cover should be on, to prevent the lining from drying out and shrinking. For a similar reason, wood barrels made for dry rolling should not be run wet. They will swell and buckle, or burst the bands. Since wood is somewhat porous, it is essential for wooden barrels to be kept scrupulously clean. After use with any solution containing chemicals, wooden barrels should be thoroughly rinsed several times. Strongly alkaline solutions rapidly disintegrate wood linings.

Burnishing barrels are also made of cast steel without wood lining, or of iron with welded sheet steel lining. For burnishing iron or steel articles, these are more durable than wood and provide increased burnishing area, but are not recommended for brass, die castings or similar alloys. Brass-lined barrels have been used for ball burnishing brass with excellent results.

Ball Buffing. When small amounts of very fine abrasive, such as rouge or Vienna lime, are used in the burnishing barrel, the effect of buffing is obtained.

Small pellets of leather about the size of a marble are coated in glue, rolled in abrasive and, when dry, are used for dry barrel buffing of intricately shaped pieces that could not be finished on a wheel.

Deburring. It is sometimes necessary to remove burrs from machined pieces, castings and stampings, or to dull sharp edges without changing the other dimensions of the piece. This work is usually done manually with files or other tools. If it is possible to deburr such parts by a selective rolling or tumbling operation, the ratio of increase in output per operator may be as much as 100 to 1.

Some pieces are too large to be processed in a barrel; other pieces are too delicate or are made with tolerances too close. However, there are many pieces that can be deburred in barrels, once the suitable speeds, abrasives and especially the lubricants have been determined.

The rolling action utilized in this method of deburring, together with the protection against metal-to-metal contact provided by the addition of a suitable lubricant, limits the "cut" of the abrasive to projecting burrs. Some work has been deburred by rolling in a mixture of sand and water. However, deburring by this method is slow and there is danger of pitting the work.

Satisfactory results have been obtained, in some instances, by the use of oils and abrasives such as sand, alundum, emery or carborundum. This method can be applied to a considerable variety of relatively small burrs, particularly when, instead of a mineral oil, a suitable solvent soap lubricant is used, which gives better protection to the surfaces where dimensional changes are not desirable, and which also ensures easy, rapid and thorough removal of the lubricant and metal particles after deburring, without the use of special washing procedures. Recent applications of this solvent soap type of lubricant with stone chips as the abrasive material, have produced satisfactory results in the short-time deburring of both steel and aluminum parts of all sorts.

* Physicist, National Bureau of Standards, Washington, D. C. and Chairman, Subcommittee on Linear Expansion of Steels. The following members of the committee assisted in the assembly of data: J. B. Austin (United States Steel Corporation) and R. B. Gordon (Westinghouse Electric Corporation). H. S. Krider (National Bureau of Standards) helped in the preparation of the table.

(a) Some of the steels included in this table have compositions not strictly in accordance with SAE specifications. *See* footnotes (b), (f) and (g).

(b) Elements not included in SAE specification.

(c) To obtain corresponding coefficients of expansion per degree Fahrenheit, multiply the coefficients in this table by 5/9.

(d) Some of the cited publications give data on phase transformations. No coefficients of expansion are included in this table for temperature ranges within which transformations occurred.

(e) The superior numbers refer to the references at the end of the table.

(f) Chemical composition not strictly in accordance with SAE specification

(g) Lies outside the range of SAE specification

(h) From 0 C or 32 F instead of ■ C or 68 F

(i) From 25 C or 77 F instead of ■ C or 68 F

(j) From — 100 to 0 C (— 148 to + 32 F)

(k) From 25 to 270 C (77 to 518 F)

The Iron Blast Furnace Process

BY CARL G. HOGBERG*

THE blast furnace process is unique among metallurgical processes, both because of its early origin and because its principles have undergone no change for several centuries. In iron smelting as practiced by the ancients, charcoal was used as a fuel to reduce the metal from relatively pure ores; then the resultant pasty mass was hammered to remove the impurities. The principle of this process is not unlike that governing a large number of low-temperature processes for direct reduction, on which time and effort have been spent in great amounts during the last several decades.

In about the fifteenth century someone conceived the idea of adding a stack over the early hearth-type furnace, in order to carry out the process of reduction prior to the entry of the materials into the hearth. This innovation resulted in an economy of heat enabling the generation of sufficient temperature in the hearth to separate the gangue in the ore from the molten iron and to permit the withdrawal of iron in essentially pure form.

In some of the ancient furnaces air for combustion of fuel was supplied by natural draft; later this was supplanted by hand-operated bellows. Still later, water power was used both in bellows and in blowers of the reciprocating-piston type. However, the real impetus to the development of the modern blast furnace came at the end of the eighteenth century with the use of the steam engine for blowing. Since the rate of iron production is limited largely by the rate at which the fuel can be burned within the furnace, and since the rate of burning is limited by the rate at which the air for combustion can be introduced, the application of the steam engine to blowing removed the greatest factor restraining increased productivity and left only the relatively minor limitations of physical size of the furnace and auxiliaries required to charge the raw materials and dispose of the products. These problems were solved by the combined efforts of enterprising engineers and daring and resourceful operators. The extent of their success is attested by the fact that in the relatively short span of 100 years the average maximum productivity of blast furnaces has increased from about 70 tons to more than 1500 tons per day for the large modern unit.

The Process. The process is essentially one in which iron ore, coke and flux are charged into the top of the furnace and air is introduced under pressure through openings called tuyeres, disposed peripherally around the bottom. Carbon in the coke is burned to carbon monoxide in front of the tuyeres and the resulting gases, rich in carbon monoxide, rise through the descending stock column; the ascending gases serve to preheat the stock and to reduce the iron oxide in the ore. Molten iron collects in the bottom of the hearth under a layer of molten slag and both are drawn off at regular intervals.

Carbon in the coke is burned by oxygen in the air blast in accordance with the following reaction:

$$2C + O_2 \rightarrow 2CO$$

This reaction takes place in front of the tuyeres and is completed before the air has penetrated approximately 40 in. into the interior of the furnace. The theoretical temperature in the zone of combustion in front of the tuyeres is approximately 3500 F when an air blast is used that is preheated to 1300 F in stoves provided for this purpose. The average temperature of molten iron in the hearth of a furnace producing basic iron approximates 2700 F; the average temperature of the molten slag is slightly higher.

* Assistant to Chairman, Blast Furnace Committee, United States Steel Corporation of Delaware, Pittsburgh.

Prepared for the Subcommittee on Melting.

In its ascent through the furnace, the carbon monoxide in the gas reacts with the iron oxide in the ore in the approximate sequence of the following reactions; these reactions fall into the classification of "indirect reduction" and account for about 85 to 90% of the reduction in a normal blast furnace producing basic iron:

$$3Fe_2O_3 + CO \rightarrow 2Fe_3O_4 + CO_2$$
$$Fe_3O_4 + CO \rightarrow 3FeO + CO_2$$
$$FeO + CO \rightarrow Fe + CO_2$$

Iron oxide is also reduced directly by contact with solid carbon during the descent of these materials through the furnace, in accordance with the following reactions:

$$3Fe_2O_3 + C \rightarrow 2Fe_3O_4 + CO$$
$$Fe_3O_4 + C \rightarrow 3FeO + CO$$
$$FeO + C \rightarrow Fe + CO$$

These are the so-called "direct reduction" reactions which account for approximately 10 to 15% of the reduction process.

The rate and the extent to which reduction reactions are completed in the various sections of the furnace depend primarily on the temperature. In normal basic iron practice, using Mesabi ores, approximately 75% of the reduction takes place in the lowest third of the furnace. In its upward travel through the furnace, the gas is burdened with an increasing weight of oxygen and carbon dioxide from the ore and from the limestone or dolomite used as a fluxing agent. Because of the equilibrium relationship among the oxides of carbon and iron, the top gases leave the furnace with a considerable amount of carbon monoxide, as indicated in the following typical composition: 26.24% CO; 12.96% CO_2; 1.87% H_2; 0.22% CH_4; 58.71% N_2. These gases leave a normally operating furnace at a temperature of approximately 300 F.

The four principal slagmaking constituents in the burden are silica (SiO_2), alumina (Al_2O_3), lime (CaO), and magnesia (MgO). As noted in the section devoted to raw materials, the gangue in the ores used in the principal iron-producing districts of the United States is generally acid in character; that is, it contains silica and alumina predominantly, so lime in the form of limestone must be added as a flux in the charge to form a slag with proper characteristics of fusibility. The lime in the slag also serves the purpose of removing the sulfur in the process by the following reaction:

$$CaO + FeS \rightarrow CaS + FeO$$

Flux is added in a quantity depending on the amount of slagmaking constituents in the ore and coke and proportioned to achieve a ratio of approximately 1 to 1 between total bases and total acids in the slag. A lower ratio of basicity normally requires a lower temperature for melting the slag. An increase in flux raises the melting point of the slag and makes it more viscous at constant temperature, but enhances its desulfurizing power.

Someone once remarked, "You don't make iron in the blast furnace; you make slag." The implication is that if the furnace is burdened to make the proper slag, the operation of the furnace and the composition of the iron will be satisfactory. Considerable progress has been made during the last 25 years in taking the slagmaking phase of the operation out of the rule-of-thumb category. The development of ternary equilibrium diagrams for the mineralogical system SiO_2–Al_2O_3–CaO, and also research on the effect of slag composition on viscosity at various temperatures and on desulfurizing power have been applied by blast furnace operators to such an extent that this phase of the process has been reduced to a technological basis.

Contact of molten iron and coke in the lower region of the furnace results in carburization of the iron, with the result that the product contains from 3 to 5% C, depending on the silicon content of the iron. Of the manganese charged, about 75% appears in the pig iron while the remainder goes out with the slag in the form of oxides and sulfides. Phosphorus is not eliminated in the process. Sulfur, which is largely derived from the coke, is almost entirely eliminated by reactions forming calcium and manganese sulfides in the slag. Silicon will enter the pig iron in various percentages from 0.5 to 2% for ordinary grades of iron, depending on the slag basicity and temperature. For special grades of merchant iron, silicon may be as high as 4.5%, and in ferrosilicon a silicon content as high as 16% can be obtained. Calcium, magnesium and aluminum are not reduced in the process. Copper, nickel and vanadium, if present, are reduced and will appear in the pig iron. Chromium is reduced only under special conditions of high temperature. Zinc and lead volatilize and are difficult to contend with because they are absorbed by the refractories to the detriment of the life of the brick lining.

Since there is a tendency to oversimplify the theoretical principles of the blast furnace process, it should be emphasized that the countercurrent nature of both its thermal and chemical phases is such that it gives rise to a series of complex intermediate or side reactions not fully understood because of the practical difficulty of obtaining accurate data while the furnace is in operation. The impression is erroneous that the blast furnace can be divided theoretically into several vertical zones, each one performing a definite function, such as flux calcination, ore reduction, slag smelting and so on. Investigation has revealed not only that the transition of the mode of reactions in the furnace occurs gradually in a vertical plane, but that considerable differences exist radially in any one plane; for instance, calcination of limestone may be completed at a point 4 ft from the inwall lining in a plane 30 ft above the tuyeres, but may just have begun at a point 8 ft from the inwall lining in the same plane. Differences such as this are brought about primarily by radial differences in the temperature and composition of gases ascending through the furnace, and these differences contribute largely to the difficulty of obtaining accurate data concerning the process.

The Furnace Plant. The furnace plant is best described by referring to Fig. 1. Raw materials in stockhouse bins are drawn into a scale car in specified weighed amounts and are subsequently discharged into a cable-operated skip car, which travels on an incline to the top of the furnace. Material from the skip discharges over the small bell, which usually incorporates a device for periodic rotation of this compartment in order to compensate for inherent differences in the trajectory and angle of repose of various materials, thus enabling the achievement of the very important objective of uniform distribution of materials in the furnace. The small bell is then opened, allowing the materials to fall over the closed large bell. After a predetermined number of skips of material have been deposited on the large bell, the small bell is held closed to prevent the escape of gases to the atmosphere and the large bell is opened, dropping the charge into the furnace. The top of the stock in the furnace is normally maintained at a level 6 to 10 ft below the bottom of the closed large bell.

The furnace proper consists of a refractory brick shaft encased in a steel shell and provided with water-cooled bronze plates embedded in the brickwork in the inwardly sloping bottom part, or bosh, of the furnace. Large vertical water-cooled plates are arranged around the outer periphery of the hearth brickwork to maintain a submelting temperature of refractories in that area.

The dimensions and the proportioning of the dimensions of the brickwork in the furnace are very important factors in furnace performance, and the "lines" of a modern furnace represent an evolution—mostly by trial and error—over a period of many years. The following dimensions are those of a typical large blast furnace:

Hearth diameter	27 ft, 6 in.
Bosh diameter	30 ft, 6 in.
Stockline diameter	21 ft, 0 in.
Large bell diameter	15 ft, 5 in.
Total height	105 ft, 3 in.
Working height (centerline tuyeres to 6-ft stock level)	79 ft, $6\frac{7}{8}$ in.
Total volume, cu ft	51,654
Working volume, cu ft	44,849
Ratio of working volume to hearth area	75.5
Bosh angle	81.25 deg
Inwall batter, in. per ft	1.080
Number of tuyeres	18

An air blast is introduced into the furnace through tuyeres leading from a bustle pipe and disposed peripherally around the hearth. The accumulation of molten

iron in the hearth is "cast" at intervals of 5 or 6 hr by drilling through the clay plug of the tapping hole and subsequently lancing the remaining iron skull with oxygen. The slag notch is usually opened 3 hr after the casting of the iron is completed.

Gas, leaving the furnace through offtakes (usually four in number, arranged around the dome of the furnace) is subsequently passed through a brick-lined downcomer to the dustcatcher, which is essentially a large chamber where the reduction of gas velocity causes the larger dust particles to collect in the bottom, whence the dust is drawn at regular intervals. From a furnace operating on the relatively fine Mesabi ores, the dustcatcher will remove from 50 to 70% of the total dust content in the gas.

Gas is piped from the dustcatcher to the bottom of the gas-washer, the lower section of which is equipped with water sprays playing over banks of baffles consisting of wooden hurdles or ceramic tile. The upper section of the most modern unit consists of an electrical precipitator for further cleaning. The precipitator is made of nests of tubes with a heavily charged anode wire running through the central axis of each tube. By a charge imparted to the fine particles of dust, these particles are attracted to the cathode or tube wall, from which they are washed by a continuously flowing film of water. The dust-bearing sludge flowing from the bottom of the gas-washer is pumped to a thickener for dehydration and subsequent filtering. The filtered product, together with the dust recovered in the dustcatcher, is shipped to the sintering plant for agglomeration and re-use in the furnace.

Typical dust contents of gas at various points in a modern gas-cleaning system are as follows:

Location	Dust Content, grains per cu ft
At top of furnace	12.5
Dustcatcher outlet	4.4
After primary washing	0.075
After electric precipitation in tower	0.015

After cleaning, part of the gas produced is utilized in the stoves employed to preheat the air blast, and the remainder may be used for underfiring boilers, underfiring coke ovens or for miscellaneous heating applications in the steel plant. Normal blast furnace gas has a heating value ranging from 85 to 100 Btu per cu ft, depending on the carbon monoxide content.

Stoves perform the important function of preheating the air blast, thus contributing much to the fuel economy of the modern blast furnace. A typical modern stove consists of a steel cylinder approximately 25 ft in diam and 100 ft high, lined with brick in such a way as to provide a tall, vertical combustion chamber to insure combustion of the gas burned at the bottom of the stove; and a checker chamber filled with refractory shapes arranged to provide openings for the passage of gas and air. Three or four stoves are usually provided for each furnace; a portion of the air blast is being passed through one stove at all times while the remaining stoves are being heated with gas. The stoves are changed from gas to blast by the manipulation of valves, without necessity for interrupting the flow of blast to the furnace. Ordinarily, a stove is "on blast" from 2 to 4 hr and "on gas" from 5 to 8 hr. Blast temperature is controlled by using a butterfly type of valve in the cold-blast main. This valve is arranged to divert a portion of the blast through the stove, and is usually provided with a motor-operated, potentiometer-controlled device that automatically enables the attainment of a uniform blast temperature despite the gradual drain of heat from the stove during the blast cycle.

The blowing equipment for blast furnaces may consist of reciprocating engines operated by steam or gas, or the modern steam-driven turboblowers. At some plants the air is passed through special equipment for decreasing the water vapor in the blast to a low and uniform level.

Molten iron flows from the furnace into brick-lined hot metal ladles. In an integrated steel plant, hot metal is transported in ladles directly to the open hearth furnaces or the Bessemer converters. In isolated furnace plants or

where iron is being manufactured for shipment to the trade or for consumption in cold form by the steel plant, the product is sent to the pig machine. This unit consists of an endless chain of individual pig molds into which the metal is continuously poured and subsequently cooled by air or water. The pigs may weigh from 25 to 100 lb each, depending on the desires of the consumer.

Slag is disposed of by transportation in steel or cast-iron pots, by granulation with a stream of high-pressure water at the furnace site, or by pouring directly into a pit at the furnace site where the slag later solidifies and is removed by power shovels.

Flue dust and filter cake are disposed of by agglomeration in a sintering plant. Two types of sintering plants commonly used are the continuously traveling grate (Dwight-Lloyd) and the intermittent pan type (Greenawalt). The carbon in a mixture of flue dust and filter cake placed on the grates is subsequently ignited by a flame; suction applied to the bottom of the grate causes the zone of carbon combustion to travel downward gradually in a horizontal plane. The heat generated by burning the carbon, fuses the iron-bearing materials into a mass which, after cooling, has characteristics of strength and size that are beneficial in the blast furnace process. At some sintering plants only ore fines or ore concentrates are handled; at such plants carbon in the form of coke breeze or coal must be added to the mixture prior to sintering. This is in contrast with the sintering of flue dust, which carries its own carbon.

Raw Materials. The physical and chemical characteristics of raw materials are important factors in the performance of blast furnaces. The iron content of the ores is the chief factor in determining the heat requirement of the process. The physical character of the ores, as well as the physical character of the coke, largely determines the efficiency of transferring the heat required to reduce and smelt the ores.

Typical compositions of ores used in important iron-producing districts in the United States appear in Table I.

The principal source of iron ores in the United States is the Mesabi Range in the Lake Superior District. Ores from the Mesabi Range are generally high in iron content but are often objectionable in the blast furnace process because of their extremely high content of fines. Where these ores are screened for direct shipment of the oversize and agglomeration of the fines, the productivity and fuel economy of blast furnaces have improved considerably.

The effect of widely differing compositions of iron ore on burden requirements at blast furnaces may be illustrated by Table II, which shows typical burden requirements for production of basic iron at plants in the Pittsburgh and Birmingham Districts.

Coke used in blast furnaces is ordinarily produced in by-product ovens, with a relatively small proportion supplied by ovens of the beehive type. The composition of ash and sulfur in coke, which depends on the chemical composition of coals used in coking, is important because it affects the thermal requirements of the process in accordance with the quantity of ash impurities, and because sulfur thus introduced requires flux for its elimination by means of slag. The washing of coals for the reduction of ash and sulfur content prior to coking has been found extremely beneficial in subsequent blast furnace processing.

Table II. Representative Blast Furnace Burdens for Production of Basic Hot Metal

	Quantity, lb per ton hot metal: Pittsburgh District	Birmingham District

Mill scale	60	....
Dolomite	138	832
Limestone	696	....
Coke	1794	2181
Slag produced	1116	2292

The physical character of coke is important because of its effect on the distribution of gases in the furnace stock column. Good coke is low and uniform in sulfur and ash content, has high strength and a size ranging from not more than 5 in. to not less than 1 in. The importance of quality of coke can hardly be overemphasized, and was summed up by a Russian blast furnace operator during a recent visit to a plant in the United States, when he remarked, "Good coke is best blast furnace superintendent!"

Limestone and dolomite when used as fluxes seldom present an operating problem, since good fluxing stone is available in large quantities in virtually all iron-producing districts.

Miscellaneous burden materials include: open hearth slag, which is used for its iron, manganese and lime content; rolling mill scale, which is nearly pure iron oxide; Bessemer converter slag, used for its manganese content; and scrap. Blast furnace smelting of scrap borings and turnings has been found to be more feasible than the disposition of these materials in the open hearth, because their light weight slows down the operation of charging them into an open hearth and their high ratio of surface area to weight increases oxidation.

Typical compositions of coke, fluxes and miscellaneous materials appear in Table III.

Blast Furnace Practice and Performance. Because of the countercurrent nature of the process, slight variations in the physical and chemical character of raw materials have a marked effect on the smoothness of furnace operation and on the quality of the metal product. Because of the speed of the process and its continuous nature, the operator must be constantly on the alert to anticipate changes in furnace conditions before they materialize detrimentally. Improper furnace operation reveals itself in increased pressure of the blast; increased temperature of top gas; fluctuating pressure of top gas, or hanging and slipping of the stock column; and visual appearance of the slag, indicating the presence of abnormal amounts of unreduced oxides. A trend toward higher sulfur and lower silicon in the metal is indicated by a visual examination of a chilled sample of the iron and by subsequent chemical analysis. All of these indications manifest a disturbance in the delicate thermal and chemical balance within the furnace, which can be corrected to a greater or lesser extent by immediate application of one or more of the following means which the operator has at his control: a change in the temperature and quantity of the air blast; a change in the ratio of the ore to the coke charged; a change in the quantity of flux in the burden; and a change in the filling sequence used in charging the furnace. These routine measures are applied as a matter of course in daily operations.

Data for a month's performance of a typical blast furnace in the Pittsburgh district, operating on 100% raw Mesabi ores and producing basic iron, are shown in Table IV.

Table IV. Typical Blast Furnace Practice and Performance Data for Production of Basic Hot Metal

Production:

Products of the Blast Furnace. Products of the blast furnace in the United States, in the approximate order of their production and importance, are as follows: (1) basic iron, (2) Bessemer iron, (3) merchant pig irons (malleable and foundry), (4) blowing iron, (5) ingot mold iron and (6) ferro-alloys (ferromanganese, ferrosilicon or "silvery" pig iron, spiegeleisen and silicomanganese).*

* For further information concerning ferro-alloys, see the article on page 337 of this Handbook.

As the names imply, basic iron and Bessemer iron are used in the production of steel by the basic open hearth and the Bessemer converter processes, respectively. Blowing iron is a special grade made for the purpose of blowing in Bessemer converters, for conversion into so-called "synthetic scrap" or blown metal used in the duplex process. Ingot mold iron is produced for the casting of ingot molds used in steelmaking, and is usually applied directly for this purpose.

Merchant grades are made in numerous compositions, depending on the specified phosphorus, silicon and manganese content. They are used for a large variety of applications in the castings industry.

Ferromanganese is used as a deoxidizer and desulfurizer in the production of steel, and as an alloying element. Ferrosilicon made in the blast furnace is of the type commonly known to the trade as "silvery iron", and is used as a deoxidizer and alloying element both in steelmaking and in the castings industry. Spiegeleisen, which might be termed a low-grade ferromanganese, is also used as a deoxidizer in steelmaking. Silicomanganese, another deoxidizer and alloying agent, is rarely produced in the blast furnace.

The amount of manganese in the product is dictated both by the manganese content of the ores and by the heat generated within the hearth, which is in turn governed by the quantity of coke consumed in relation to the quantity of product. Phosphorus content of the product is determined solely by the phosphorus content of the charge. The silicon content of the product is established largely by the heat generated within the furnace (higher temperature is required for increased silicon), and to a lesser extent by the chemical compositions of the ores and slag. The quantity of coke and slag associated with production of various grades has an important bearing on the rate of production and the manufacturing cost of iron.

Typical compositions of various grades of blast furnace products and representative coke rates in pounds per ton of product are shown in Table V.

Table V. Compositions and Required Coke Consumption Rates for Various Grades of Blast Furnace Products

Grade	Representative Composition, % Si		P	Mn	Typical Coke Rate, lb per ton iron
Basic—Northern	0.96	0.028	0.274	2.38	1766

The Acid Bessemer Process of Steelmaking

By G. B. Waterhouse*

THE invention of the Bessemer process of steelmaking was a great event in the world's economic history. Previously steel had been scarce and expensive, made chiefly by the crucible process. It was reserved for special purposes, while wrought iron, cast iron, and bronze were used for structures, engines, and ordnance. Henry Bessemer developed the process during his search for an improved material for guns. He started his experiments in Dec 1854, shortly before his forty-second birthday. The first public description of the process was in Aug 1856 before it had been perfected. Many difficulties were encountered, later, principally because of phosphorus in the pig iron which was used as the raw material.

Application for a patent disclosed that William Kelley had worked on a similar method since 1847 and a patent was granted to Kelley in 1857. As soon as the patent controversy was ended in 1865, developments were rapid, mainly because of the energy and genius of the great engineer, Alexander Lyman Holley.

The American steel industry grew up on Bessemer steel. More than three-fourths of the steel made in the United States between 1885 and 1900 was made by this process. Even in 1900, 65.7% of all the steel made in the United States was Bessemer grade.

The application of this process to pig iron high in phosphorus was developed in 1877 by Sidney Gilchrist Thomas, who discovered the proper basic refractories and the importance of a basic slag. His method, the basic Bessemer or Thomas process, is of great importance in Europe.

The Bessemer Converter. Molten blast furnace iron (pig iron) of the proper composition is poured into the Bessemer converter, a pear-shaped steel vessel mounted on trunnions. The converter is tilted to receive the metal. The charge varies from 5 to 30 tons. The lining of the converter is of acid refractory material and the slags produced consist of more than 50% silica, so the process is known in this country as the "acid Bessemer". When the vessel is charged, air is admitted from the blowing engines or turboblowers through one of the two trunnions supporting the vessel, to a blast box at the bottom of the converter. From this box the air passes through numerous holes or tuyeres, ½ to ⅞ in. in diam, to the interior of the converter. The blast pressure is about 20 psi, but often ranges from 25 to 32 psi. Several plants use automatic controls to deliver the necessary volume of air at a uniform rate per minute, so as to avoid peaks and valleys in volume delivery, caused by a number of variables such as blanked tuyeres and variations in depth of bath. These converters are known as "bottom blown". This article will not describe the process carried out in side-blown converters used in foundries that make steel castings. These vessels, often called "baby Bessemers" (Tropenas converters), usually vary from ½ to 3 tons capacity.

Operation of Acid Bessemer Converter. After the blast is turned on, the vessel is slowly turned upright. The air blows through the charge and oxidizes the silicon, manganese, and carbon, in the order given. The combustion of these materials, especially of silicon and some of the iron, furnishes the heat to carry on the process. The progress of the operation is shown by the flame issuing from the mouth of the converter. At first this flame is short and dry with very little visibility; then a reddish-brown flame of low luminosity occurs during the period when silicon and manganese are oxidized. As the carbon burns, the flame changes in character and increases in size, becoming yellowish white and reaching about 30 ft in height (Fig. 1). When the flame drops in a characteristic way at the end of the blow, the vessel is again turned down on its side and the blast is shut off. The photocell is now being used in some plants to control the blow, to determine when to turn down the vessel, and also to aid in better control of temperature.

This whole operation or "blow" usually takes from 12 to 18 min. The material now known as "blown metal" contains traces of silicon and manganese and 0.06% C or less. Substantially all the phosphorus and sulfur of the original pig iron are present in the blown metal, which also contains about 0.2% FeO (iron oxide). This last constituent makes the metal "red short", incapable of being successfully forged or rolled; consequently a deoxidizing agent is added to the blown metal. In making soft or low-carbon steel, ferromanganese, crushed to egg size, is usually added to the blown metal while it is being poured from the converter into the ladle. Then the ladle is swung or carried over the ingot molds and the ingots are poured.

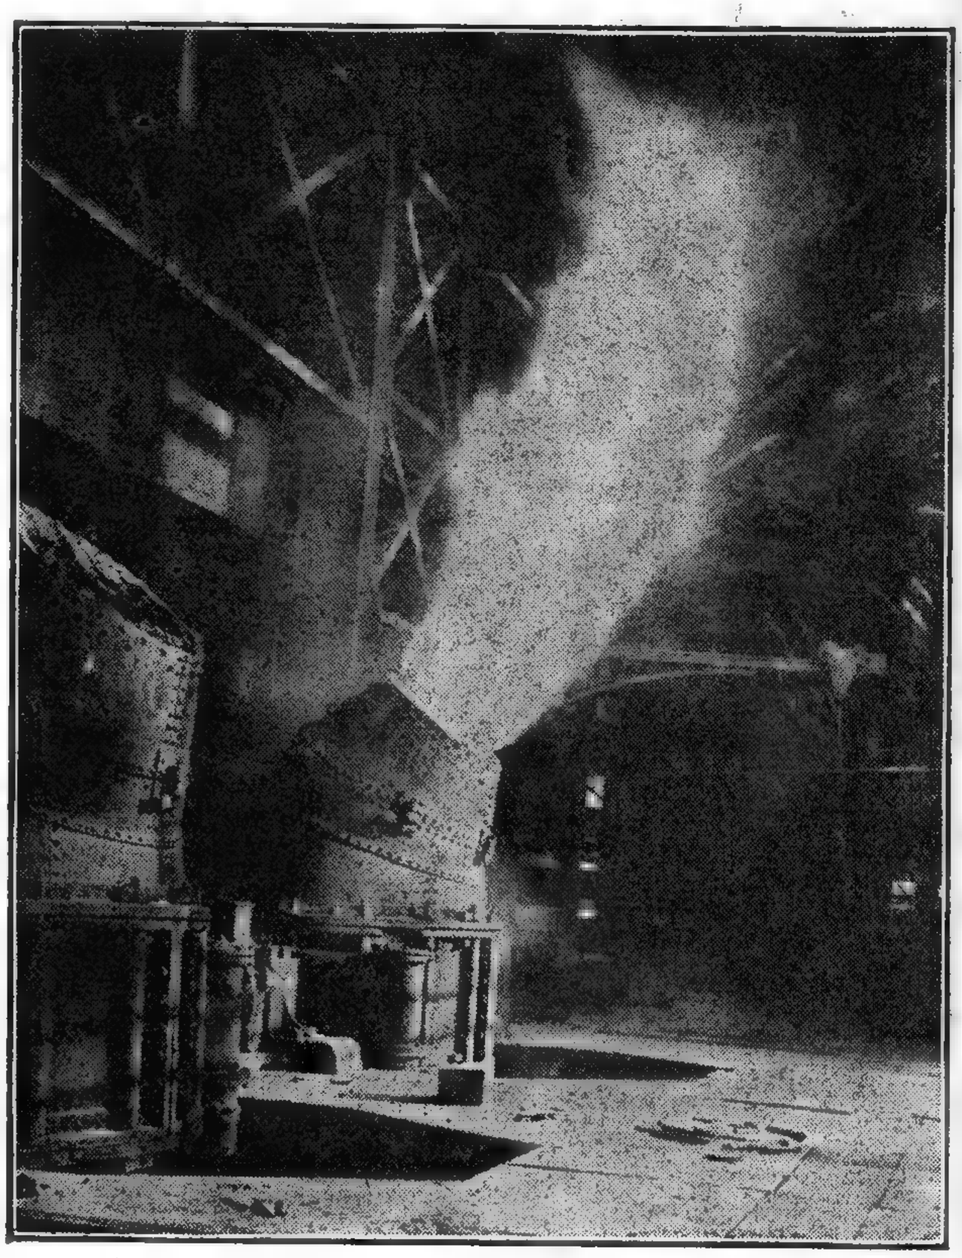

Fig. 1 A Bessemer blow

The work of the physical chemists during the last 20 years has shown that the chemical processes during Bessemer steelmaking are very similar to those taking place in the open hearth furnace. Thermodynamic studies of the effect and intensity of different deoxidizing agents have shown that fully blown Bessemer metal, treated with selected quantities of molten pig iron in the converter, can be deoxidized readily, much as open hearth steels are "blocked" during the refining operations. Such deoxidized blown metal can then be poured into the teeming ladle and manganese, silicon, aluminum, titanium, and other elements can be added in proper amounts to produce killed steel (as contrasted with open, effervescing, or rimmed steel, mentioned in the previous paragraph). In recent years about a million tons of killed Bessemer steel made by this procedure has been used satisfactorily for all sizes of seamless pipe, for carburizing steels and for forging steels.

Raw Material. The main raw material is liquid pig iron. This is usually brought from the blast furnace or furnaces in ladles and poured for storage into containers known as "mixers", because various casts are mixed or averaged. These mixers hold from 200 to as much as 1200 tons. They are constructed of steel lined with firebrick or other re-

* Professor Emeritus, Massachusetts Institute of Technology, Cambridge, Mass.

Prepared for the Subcommittee on Melting.

fractory material and can be rotated electrically or by hydraulic power. When needed, metal is poured from the mixer through a spout into a ladle standing on a scale. Mixers are equipped for heating by gas, oil or tar so that heat may be added to the bath when necessary, to offset losses from radiation. Care is taken to prevent blast furnace slag from entering the mixers with the iron, since it would cause slopping and bad working in the Bessemer converter.

The composition and amount of iron entering the mixer is very important to the operation of the converter. For good practice the pig iron is held within fairly close limits.

Silicon, the most important element, varies from about 1.00 to 1.80%. It should be held as nearly constant as possible and at the particular amount found to work best for the individual shop.

The total carbon content does not vary much in a given plant combination of blast furnaces and Bessemer converters. The carbon content of each cast of iron is not usually determined, and may vary from about 3.80 to 4.50%, depending on individual blast furnace operations.

The manganese content is usually less than 0.60%. The percentage should not be much higher, for high manganese makes a thin slag in the converter, which slops out of the vessel onto the floor of the shop, causing a loss of steel and handicapping the operator in producing steel of a specified composition.

All the phosphorus entering the blast furnace with the charge is reduced and ultimately enters the liquid iron. Phosphorus in the iron varies from about 0.080 to 0.100% and almost all of this remains in the blown metal and in the finished steel. Thus the phosphorus content of the iron governs the phosphorus content of the finished steel to a certain extent, and it is important that this content be kept sufficiently low to prevent exceeding the maximum allowed in the final product. In general this is 0.110%, although some specifications for Bessemer steel allow a maximum content of 0.13%. The reason why iron ores are classed as Bessemer and non-Bessemer now becomes obvious. The Bessemer ores are so low in phosphorus that the blast furnace iron made from them is low enough in phosphorus to be used in making Bessemer steel.

The sulfur content, usually about 0.04%, varies from 0.03 to 0.08%. Both phosphorus and sulfur are about 8% higher in the finished steel than in the blast furnace iron, because of loss of iron and other elements and the resulting concentration of phosphorus and sulfur.

Temperature Control. After the liquid iron has been poured into the vessel, the blast turned on and the vessel turned upright, the scrap chute is swung into the nose of the vessel and the correct amount of scrap is added. This scrap addition affords the operator a means for adjusting temperature, the control of which is his most important duty.

The finished steel in the ladle must be at the proper temperature for the grade of steel being made. It must pour cleanly from the ladle into the ingot molds so that the ingots will set properly. If the metal is too cold, a large skull* will be left in the ladle and there may be trouble in pouring the ingots. If the metal is too hot, the internal structure of the ingots will not be correct and surface as well as interior defects may develop during rolling.

In general, the operator tries to control the temperature so that a small skull is left in the ladle after pouring the finished steel. There are two possible methods for reducing temperature. One is by the addition of scrap; the other is by using steam admitted with the air. In the first method, bloom butts or crop ends of steel weighing about 100 lb are ordinarily added, but sometimes cold pig iron is employed. Only about 15% by weight of the liquid iron can be used, so the Bessemer is not a scrap-using process.

The chemical composition of the liquid iron, particularly the silicon content, is generally maintained to give a reserve of temperature during the blow; consequently scrap or steam is usually needed. Occasionally cold heats are encountered. If these are recognized in time, ferrosilicon can be added with the liquid pig iron, or added down the scrap chute, or the vessel can be blown on its side so that part of the air rushes over the surface of the metal. This causes excessive loss of iron, but does raise the temperature.

Additions. In the production of most of the steels listed in Table I, ferromanganese is added while the blown metal is being poured into the ladle. This brings about deoxidation and adds the amounts of carbon and manganese required to give good rolling and working properties and to meet the specifications. During this operation there is a loss of about 35% Mn, which is allowed for, and experience soon shows the correct weight of ferromanganese to be added. The sulfur needed for the free-cutting steels is added to the converter in the form of pyrites, or to the converter or ladle as stick sulfur in a strong paper bag. About 45% of the sulfur addition is lost.

For the higher-carbon steels, the proper weight of liquid iron is brought from the mixer and added to the blown metal in the converter. It is often the practice, in making such steels, to turn on the blast and then turn the vessel up and down to give a "puff" and mix the materials thoroughly. Ferromanganese is added, as usual, while the steel is being poured into the ladle. Sometimes the required carbon content is obtained by adding bags of dry crushed anthracite coal or coke to the blown metal while it is being poured from the converter.

Rail steel and other high-carbon steels were formerly made by adding a molten mixture of spiegeleisen and pig iron to the blown metal in the converter. This mixture was first melted in cupolas and carefully calculated to take care of losses. The requisite amounts of carbon, manganese and silicon were added, by means of the correct weight tapped from the cupolas. Additions of molten pig iron have been found to be entirely satisfactory for steels containing between 0.20 and 0.50% C, avoiding the use of spiegeleisen and the expense of separate melting equipment for handling molten spiegel. Almost any grade of carbon steel can be made by the Bessemer process, if the use of steel high in phosphorus can be allowed.

Dephosphorized and Low-Phosphorus Acid Bessemer Steel. Several steel companies are making or planning to make Bessemer steel from low-phosphorus pig iron, with the final percentage of phosphorus in the steel ranging from 0.050 to 0.070%.

A process has now been developed for the dephosphorization of blown Bessemer metal while it is in the ladle. More than a million tons has already been made with final phosphorus content less than 0.050%. The iron is of controlled silicon and manganese content, so that a thick viscous vessel slag is produced when the metal is blown with proper control of temperature. This slag is easily prevented from entering the ladle with the blown metal. Additions to the ladle of readily fusible slag-producing materials then cause a reaction that brings about the dephosphorization. The steel is used in many ways: as cold reduced sheet for corrugated roofing, as galvanized sheet, black plate, blue iron, building materials, conduit pipe and other welded pipe, oil-well and water-well tubing. The steel is soft and ductile, can be cold rolled, formed and drawn, and is said to produce a finished product of better final stiffness and rigidity than soft open hearth steel.

Composition of Acid Bessemer Steel. During the first part of the blow, silicon and manganese are rapidly oxidized and enter the slag. This is characterized by a short dry flame. The flame then turns to a yellowish white as the carbon is oxidized, and begins to increase in size until it is 25 to 30 ft in height. At the end of the blow there is a well-marked drop of the flame, and the vessel is turned down. The heat may be turned down "green" or it may be "full blown", depending on the type of steel being made.

The blown metal contains from about 0.04 to 0.10% C, traces of Mn and Si, from about 0.085 to 0.110% P, and about 0.03 to 0.07% S, except when sulfur has been added in the vessel. The additions required to make the finished steel are added usually in the ladle or else both in the vessel and in the ladle.

Typical compositions of finished Bessemer steel are shown in Table I.

Table I does not include bars, small structural shapes, and materials for railroad purposes, such as spikes, bolts, and nuts, for which considerable Bessemer steel is used.

* The term "skull" refers to the frozen shell of metal sometimes remaining in the bottom of the ladle.

Table I. Chemical Composition of Acid Bessemer Steel

Material	Carbon, %	Manganese, %	Phosphorus, %	Sulfur, %
Soft Bessemer Steel Grades				
Skelp	0.10 max	0.30 to 0.60	0.11 max	0.06 max
Sheet and tin bar	0.10 max	0.30 to 0.50	0.11 max	0.07 max
Soft wire	0.08 max	0.45 max	0.11 max	0.06 max
Medium wire	0.08 to 0.13	0.30 to 0.70	0.11 max	0.06 max
Hard wire	0.12 to 0.17	0.70 to 1.00	0.11 max	0.08 max
Screw Stock				
AISI B 1111 SAE 1111	0.08 to 0.13	0.70 to 1.00	0.07 to 0.12	0.10 to 0.15
B 1112 1112	0.08 to 0.13	0.70 to 1.00	0.07 to 0.12	0.16 to 0.23
B 1113 1113	0.08 to 0.13	0.70 to 1.00	0.07 to 0.12	0.24 to 0.33
Reinforcing Bar[a]				
Reinforcing bar	0.15 to 0.35	0.70 max	0.12 max	0.08 max
	0.08 to 0.15	1.00 max	0.12 max	Normal or added

Deoxidized or Killed Steels					
			Phosphorus, %	Sulfur, %	Silicon, %
Seamless pipe	0.15 to 0.50	0.30 to 1.25	0.11 max	0.06 max	0.15 to 0.30
Forging steel	0.25 to 0.40	0.60 to 0.90	0.11 max	0.06 max	0.15 to 0.30
Carburizing steel	0.15 to 0.25	0.60 to 0.90	0.11 max	0.06 max	0.15 to 0.30

[a] Specifications governing reinforcing bars prescribe mechanical test requirements rather than chemical composition. The compositions shown above are an approximative equivalent expression for the tensile test requirements of the several grades.

The composition of steels for these purposes does not vary greatly from that shown for skelp and sheet bar, except that as a rule only the phosphorus is specified and tensile test requirements are imposed. In many of these steels, especially those exposed to atmospheric corrosion, from 0.20 to 0.30% Cu is present and has been found very helpful.

Application. The main uses of Bessemer steel, as indicated in Table I, include skelp for making lap-welded and butt-welded pipe, especially the smaller sizes; sheet bar for rolling into sheet for tin plate and galvanized material; bars and special shapes for free-machining purposes, especially automatic screw-machine products; and wire products of many different kinds. The Bessemer process is the third steelmaking method of the country in regard to tonnage. Its capacity is about 5.60% of the total steelmaking capacity.

Also considerable steel is made by the duplex process, a combination of the acid Bessemer and the basic open hearth processes. The steel produced in this way is known and shipped as open hearth steel. One other application of the Bessemer process is the Aston process for making wrought iron. Various combinations of the Bessemer and electric furnace processes are listed on page 329 of this Handbook.

The Open Hearth Process of Steelmaking

By C. H. Herty, Jr.*

SINCE pig iron is unsuited to the purposes for which steel is used, it must be refined. The refining consists of removing carbon, manganese, and silicon by oxidation; sulfur by reaction with the slag; and suspended oxide material and gases by scrubbing. In the basic process it is necessary to supply a strong base that will form stable compounds with the oxides of phosphorus and silicon, and with sulfur, in order to hold these permanently in the slag—which is the molten magma formed when the lime and various oxides unite with or dissolve in one another.

The Basic Open Hearth Process

The Open Hearth Furnace. Figures 1, 2 and 3 show sections through an open hearth furnace having a capacity of 175 tons. The basic furnace consists mainly of a shallow, elliptical vessel lined with some suitable basic refractory. This hearth, on which the steel is made, is covered with a silica roof to form a combustion chamber. On one side of the furnace suitable spaces are left for doors through which the operations can be controlled.

*Assistant to Vice President, Bethlehem Steel Company, Bethlehem, Pa.

Prepared for the Subcommittee on Melting

The hearth is usually lined with magnesite brick and covered with a mixture of burned magnesite or dolomite and open hearth slag. The bottom is kept in repair with raw or clinkered dolomite, or both, or in certain instances with ground magnesite and open hearth slag. The banks, particularly above the slag line, are protected with dolomite or chrome ore.

In many modern furnaces the backwall slopes at an angle instead of being straight. This sloping backwall prolongs the life of the furnace because the flame cannot cut the brick so readily as it can when a straight backwall is being used. A sloping backwall also facilitates repairs.

In the rear of the furnace, at the center and bottom of the hearth, is the tap hole, which is between 4 and 8 in. in diam, depending on the size of the furnace and the type of practice. During the steelmaking period, this hole is filled with a suitable refractory material that can be removed easily when the heat of steel is to be tapped. In a tilting furnace, the tap hole is put in above the level of slag and metal and the metal flows out through this hole when the furnace is tilted.

Open hearth furnaces are of the regenerative type, in which the hot gases are passed through checker chambers and transfer heat to the brickwork. Approximately every 15 or 20 min, the flow of gases through the furnace is re-

versed and cold air enters the hot chambers, where it is heated to about 1800 F, a system promoting economy of fuel and control of temperature.

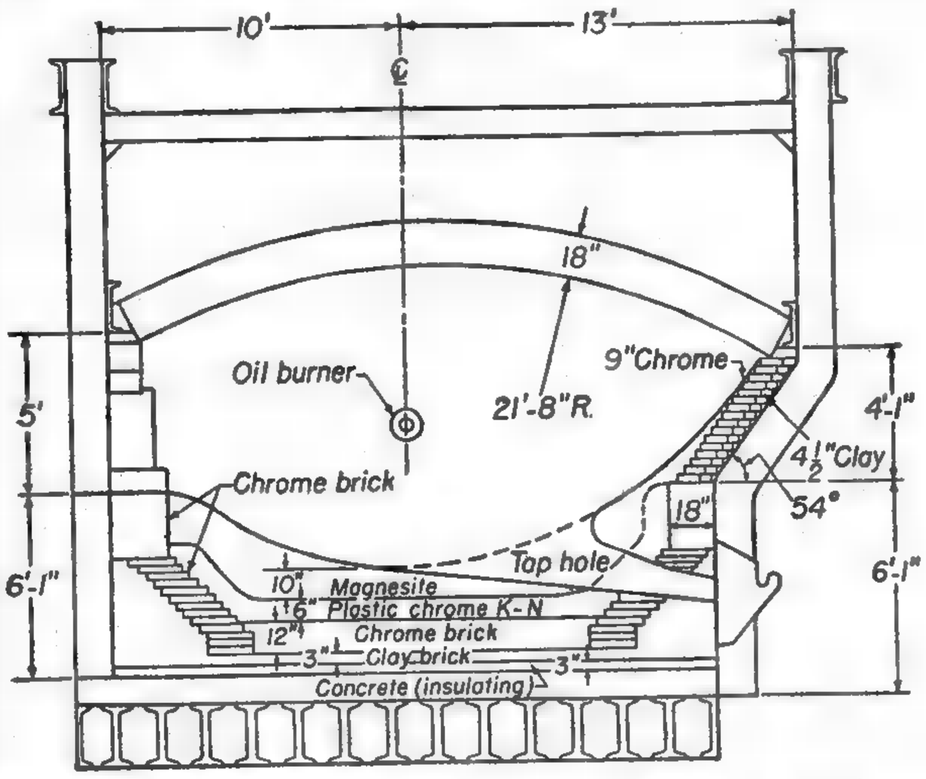

Fig. 1 Cross section of a 175-ton stationary open hearth furnace showing bottom construction and the principal dimensions (Ref 1)

Producer gas, and sometimes mixtures of blast furnace and coke-oven gas are fuels that are preheated in the checkers before they enter the furnace. Tar and oil are brought directly to the port and atomized with high-pressure steam or air, after preheating to about 300 F in order to increase their fluidity. Natural gas and coke-oven gas are delivered directly to the port. The design of the port depends on the type of fuel used.

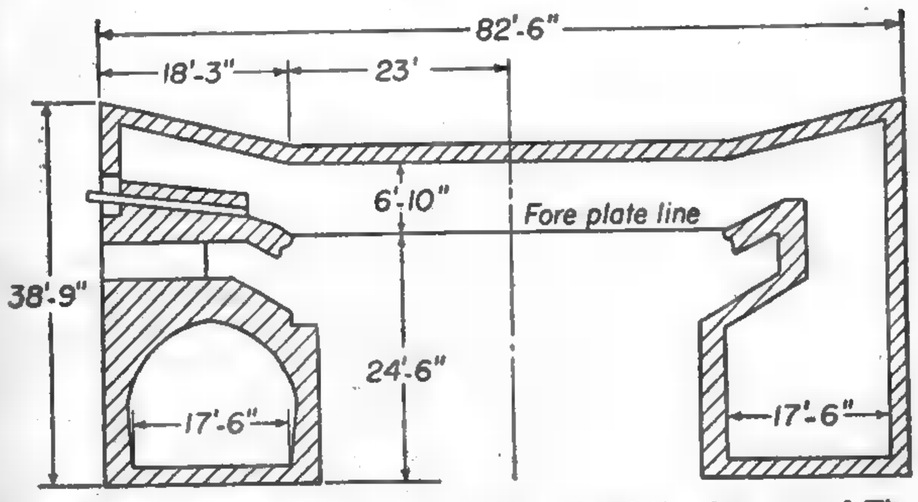

Fig. 2 Vertical section through the length of the furnace of Fig. 1. Centerline of burner at left, center of air uptake at right (Ref 1)

Oil is the fuel most commonly used today in American open hearth furnaces.

Most of the open hearth furnaces that have been built during the last few years, have capacities between 150 and 200 tons per heat.

Charging the Furnace. The scrap, cold pig iron, limestone and ore are loaded into charging boxes. A charging machine picks up the individual boxes and places the contents on the hearth of the furnace. When a charge consists of limestone and scrap, the limestone is placed on the hearth first, followed by the scrap, until the charging is completed or the furnace is full. If large amounts of light scrap are being charged, it is often necessary to fill the furnace and then melt down the scrap somewhat, before charging the rest of the scrap. It is sometimes advisable to charge a layer of scrap on the hearth of the furnace before adding the limestone, particularly if the limestone shows a great tendency to stick to the hearth. If ore is charged, it is usually added prior to or immediately after the limestone addition, depending on the condition of the bottom. When cold pig iron is used, it is ordinarily charged after the scrap. If hot metal (molten pig iron) is used—and the largest tonnage of steel is made by this method—it is brought to the furnace in a ladle and poured through a spout inserted in one of the charging doors. The hot metal is added after the scrap has melted down somewhat and after the furnace is well heated.

Since large amounts of alloy steel scrap were produced during World War II, it was necessary, in almost all steel plants, to segregate the scrap in order to recover the alloying elements. It has now become general practice to inspect and segregate incoming scrap much more carefully than before the war.

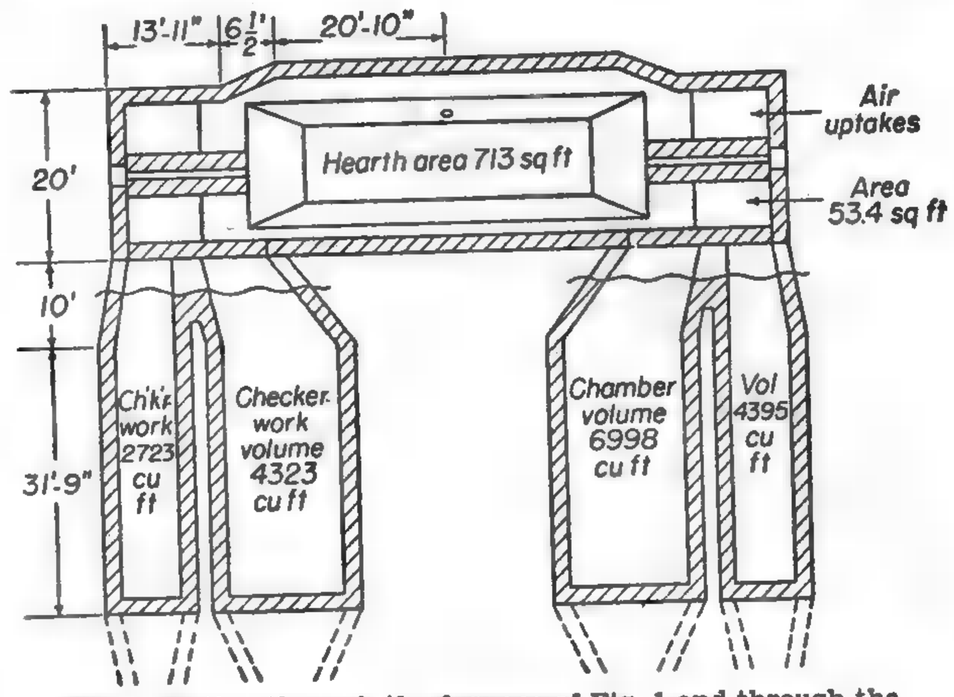

Fig. 3 Section through the furnace of Fig. 1 and through the checker chambers (Ref 1)

Melting the Charge. During the period between the charging of the scrap and the addition of hot metal, two chemical reactions take place in the bath: oxidation of the scrap while it is melting, and calcination of part of the limestone. As soon as the hot metal is added, much of the scrap and all of the limestone are submerged in liquid metal. The oxidation of the exposed scrap proceeds until sufficient scrap has melted to raise the level of the liquid metal enough to cover all solid material. During this melting period large amounts of carbon dioxide are being evolved from the calcination of the limestone by the reaction:

$$CaCO_3 = CaO + CO_2$$

A heavy boiling action results from the evolution of CO_2, and simultaneously this gas reacts with the liquid iron to form iron oxide.

$$CO_2 + Fe = FeO + CO$$

As the scrap continues to melt, pieces of limestone, which have been held on the bottom by the scrap, begin to rise through the metal bath and float in the slag. The period during which the lime rises is known as the "lime boil", and the agitation caused by the evolution of gas assists greatly in the transfer of heat from the fuel to the bath, because the hot upper layer of metal is mixed thoroughly with the colder lower layers.

Function of Slag in the Steelmaking Process. In order to remove carbon, manganese, phosphorus and silicon as oxides, and to prevent phosphorus from reverting from the slag to the metal during the later stages of refining, it is necessary to have a large percentage of lime in the slag, to form a stable calcium phosphate. The iron oxide in the slag removes a large amount of the manganese, carbon, phosphorus and silicon from the steel, by oxidation. Thus the slag acts as a regulator of oxidation and as a carrier of undesirable impurities. If the slag is weakly basic, considerable erosion of the furnace lining will take place. If the slag is too basic, it is usually very viscous and the reactions that occur will be retarded. According to the best data available at the present time, the slag is evidently calcium silicate, which changes in composition as the heat progresses, and contains dissolved CaO, $3CaO \cdot P_2O_5$, MnO, FeO and CaS. The magnesia in open hearth slags is generally assumed to be suspended as periclase (MgO), in which some iron oxide may be dissolved.

It is very desirable that the slag have a certain definite consistency during the working period, because the oxidation of the bath is controlled not only by the amount of iron oxide in the slag, but also by the rate at which iron oxide diffuses from the slag into the metal, and this rate of diffusion depends on the viscosity of the slag. If the slag is too viscous it may be thinned out by addition of fluorspar; if the slag is too thin (too fluid) it may be thickened (made more viscous) by additions of burnt lime.

The Formation of the First Slag. During the initial melting period a large amount of iron oxide is formed by the oxidation of the scrap. This oxide combines with some of the calcined limestone on the hearth of the furnace and with some of the dolomite on the banks to form a slag high in iron oxide and lime. As soon as the hot metal is added, the slag formed during melting reacts with silicon and manganese, eliminating them rapidly. This decreases the iron oxide content of the slag and increases the SiO_2 and MnO content. These slags are weakly basic and cause severe erosion of the furnace banks; if high-silicon pig is used, this corrosive action is intensified. For high-iron charges in stationary furnaces, about 5 to 10% (metallic) of iron ore is charged with the scrap and, when this ore reacts with the hot metal, a large amount of the early slag is flushed out through a suitable hole in the back of the furnace.

The composition of the slag at the time the heat is melted, has a pronounced effect on its oxidizing power during the finishing period of the heat. The reason for this is that a great deal of oxidation takes place through the action of the furnace gases on the FeO in the slag, and the higher the FeO content of the liquid slag, the greater the oxidation throughout the heat.

Working the Heat. After the heat is melted, a sample of metal is taken from the furnace and the carbon content is estimated. In this way the furnace operator judges the quantity of ore that should be added in order to lower the carbon content of the metal to a desired figure. The ore is introduced either by shovel or charging box, and a lively reaction starts at once because of the oxidation of the carbon. While the carbon is being eliminated, samples are taken to determine the carbon content. This determination is usually accomplished by means of a "carbometer" or other magnetic device instead of by methods of chemical analysis or estimation of the carbon content by fracture. While the carbon is being eliminated, the operator attempts to "shape up" the slag so that, at the finishing period, the slag is of a creamy consistency and the metal is at the proper temperature. The temperature of the bath may be judged by stirring a rod through the heat and noting the appearance of the end of the rod when it is withdrawn from the furnace; by pouring a test specimen and noting the tendency of the skull (solidified crust) formed in the spoon; and also by noting the fluidity and nature of the steel during pouring. The temperature of the bath is regulated by the amount of fuel used, and this is ordinarily under the control of the operator. If the amount of fuel is kept constant, the temperature of the bath will be influenced by: (1) the amount and viscosity of the slag; (2) the amount of agitation; and (3) the chemical reactions in the bath, which may or may not influence the agitation. All these factors are controlled to some degree by the operator and must be considered in securing the desired temperature in the bath. A great deal of work is in progress on the methods of determining bath temperature. In many shops the fuel rate is determined by measurements of roof temperature, and the fuel is automatically cut off when the roof becomes too hot.

Finishing the Heat. Unfortunately, during the process of eliminating unwanted elements from the metal by oxidation, a considerable amount of iron oxide dissolves in the steel bath. Before the steel can be poured into the molds, it must be deoxidized, partially or fully, either in the furnace, the ladle or the molds. For so-called "quality steel", as much deoxidation as possible is done in the furnace, because the elimination of nonmetallic matter resulting from deoxidation depends, to a considerable extent, on the distance the inclusions must rise before leaving the metal. Since the average depth of the steel bath is about 30 in. and the average height of a ladle about 12 ft, it is obvious that less time will be required for the elimination of nonmetallic matter if the steel is deoxidized in the furnace instead of in the ladle. On the other hand, when the steel is deoxidized in the furnace, if the heat is held in the furnace to allow nonmetallic matter to rise out of the metal, iron oxide will diffuse from the slag into the steel.

Since the area of the slag-metal interface in the furnace is much greater than in the ladle, it is evident that more iron oxide will diffuse back from the slag in the furnace than from the slag in the ladle. There is therefore a balance between the factors favoring deoxidation in the furnace and those favoring deoxidation in the ladle. However, when the viscosity and iron oxide content of the slag are regulated properly, deoxidation in the furnace is found more satisfactory than in the ladle. Some deoxidizing additions must be made in the ladle because of the oxidizing conditions in the furnace. Thus, if a heat is being deoxidized with ferromanganese and ferrosilicon, it is customary to add ferromanganese in the furnace and ferrosilicon in the ladle. The selection of deoxidizers and the manner of deoxidation are extremely important in making the best steel from a given open hearth heat. In some instances the steel is deoxidized in the mold and for many applications this practice is very satisfactory. Ordinarily aluminum is the only deoxidizer used in the molds. Ferrosilicon is used for some grades of steel, but this is the exception rather than the rule.

The time required to make a 200-ton heat of open hearth steel is about 11 hr divided as shown in Table I.

Table I

Division of Time for Making a 200-Ton Open Hearth Heat

Total Time, 11 hr

Operation	Percentage of Total Time
Start of charge to end of charging	19
Actual time spent in charging	6
Start of charge to hot metal addition	35
Final charging of scrap to hot metal addition	15
Duration of lime boil	27
Working the heat	23
Deoxidation to tap	1 to 5
Tapping	1
Finish of tap to start of repairs on banks	1
Repairs on banks and bottoms	2
Finish of tap to start of charging	4

Killed, Semikilled, and Rimmed Steels. There are three classes of plain carbon steels: killed, semikilled, and rimmed. All forging steels and, in general, all steels containing more than about 0.25% C are killed. Structural steels containing from 0.15 to 0.25% C are generally semikilled, and many steels with less than 0.15% C are rimmed.

Killed Steel. In forging steels and other high-carbon steels, the essential quality is soundness (freedom from blowholes and segregation), because this material usually goes into a product where soundness is desired. The term "killed" indicates that the steel has been deoxidized sufficiently (by proper additions of ferrosilicon, aluminum and other strong deoxidizers) for the metal to lie perfectly quiet when poured into an ingot mold. In killed steel there is no evolution of gas, and the top surface of the ingot solidifies almost immediately.

In making killed steels, the general practice is to "catch the heat coming down", that is, to bring the carbon content to the desired percentage and then to tap the heat. The heat is usually left in the furnace from 6 to 30 min after the addition of the deoxidizer, depending on the type of deoxidation employed.

Semikilled Steel. In making semikilled steels, the heat is caught coming down at the desired carbon content, and manganese is added either in the furnace or in the ladle. If silicon is used, it is added in the ladle as 50% ferrosilicon. When aluminum is used, it is sometimes added in the molds, although in most plants additions of aluminum are made both in the ladle and in the molds.

Rimmed Steel. For many applications, particularly in soft steels where the surface of the product is important, the process called rimming is preferred, in which the steel is partially deoxidized with manganese, used alone or with some other deoxidizer. When the metal begins to solidify,

a brisk evolution of gas cleanses the surface of the growing crystals. The result is a skin of very clean metal. The thickness of this skin depends on the skill of the steelmaker. When the metal has cooled to the point where solidification proceeds throughout the liquid, a great deal of gas is trapped and a porous interior results. In making rimmed steel, the steelmaker attempts to obtain the proper rimming action in the molds, because this action determines to a large extent the solidity of the surface of the ingot. The rimming action is controlled by the iron oxide content of the slag, the slag viscosity, the temperature at which the metal is poured, and the deoxidizers used.

In rimmed steel the outside surface of the ingot is quite clean and low in carbon; this gives an excellent surface to the finished product. A wide variety of steels for deep drawing, where ease of forming is the major consideration, are made by the rimming process.

The Acid Open Hearth Process

In the acid open hearth process, the lining of the furnace is made of silica sand, an acid material. Since any basic material in the slag would tend to attack the lining rapidly, the acid process is confined to materials low in sulfur and phosphorus content, because these two elements require lime for their elimination.

In an acid slag, a large part of the iron oxide is combined with silica as silicate of iron and manganese. This combined iron oxide will not diffuse into the metal, nor will it be oxidized readily by the furnace gases. Therefore, for a given amount of iron oxide in the slag, the metal will be much less oxidized in the acid open hearth furnace than in the basic open furnace, and consequently there will be fewer products of deoxidation to be removed.

One of the most important advantages of the acid process over the basic is that the composition and nature of the slag can be controlled almost at will.

A typical percentage composition of an acid slag is: FeO, 15; MnO, 21; SiO_2, 53; CaO, 4; and small amounts of Al_2O_3, Cr_2O_3, and other oxides. The amount of FeO plus MnO is automatically regulated by the fact that iron-manganese silicates will dissolve as much as 60% of the SiO_2 from the furnace banks. By regulating the amount of MnO in the slag, the FeO can be closely controlled.

The acid open hearth process is used almost entirely for the manufacture of killed steel. A very small tonnage of rimmed steel is made by this process.

The Basic Electric-Arc Process of Steel Melting

By Gilbert Soler* and James P. Gill*

THE first attempt on record to melt steel electrically dates back to 1878 when Siemens conducted his initial experiments with arc melting in a small crucible, although the discovery of the carbon arc was made by Sir Humphrey Davy in 1800. The development of electrometallurgy was rather slow during the next 20 years, because the availability of electric power was limited and the cost was comparatively high. In about 1890 Heroult developed a furnace for the production of ferro-alloys. In 1899 Heroult placed in operation the first successful commercial direct-arc furnace for melting steel. During and following Heroult's work there was great activity in developing direct-arc furnaces abroad. Among these furnaces may be mentioned the Girod, Harmet, Keller, Nathusius, Electrometal, Gronwall, Stobie and Greaves-Etchells designs.

No arc furnaces were developed in the United States until the first Heroult furnace was installed at Syracuse, N. Y. in 1906. It was a single-phase, two-electrode furnace of four-ton capacity. The first three-phase direct series arc furnace was installed at South Chicago in 1909. This 15-ton furnace was the counterpart of the modern Heroult type of electric-arc furnace used today. American designs or modifications include the Ludlum, Vom Baur, Booth-Hall, Moore, Greene, Swindell and Volta furnaces.

The Furnace. Of the many arc furnaces designed to melt steel electrically, it appears that only the system employed first by Heroult has stood the test of time. In this system, the steel in the furnace forms the common conductor for the current flowing between the electrodes, which enter the furnace through the roof. The mechanical details of this general type of furnace vary. For example, some furnaces tilt on rockers, others on trunnions; work material is charged into some through the doors, into others through the top by removing the roof. Figure 1, showing a trunnion-type of six-ton furnace, will serve to illustrate the essential parts of a typical arc furnace.

The tilting mechanism, the electrode control motor, and the switchboard control apparatus are often installed in separate rooms, a practice which affords protection from dirt and from the danger of heats burning through the bottom into the pit.

Current is supplied from a suitable source, through the bus bars *F* and electrode holders *G* to the electrodes (three in number) arranged in the form of a triangle. Electrodes may be either graphite or amorphous carbon. Arcs are sprung from the electrodes to the bath *K*, thus heating the metal both by direct conduction from the arc, and by radiation from the roof and walls. The height of the electrodes above the bath, and consequently the heat input, are controlled automatically by the winch motors *H*, which raise and lower the electrodes.

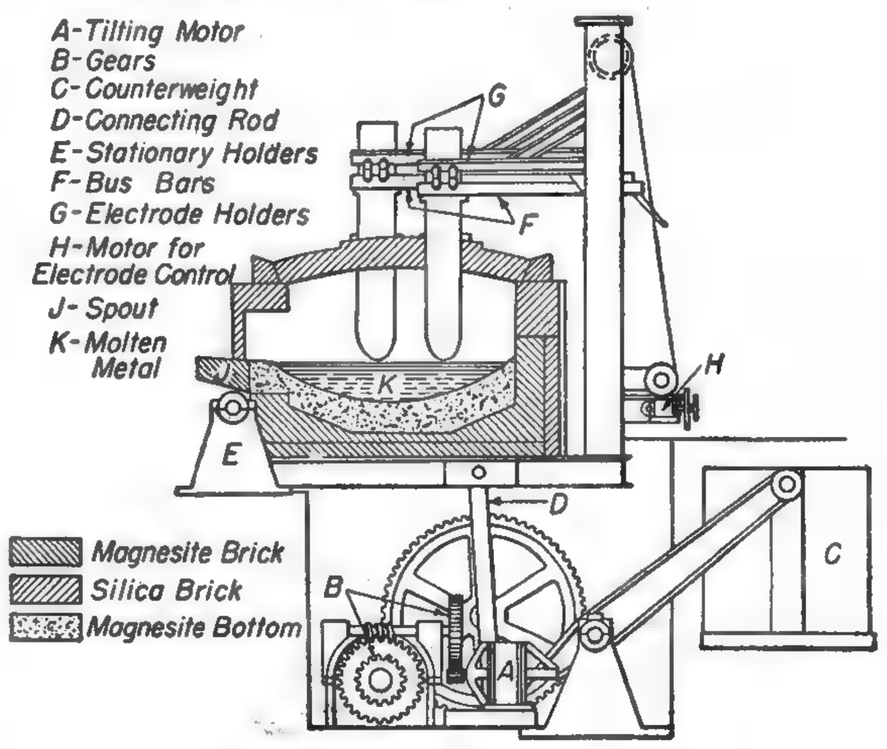

Fig. 1 Basic electric-arc melting furnace

The furnace proper consists of a cylindrical steel shell, lined with refractories as indicated in the legend. The detachable roof may be removed for top charging. The furnace is tilted about the stationary axis or trunnion *E*, placed directly under the spout *J*. The tilting mechanism consists of a motor *A*, which raises the furnace by means of the connecting rod *D*, operated through a series of gears *B*. The weight of the furnace is balanced by the counterweight *C*.

The refractories for the basic electric furnace should be carefully chosen. The hearth itself must be a basic material, such as magnesite or burned dolomite, to withstand

Prepared for the Subcommittee on Melting.

the lime slags used in the basic process. The walls and roof, on the other hand, need not be of basic material but must be capable of withstanding extremely high temperatures. Silica brick and magnesite encased in metal are used for sidewalls, and silica brick is used almost exclusively for roofs.

The hearth is either rammed in by layers, using a grain material with a suitable binder, and then burned in as a whole, or the bottom material, often mixed with a suitable flux such as open hearth slag, is shoveled into the hot furnace and burned in, layer by layer. This is done by the heat of electric arcs formed between the furnace electrodes and other electrodes placed across the hearth.

Electric furnace refractories are subjected to severe service. The arches, jambs, and door brick have an especially short life, which can be lengthened by the use of water-cooled doors and frames. Protection of refractories by water cooling is an advantage of the larger furnaces.

The tonnage capacities in which commercial units of this type of electric furnace are built, together with the transformer capacities, are as follows:

Nominal Furnace Capacity, tons	Shell Diameter, feet (approximate)	Transformer Capacity, kva
1	6 ft, 0 in.	1,000 to 1,200
3	8 ft, 0 in.	2,000 to 3,000
6	10 ft, 0 in.	3,000 to 4,000
10	12 ft, 0 in.	4,000 to 7,500
15	13 ft, 0 in.	4,000 to 7,500
25	14 ft, 6 in.	7,500 to 10,000
40	16 ft, 6 in.	10,000 to 13,500
50	18 ft, 0 in.	10,000 to 13,500
60	19 ft, 0 in.	10,000 to 15,000
70	20 ft, 0 in.	10,000 to 15,000
100	29 ft, 0 in. by 20 ft, 0 in. (elliptical)	15,000 to 20,000 (2 transformers)

All sizes except the 100-ton size have three electrodes on the one three-phase circuit, while the 100-ton furnace has 6 electrodes with the two three-phase circuits.

The tendency is toward higher voltages during the melting-down period—voltages as high as 250 for some furnaces. During the refining period, the voltages may be as low as 85 to 100. Switches are usually provided, so that two to five voltages are available and numerous variations of power input are thus possible.

Capacity and Production. In the early period of development of the electric-arc furnace in the United States, furnace sizes ranged from 1-ton to 35-ton capacity. In 1927 a 100-ton unit was installed at Canton, Ohio, followed by a 50-ton unit installed at Detroit in 1935. During the period from 1925 to 1938, continued developments were made in mechanical and electrical improvements for the electric-arc furnace. These developments were followed by extensive expansion in electric furnace capacity during the period from 1939 to 1943. Steel capacity of electric furnaces was placed at 5,455,890 tons annual capacity in 1945 as compared with 1,490,858 tons annual capacity in 1938. This increase in electric furnace capacity was comprised, to a great extent, of large arc furnaces of 50-ton to 70-ton nominal rating.

The electric-arc furnace is used both for the production of steel ingots and for the production of steel castings. The greater tonnage of steel ingots is made in the basic furnace, but the greater tonnage of steel castings is made in the acid furnace. In the United States during 1945 there were 185 electric-arc furnaces actively engaged in making steel ingots. The size distribution was as follows:

Furnace capacity, tons	1 to 5	6 to 10	11 to 50	51 to 100
Number of furnaces	37	64	64	20

In the casting industry, which employs small furnaces of 1-ton to 5-ton capacity almost exclusively, mostly of the acid type, the total number of electric-arc furnaces is estimated at 508 units.

The electric-arc furnace is used primarily for melting alloy, stainless, and tool steels. Stainless grades and tool steels are made almost exclusively by this process. In the alloy grades, the electric furnace produces bearing steels, valve steels, steels that resist corrosion and heat, ordnance steels, aircraft steels, automotive steels, and alloy constructional steels for a variety of purposes. Compared with other melting processes, the basic electric furnace process has certain inherent characteristics that can be readily translated into quality. These characteristics include: (1) almost unlimited, yet completely controlled, heat input during melting and refining; (2) furnace atmospheres and slags that are under close control, and quickly reach equilibrium with the bath; (3) almost complete sulfur elimination; (4) a degree of deoxidation that makes it possible to add alloying metals directly to the bath with little loss; (5) a relatively complete and rapid control of oxygen in slag and bath, as well as control of the amount and character of the deoxidation products in the metal.

General Description of Process. In brief, the process consists of charging into the hearth of the furnace a known weight of scrap of suitable physical and chemical character, and melting down the material as quickly as possible. When the charge is melted, the usual practice is to add a quantity of burned lime with some fluorspar or sand to act as fluxes which, together with the oxides resulting from the melting of the scrap, form a highly oxidized basic slag. This same end is sometimes accomplished by adding limestone or burned lime to the charge. Iron ore or mill scale is added as required in order to oxidize carbon, phosphorus, chromium, and manganese from the bath.

The procedure from this point depends on the practice best suited to the type of steel being made. The customary practice in alloy steelmaking is to tilt the furnace slightly and rake off the black oxidizing slag. A new reducing slag to finish the heat is made of burned lime, fluorspar and sand, with coke or crushed ferrosilicon as a reducing agent. In making tool steels or other grades in which a high recovery of alloying elements from the charged scrap is desired, the first or oxidizing slag is not removed, but is deoxidized by additions of coke or crushed ferrosilicon until it becomes "white" or reducing. At intervals during the melting process, samples of the bath are taken for quick chemical analysis, so that chemical composition is known at all stages of the process. The melter is thus enabled to make accurate adjustments in composition with carbon or ferro-alloys.

Since the electric-arc furnace is quite flexible in its operation, many variations in practice are possible. Any combination of oxidizing, reducing, or neutral slags can be utilized to attain the objectives sought. These may be applied to the so-called "cold melt process", or to the hot metal process used in the production of tonnage steels. There are wide differences among the practices employed in various electric melting plants, and it would be beyond the scope of this article to discuss all of them. Typical, however, is the so-called "cold charge two-slag process", and since this is the process most commonly used, it will be described in some detail.

Cold Charge Process. The operation of the electric furnace on cold scrap charges may be divided into two periods—the oxidation period and the deoxidation period. The former may be subdivided into four operations, namely: charging, melting, oxidizing, and slagging off. This last operation takes place in several steps—making the reducing slag, adding ferro-alloys, and recarburizing, finishing the heat, tapping and pouring.

Charging. Electric furnaces are either of the top-charge or door-charge type. In the first type, the charge is assembled in a large orange-peel bucket, lifted over the open furnace shell and lowered into place. In the latter type, either machine or hand charging is employed. Furnaces of medium and large size use charging machines; hand or chute charging is confined to small furnaces.

The bulk of the charge consists usually of selected steel scrap of such composition that when the material melts, the bath will contain a lower percentage of the various elements than is required for the final composition. This obviously allows for proper final adjustment with ferro-alloys and carbon additions. Of equal importance is the physical condition of the charge, the thermal and electrical conductivity, and the distribution in the furnace. All these factors influence the economy of furnace operation. Consequently, considerable care is taken in obtaining the proper balance between heavy and light scrap, in distrib-

uting these properly, and in distributing any other materials used, such as ore, scale and certain ferro-alloys.

Melting. The proper handling of the electrodes and regulation of power input during the melt-down are of extreme importance. If the heat has been charged properly, little difficulty is encountered. The melting down of the charge is conducted at a voltage as high as possible in order to hasten the process, thus increasing furnace economy and decreasing melting losses.

For the first few minutes after the arcs have been struck and the furnace is operating under automatic control, the electrodes "search" their way through the scrap, rising and falling, until each electrode melts a hole through the scrap. The current fluctuates widely but is steadied by the reactors. As soon as a pool of molten metal is formed beneath each electrode on the bottom of the furnace, the general movement of the electrodes is upward while the scrap in the vicinity melts and augments the pool. When the charge is partially melted, a single pool of appreciable size is formed, and the furnace man starts pushing the unmelted scrap toward the center of the furnace, cleaning off the banks, and gradually working all loose scrap into the bath. As soon as this is accomplished, a test can be taken for early carbon, and ore or slagmaking additions can be made.

Oxidizing. The oxidation period actually starts with the melting of the charge and ends only when the heat is slagged off. The electric furnace is a flexible unit allowing the melter considerable leeway in handling lime, fluxes, and oxidizers. These additions can be made to the charge, to the heat when partially melted, to the bath when melting is complete, or at any time before the oxidizing slag is removed. In the oxidizing period, the hot metal is refined by oxygen introduced in solid form as iron ore, roll scale, or rust on scrap. By oxidation, silicon can be removed almost entirely; and the other easily oxidizable elements—carbon, phosphorous, manganese, and chromium—are removed either wholly or in part, according to the conditions present, and the preference of the operator. Also during the oxidizing period the bath is cleansed of hydrogen and solid nonmetallic matter by means of the "boil", which results from the reaction: $2C + O_2 = 2\,CO$.

Limestone or burned lime is added for slagmaking purposes during the oxidizing period. The amount of limestone or burned lime added, regardless of whether the addition is made with the charge or after the heat is melted, depends on the nature of the scrap and its silicon content, the amount of phosphorus removal required, the amount of silica introduced with the iron ore, and the slag basicity desired. The slag must be sufficiently basic to prevent bottom erosion, which would result from a slag that was too acid, and must provide a suitable covering to protect the molten metal from the arc. Greater basicity may be required for phosphorus removal or partial elimination of sulfur during the oxidizing period. The control of manganese and chromium is related to basicity; greater elimination is obtained under semibasic slags and greater recovery is obtained under basic slags.

The first slag is formed during the melt-down from the addition of lime or limestone and oxidizers to the charge, or to the partially molten bath. The lime (CaO) combines with the oxides formed during melting, from the reaction of the oxidizing agents with silicon, phosphorus, manganese, and chromium to form a slag on top of the molten metal bath. After the scrap is all melted clear of the bottom and the heat is completely molten, refining can proceed. A preliminary sample is taken and an analysis is quickly made by the laboratory. On the basis of the preliminary test, additional iron ore may be added for further oxidation of carbon and phosphorus as required. Sufficient lime must be added to produce a satisfactory basic slag. Fluorspar may be added from time to time to thin the slag, or burned lime may be added to thicken the slag. When the oxidizable elements—carbon, phosphorus, manganese, and chromium—are low enough for the final specification to be met when the alloying additions are made during the reducing period, the heat is ready for slagging off. Another chemical analysis is usually made before slagging off. If temperature is under control and the melter is sure of the composition, slagging is started.

Slagging Off. In slagging off, the furnace is tilted backward very slightly. Then the furnace man introduces a rabble or skimmer into the furnace door and, by a raking motion, scrapes or pulls the slag off the metal and out the door into the pit. In this way the black or oxidizing slag is completely removed from the metal.

Making the Reducing Slag. After removal of the oxidizing slag, a new slag is made up by additions of burned lime, fluorspar, and silica sand, with sufficient crushed coke or fine ferrosilicon to make it reducing. This reducing or finishing slag has several functions. It serves as an insulating blanket over the molten steel, protecting the hot metal from oxidation. It also protects the bath from the direct heat of the arc and avoids excessive pickup of carbon from the electrodes. The reducing slag also acts as a medium by which any excess oxygen in the bath is reduced to the equilibrium value, as regulated by the carbon or silicon content of the steel. A major function of the reducing slag is to remove sulfur from the steel, and to reduce the content of this impurity to a low value. The removal of sulfur to low values is unique with the basic electric process. In no other steelmaking process can sulfur be removed so easily.

Two varieties of finishing or reducing slags are common in electric furnace practice. The carbide slag employs powdered coke or crushed electrode as a reducing agent, while in the white silicon-type slag the medium for slag deoxidation is fine ferrosilicon (50 to 75% grade) or calcium-silicon. Both types are made up with lime as a base and fluorspar as a flux. Some silicon may be used as a flux in either type of slag. When white silicon-type slags are used, the silica content builds up as a result of oxidation of the silicon employed as a slag deoxidizer. The carbide slag is normally used for steels over 0.10% C, and the white silicon-type slag for steels of 0.10% C or lower. Other types of finishing slags are used for special purposes; for instance, the cement clinker slags for finishing stainless steels. During the finishing period of the heat, which will vary from 1½ to 2½ hr, alloying elements and recarburizers are added.

Additions of Ferro-Alloys and Recarburizers. On the basis of the chemical test taken before slagging off, the bulk of the ferro-alloys and recarburizers may be added to the bare bath immediately after slagging off and before the reducing slag is made up. This practice allows ample time for the ferro-alloys to melt and dissolve in the steel. Elements that may be added at this time are chromium, manganese, nickel and molybdenum. However, certain elements cannot be added until late in the heat. Vanadium, silicon, aluminum, titanium, and columbium, all readily oxidizable elements, are added late in the heat, usually 20 to 30 min before tapping. In the making of stainless steels, the large amount of ferrochromium required would chill the bath excessively, if added all at once. For this reason, ferrochromium is preheated and added in several batches when stainless grades are being made. The nonoxidizable elements—nickel, molybdenum and copper—may be added with the charge. Alloy scrap containing these elements can be charged, and such practice has considerable economic justification.

At slag-off the carbon content of the bath should be 4 to 10 points (0.04 to 0.10%) below the desired aim, depending on the probable increase to be expected from later ferro-alloy additions and pickup from the reducing slag and electrodes. In some baths, the carbon will be considerably lower and recarburization will be required. It is possible to recarburize after slag-off, since the bare metal quickly absorbs any carbonaceous material added to it. For this purpose, either coke, anthracite coal, or broken pieces of electrodes can be used. Recarburization can be accomplished by dipping the furnace electrodes into the bath, but this is an expensive and hazardous procedure. For adjustment of carbon late in the heat when only a few points are required, the addition of wash metal, low-phosphorus pig iron, or carbon briquettes is satisfactory.

Finishing the Heat. After the additions have been made at slag-off, and the finishing slag has been deoxidized and is strongly reducing, the slag must be maintained in this condition until the heat is tapped. Final preliminary tests are then taken, alloying elements are added to ad-

just the composition of the steel, and the temperature is adjusted according to the grade of steel being made. Deoxidizers are then added to finish the heat, including any that may be required for grain-size control.

At least one, and sometimes two samples are taken during the deoxidation period to determine the progress of the heat and to provide an accurate analysis of the bath, so that the melter can make proper final additions. Knowing the composition of the metal before slagging off, the melter makes his additions after slag-off accordingly, builds up the deoxidizing slag, and then takes out the final samples. The time from slag-off to the final preliminary test will be from 45 min to 1 hr. It is essential that the slag be completely deoxidized to insure that the bath will remain constant in composition throughout the rest of this period (except for the carbon, which increases slightly). The results of the final preliminary test are reported and the alloy additions necessary to meet the final specification are added to the bath. The additions of easily oxidizable alloying elements and of deoxidizers are also made late in the heat, or in some steels may be used as ladle additions.

Possibly some deoxidation of the metal bath is accomplished by the reducing slag; however, for complete deoxidation, silicon, aluminum or both must be added to the metal. Preliminary deoxidation may start as early as slag-off, but final deoxidizing additions cannot be made earlier than 20 to 40 min before tapping. Deoxidation consists in converting those oxides that are soluble in the steel (FeO and CO) into insoluble ones (such as SiO_2 and Al_2O_3), and in their separation from the metal by gravity. These insoluble oxides may be highly infusible, or certain combinations of insoluble oxides may readily flux one another to form fusible slags. For this reason the order and timing of deoxidizing additions is extremely important. In addition to aluminum and silicon, other deoxidizers, such as calcium silicide and aluminum-silicon alloys, may be used for final deoxidation. For grain-size control, definite amounts of aluminum must be added carefully late in the heat.

During the finishing period, temperature must be carefully controlled by regulating the power input from slag-off until the furnace is tapped. Temperature may be judged visually by the color and brightness of the molten metal when it is poured from a well-slagged spoon and viewed through dark glasses. Other indications of temperature level are shown when a spoonful of metal is poured slowly onto the floor. Various means of determining temperature include the set test, sighting the optical pyrometer on a spoonful of molten metal, the recently developed immersion-type platinum thermocouple and the immersion-tube photocell method.

Tapping and Pouring. The heat of steel, now of proper composition and temperature and properly deoxidized or "killed", is ready to tap into the ladle. This operation, as well as the final pouring, is performed with the greatest care. The ladle (of the bottom-pour type) has been properly dried and is now brought up to the furnace and placed under the spout. The furnace is slowly tilted into the tapping position, and the metal is allowed to flow in a steady stream into the ladle. The exact practice employed in tapping varies in different plants. Some operators tap through a runner-brick walled into the spout, thus holding back the slag until the tap is finished; others prefer to tap slag and metal together. During tapping, temperatures are often taken with the optical pyrometer for record, and for the guidance of the melter.

In pouring the ingots, the ladle is usually suspended directly from the ladle crane, which travels over the line of molds. The molds may be placed on ingot buggies adjacent to a pouring platform or may be placed in a pouring trench below ground level. The principal precautions in pouring are to regulate the pouring rate properly and the character of the stream, so as to pour with a minimum of splashing in the molds, thus insuring a good ingot surface. Soundness of ingots and freedom from shrinkage cavities are insured by proper mold design of the big-end-up type and by application of the so-called "hot top". The latter consists of a refractory form placed on top of the mold or partially inserted into it, and acts as a reservoir of molten metal, from which the ingot is continuously fed until completely solidified.

Variations in Practice. The flexibility of the electric furnace provides for many possible variations in practice. The most common variation in cold charge processes is the single-slag practice. Hot metal processes have been developed in an effort to lower the cost of intermediate grades of electric-furnace steel or to increase unit production during periods of peak demand for electric-furnace steel.

Single-Slag Practices. Single-slag practices are employed for two distinctly different methods of electric steelmaking. In the first method, conditions similar to those of open hearth practice are maintained. The heats are made as rapidly as possible under an oxidizing or black slag. By this method, rimmed, semikilled, and fully killed steel of a quality comparable with open hearth steel can be produced in the electric furnace.

The second method involves a practice of melting down and turning the slag with crushed silicon, coke, or exothermic silicon compounds, in sufficient quantity to form a reducing slag. This method is used generally for the maximum recovery of oxidizable elements—such as chromium, vanadium, and tungsten—that may be contained in the scrap charge. The practice is widely used in the making of high speed tool steels and other high-alloy grades.

Modified Two-Slag Process. Heats of stainless steel, in which considerable stainless scrap may be charged, are made by a modified two-slag practice. Stainless steels are usually made to ■ low-carbon specification; consequently, under the highly oxidizing conditions necessary during melting, large amounts of chromium are oxidized to the slag. In order to return this chromium from the slag to the bath, a considerable quantity of silicon or of silicon-containing alloys must be used as a slag deoxidizer. Coke cannot be used because the bath would pick up carbon. Thus, the slag is made quite acid and the slag volume is large. If sufficient lime is added to make the slag basic so that a satisfactory reducing slag can be obtained, slag volumes will be excessive. For this reason it is simpler to remove the first slag, after the chromium has been reduced from the slag to the steel, and to finish the heat under a second reducing slag. Finishing slags may be either of the white silicon type, cement clinker type, or various lime-alumina combinations that will avoid carbon pickup and gasiness.

Variations in oxidizing practice may be utilized in making alloy steels of the various carbon grades. The heat can be melted under conditions of complete or partial oxidation. A complete or partial slag-off of the oxidizing slag early in the heat, followed by a second oxidizing slag and a final reducing slag, is not an uncommon practice when excessive phosphorus, chromium or manganese must be removed from the metal.

In some practices, two finishing slags are employed in making the electric-furnace heat. The first is the conventional reducing slag which removes oxygen and sulfur from the metal; the second finishing slag is used merely as a cover to protect the surface of the bath from oxidation while adding a high-melting-point oxidizable alloy late in the finishing period of the heat. A typical practice employing such a protective slag is that used in making stainless steels with additions of titanium or columbium.

Hot Metal Processes. Interest in hot metal processes, in which the raw materials for electric-furnace steel are delivered to the electric furnace in premelted form, was heightened by the tremendous need for electric-furnace capacity during World War II. Various hot metal processes have been considered and tried on a large scale. If iron ore is used as the basic raw material, then the suitable premelting unit is the blast furnace; if steel scrap is used as a raw material, then the cupola or open hearth furnace is chosen as a premelting unit. In either the blast furnace or the cupola, it is desirable to refine the premelted metallics further before finishing in the electric furnace. This refining is done in the Bessemer converter, in the open hearth furnace, even in the electric furnace, or in various combinations of these steelmaking units. The open hearth combines the melting and refining functions if it is used as a premelting unit. The various combinations that have been used are listed here:

1 Blast furnace—open hearth—electric furnace process.
2 Blast furnace—Bessemer—electric furnace process.
3 Blast furnace—Bessemer—open hearth—electric furnace (triplex) process.
4 Cupola—Bessemer—electric furnace process.
5 Cupola—electric furnace process.
6 Open hearth—electric furnace process.

Various slag combinations are used in the electric furnace in conjunction with hot metal practice, depending on the degree of refining required. In the most simple practice, the hot metal is transferred to the electric furnace and finished under a reducing slag. Usually, however, an oxidizing slag is made up so the metal can be brought to the proper temperature, the oxidizing slag removed, and the heat finished under a reducing slag. If considerable refining must be done in the electric furnace, then the time under the oxidizing slag must be increased proportionately. For instance, in the cupola–electric furnace process, the electric-furnace bottom is first bedded down with hematite ore before the hot cupola metal is added. Considerable boiling is required to oxidize the silicon and carbon from the hot metal, and large additions of burned lime are required to keep the slag basic.

In practice, two main problems are encountered in hot metal processes: (1) to co-ordinate all units by size, rate of production, and tapping time so that down-time and delays are held to a minimum; (2) to avoid excessive yield and transfer losses, by proper selection of melting and refining processes. Proper co-ordination cannot be obtained in a small shop, so by necessity a hot metal electric-furnace process requires a large, fully integrated shop, especially planned and engineered for this purpose. Furthermore the type of product must be of such a nature that finishing times in the electric furnace are nearly equal and can be predicted well in advance of the tapping of other units.

Tool Steel Practice. The practices used in the melting of tool steels are quite varied, depending on the grade; in general, however, they are covered in the preceding sections. The melting of high-quality carbon and low-alloy tool steels, in which the recovery of alloying elements is a minor consideration, is usually conducted by the normal two-slag practice. For high-alloy steels in which large amounts of tungsten, vanadium, and chromium (oxidizable elements) must be recovered from the scrap to make operation economical, single-slag practice is employed. This single-slag practice, though capable of removing some impurities from the charge, places a heavy responsibility on the selection of high-grade scrap; since phosphorus may be readily reverted to the metal from the oxidized slag, along with chromium, tungsten and vanadium, when the slag is made reducing with silicon, coke or exothermic silicon compounds. This practice is employed widely in the making of tungsten tool steels, in which the tungsten exceeds 3 to 4%; such steels include the tungsten hot work steels and high speed steels. Methods of refining, deoxidation, temperature control and pouring practice do not differ greatly from those described previously, with the possible exception that deoxidizers used in the tool steel industry may include those elements, such as titanium, zirconium, and calcium, which have an especially strong affinity for oxygen. These are used in conjunction with preliminary silicon deoxidation and may or may not be accompanied by aluminum.

The Acid Electric-Arc Process of Steel Melting

By John W. Juppenlatz*

IN the acid electric practice, the term "acid" refers to the silica-base refractory lining used to withstand the silica-base slags common to the process.

In the United States the acid electric furnace is now one of the major sources of molten steel for castings. Over two million tons of acid electric steel was poured into steel castings during 1943. An abundant supply of low-phosphorus, low-sulfur steel scrap for remelting has contributed largely to the popularity of the acid electric process. In addition, the process is particularly suited to the production of high-grade carbon and alloy steel castings. Some of the reasons why steel foundrymen prefer this process may be briefly stated as follows:

1 Rapid production of carbon and alloy steels for castings.
2 Favorable power and refractory costs when compared with other processes.
3 Very high temperatures obtainable for fluidity.
4 A viscous slag that is readily controlled when the metal is poured from top-pour ladles.

The methods for producing acid electric steel have not become standardized, so it is impossible in this review to cover the minor variations of practice. Only the major principles and practices will be outlined.

General Melting Procedure. The procedure for making a heat of steel consists briefly of placing on the bottom of the furnace a known weight of steel scrap of suitable composition, referred to as the "charge". Power is introduced through the electrodes. An electric arc is produced between electrode and charge, and melting begins. The metal is usually melted as rapidly as possible, while a molten pool forms and grows on the bottom of the furnace. The "melting-down period" is accompanied by oxidation of the bath, resulting in partial elimination of carbon, manganese and silicon. As the molten pool of metal forms, the products of oxidation combine into a complex silica-base slag. Since it is lighter than the steel, this slag rises and covers the metal bath. Oxidation may be increased by the addition of iron ore or mill scale. As the temperature increases under oxidizing conditions, a boiling action starts. This indicates the removal of carbon from the bath by oxidation with the evolution of carbon monoxide gas. As the temperature increases toward the end of the oxidizing period, the boiling action will slow down because the oxidizing power of the bath and slag has been substantially decreased. The input of power to the furnace is usually reduced at this time, since the metal is quite hot, and the "refining and deoxidation" period begins. Preliminary tests are conducted to ascertain conditions of bath and slag, and the composition is adjusted by additions in order to meet requirements. Temperature tests are taken and the heat is ready to be deoxidized with the final addition of ferro-alloys, such as ferromanganese and ferrosilicon. Steel for casting purposes must be thoroughly deoxidized or "killed", so that gas pockets do not form during solidification. When a thoroughly killed heat of steel is assured, with the proper temperature and composition, the molten bath is then tapped by tilting the entire furnace and pouring the metal into suitable ladles. A further deoxidizing treatment consists of adding about 2 lb Al per ton of steel, in the ladle. While tapping, it is desirable to trap the slag in the furnace until most of the metal has drained into the ladle. The slag then drains from the furnace and covers the metal protectively.

Now that the practice has been briefly outlined, the various phases will be discussed in greater detail.

Furnace. Modern acid electric furnaces are of strong construction with mechanical features for charging. The steel shell is usually circular and lined with silica brick or siliceous material of "acid" type with a saucer-shaped bottom and removable silica brick roof. (See Fig. 1 for diagrammatic sketch.) In the roof three openings are provided for the electrodes. Heavily powered for rapid melting, the electrodes produce an arc when contact is made with the scrap charge. Many furnaces are provided

* Chief Metallurgist, Lebanon Steel Foundry, Lebanon, Pa.

Prepared for the Subcommittee on Melting.

with mechanized removable roofs that permit mechanical charging.

Water cooling is often desirable for refractories and furnace parts subject to severe temperatures and operations. Figure 1 shows water coolers around every electrode, the roof ring, the door arch and the door. These features vary with the design and the rated capacity of the furnace.

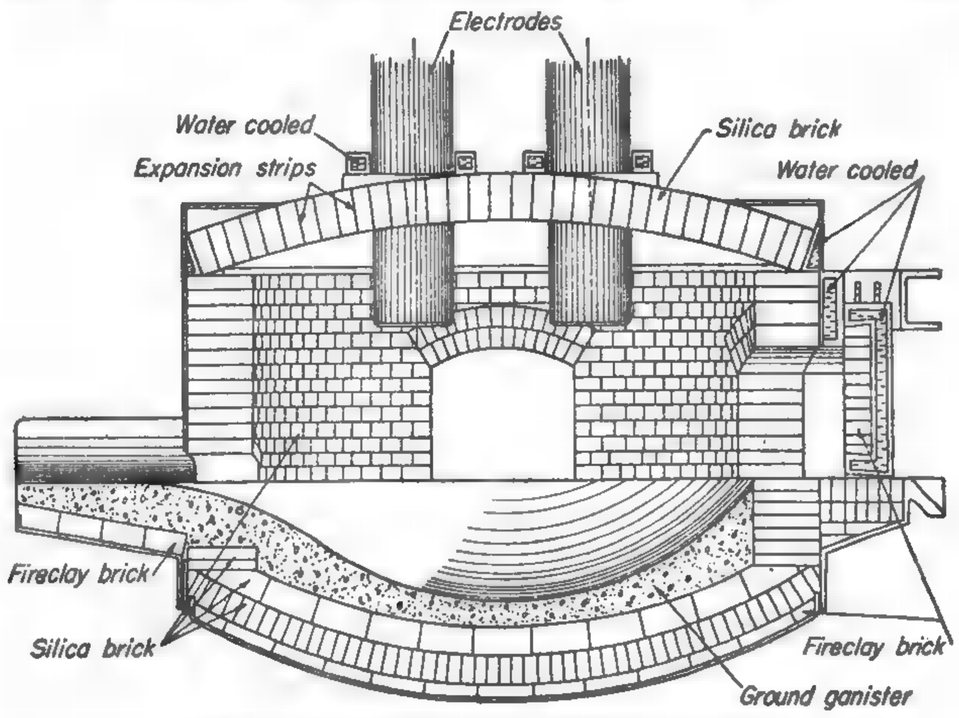

Fig. 1 Acid electric-arc melting furnace

Furnace capacities vary from about 500 lb to 30,000 lb of charged weight. The majority of furnaces are capable of melting from 3 to 5 tons of charged material. The time of making a heat will vary according to the input of power and the grade of metal being produced. The average time for a 4-ton heat of carbon steel is usually less than 2 hr, increasing with increase in furnace capacity. Because of variation in the size of furnace, power input, plant facilities and plant requirements, furnace operation is not uniform and must be compensated for accordingly.

Lining. Silica bricks, which are "acid" refractories, are commonly used for construction of sidewall and roof with very satisfactory results and low cost for continuous operation. Intermittent operating schedules often cause considerable deterioration of the lining—chiefly spalling as a result of the heating and cooling cycles. To compensate for thermal expansion and contraction with physical changes of the silica refractories, ample allowance for expansion—about ¼ in. per ft—is commonly needed when silica bricks are laid in roofs and side walls. Rammed siliceous linings and even rammed roofs on small units are used with good results. Mullite, sillimanite and other "super-refractories" may be used around electrode openings in the roof and in other locations where spalling conditions are unduly severe.

A new bottom is usually made from a ganister or silica sand mixture that is firmly rammed on a base lining of silica brick, as shown by Fig. 1. These materials of the proper grain size are mixed with small amounts of refractory clay, possibly some organic binder, and sufficient water so that the green and dry strengths are adequate for retaining the proper shape of the bottom and for bearing the burden of the charge. To aid in the preservation of a newly prepared bottom before surface sintering has been effected, steel plates are often placed over the bottom so that the impact of the charge will not impair its rammed form.

It is always good practice to dry free moisture from the lining before attempting to produce a heat of steel. The top surface of the rammed bottom is sintered by the heat from the electrodes as the scrap is melted. Acid slag from a previous heat is usually added to form a slag that has better chemical balance for aiding in the sintering operation. This method of making a new bottom is being successfully practiced but must be performed with skill and care.

Completely sintered bottoms are made by building up successive layers on the base made of silica brick. Heat is obtained from the electrodes which arc on triangularly placed pieces of other electrodes on the bottom. Thin layers of ganister or a fine grade of silica sand are placed on the bottom bricks and sintered by heat radiated from the arc. This operation is repeated until the bottom and side walls above the slag line are properly shaped and uniformly sintered.

Lining and bottom repairs are often required between heats, particularly around the slag line. Such repairs are made by placing ganister or silica sand in a slightly moistened condition, in proper position to maintain the desired shape of the banks. Often some admixtures are added to the patching material to promote a low-temperature frit so as to prevent sliding of the patch.

The taphole shown in Fig. 1 is quite large. Some operators prefer a smaller hole, which aids in the retention of slag in the furnace while the metal is being tapped. This is accomplished by lining the taphole with silica brick or tile to the desired size. However, the hole should be large enough to permit full drainage of both metal and slag.

Electrical Equipment. The power per square foot of bath area and per ton of capacity of the acid furnace is usually somewhat higher than that of the basic furnace of equal capacity. The kilovolt-ampere capacity per square foot of bath area is often as high as 100, which contributes toward the speed of melting considered essential in the industry.

Many of the more modern installations are powered with overcapacity air-cooled or water-cooled transformers. Tap changes provide the operator a choice of several voltages, varying from about 90 to 250. Current conductors, bus bars, and other electrical fixtures are also extra heavy, to avoid the necessity for water-cooling these parts. Designers have given considerable attention to the transformer and electrical parts, in an effort to minimize resistance, reactance and hysteresis losses.

Electrodes may be either graphite or amorphous carbon. For the smaller furnaces, graphite seems to be preferred because of its increased strength and the smaller electrode opening required in the roof. Electrode controls, drives and the features of mechanical alignment should be properly constructed and maintained for maximum efficiency. The smooth operation of the furnace depends on sensitive, quick-acting regulators for positioning and maintaining the correct arc length. Electrode clamps should provide a positive electrical contact. The joints of electrode assemblies should be close-fitting and snug for best operation.

When the proper electrical and mechanical equipment is used, coupled with good operation, maximum efficiency and speed may be expected. Energy consumptions of 500 kwhr per ton are not uncommon with continuous operation and high tapping temperatures. Electrical capacities capable of overload are desirable, as mentioned; however, there are optimum values of current (arc) input. Excessive input of power can actually result in slower melting, with increased maintenance costs of electrode clamps, bus bars, and refractories. These conditions are controllable by the operator.

Charging. Phosphorus and sulfur contents are not reduced by the acid process. Therefore it is necessary to select scrap with these elements below the maximum specified for the final composition. Copper, nickel and molybdenum as constituents of the charge are recovered.

The scrap for the charge should be free from excessive rust or oil. Fine scrap and turnings, if not long and curly, are desirable for a small percentage of the charge. Larger and more bulky scrap—foundry scrap, plate, forgings, and the like—usually constitutes the remainder of the charge. Unwieldy, protruding shapes that cause bridging are not desirable and should be avoided. If compact scrap is available, the entire charge can be made at one time; if not, it will be necessary to charge additional scrap during the melting of the heat.

Most modern furnaces are mechanically charged by removing the roof and placing the charge on the bottom with a drop-bottom bucket. By this method of charging from the top, the entire charge is quickly put in with a minimum of labor.

Scrap should be placed in the charging bucket or furnace in such a way that melting can proceed without interruption. Heavy scrap that would cause delays or breaking of electrodes, should therefore be placed on the bottom with lighter scrap on the top.

Consideration should be given to the carbon and manganese contents of the over-all charge. Some scrap may be deficient in these elements for normal slag requirements and for the carbon boil. It is also true that reverse conditions result in an excessive volume of slag or a prolonged period of boiling. Proper balance of these elements aids greatly in the efficient processing of a heat.

Melting and Oxidation. When the charge has been placed properly on the bottom of the furnace, the electrodes are mechanically lowered until more than one electrode has made contact to produce an electric arc, and melting begins. Melting is usually started with an intermediate voltage (about 175) until the electrodes have worked into the scrap. Melting is then continued at higher voltages (about 235), producing long flaring arcs that cause melting over a greater area, thereby forming a larger pool of molten metal beneath the electrodes. The electrodes arc on this molten pool and the melting process continues from the bottom upward. When the bulk of the charge has melted, a lower voltage (about 140) is employed with a shorter arc that does not excessively attack the refractory lining. When molten metal is formed, a complex metal oxide slag, lighter than steel, rises and covers the bath. Oxidizing, slag-forming materials, such as iron ore and lime, are often intentionally added to promote reactions, so that the slag and its volume become significant factors in the process.

In the absence of a uniform or standardized melting procedure, oxidation may be partial or complete. Partial oxidation requires the addition of limited quantities of oxdizing materials, such as iron ore or mill scale. This practice results in rapid production with low refractory, power and electrode consumption. Partial oxidation has the disadvantage of producing a somewhat inferior metal that often has lower ductility, lower fluidity and a higher gas content.

The complete oxidation method, more widely employed, requires the judicious use of ample quantities of iron ore or mill scale. The final product from this practice has the advantage of good fluidity, good mechanical properties and low gas content. The time required for making such a heat is somewhat greater, and refractory and other production costs are higher. The iron oxide content of the bath will be high and the slag will be fluid and very black in color. Composition of a typical oxidizing slag would be 42% SiO_2, 40% FeO, 12%MnO and 6% CaO. If lime is not used, the iron and manganese oxides will be proportionately higher. Limestone is occasionally used for the purpose of fluxing and increasing the total basic oxides of the slag. A large portion of the silica of the slag is obtained from the silica lining as a result of the fluxing action of the basic or oxidizing materials.

According to best practice, oxidation of the melt is highly desirable for quality steels. This process is based on the following fundamental reactions:

$$Mn + FeO \rightarrow MnO + Fe \quad (1)$$
$$Si + 2FeO \rightarrow SiO_2 + 2Fe \quad (2)$$

With sufficient ore present to produce free FeO in the bath and the slag, reactions (1) and (2) proceed after melting, and are independent of heat input, since the reactions are exothermic. This oxidation should continue until the silicon is well below 0.10% and manganese below 0.15%. As the temperature of the bath increases and free FeO is available, the carbon boil will start.

$$C + FeO \rightarrow CO + Fe \quad (3)$$

Since the carbon boil, reaction (3), is endothermic, considerable heat input is required for an active boil and the reduction of the carbon content of the bath to the desired level. With continued heat input, this carbon boil will continue until the FeO content is reduced to a point where little or no available FeO in bath or slag is free for reaction.

Some operators prefer to add the amount of iron ore required for oxidation and permit the carbon boil to continue until it slows down as the bath becomes deficient in oxidizing power. This practice may result in the carbon content of the bath dropping to lower levels than desired, so that recarburization becomes necessary. Some operators prefer to check or stop the carbon boil by adding ferrosilicon or other deoxidizers when the carbon content of the bath has reached the desired level.

Refining and Deoxidation. When the carbon boil subsides or is checked, the refining period begins, the purposes of which are composition adjustment and the "shaping up" for final deoxidation. At this time the temperature of the metal is usually above 3000 F, and the power input is reduced. Preliminary tests are made in order to determine the composition of the bath and the amount of oxidizing power remaining, which is often indicated by the slag. Before final deoxidation, the slag will have a lower iron oxide content, approximately 18%, with a silica content above 50%, and will be fairly viscous and green in color. Recarburization of the bath is ordinarily required, and is effected by using low-silicon pig iron, by dipping the electrodes, or by adding carbonaceous materials. Pig iron is preferred, reducing any excessive oxidation, according to reaction (3), and thus permitting the bath and slag to approach equilibrium. Adjustments of the slag are often necessary also, and additions to the slag for this purpose vary considerably, depending on the degree of deoxidation; such additions consist of silica sand, limestone, powdered ferrosilicon or ferromanganese, coke and the like. When the bath and slag have been adjusted and the desired temperature has been reached, ferro-alloy additions, such as chromium and vanadium, are made prior to the final deoxidation, which will be discussed later.

When the iron oxide content of the bath and slag has been drastically reduced as a result of high temperatures and heavy power input, silicon and manganese can be reduced from the slag by the following reactions:

$$SiO_2 + 2C \rightarrow Si + 2CO \quad (4)$$
$$MnO + C \rightarrow Mn + CO \quad (5)$$
$$2Mn + SiO_2 \rightarrow Si + 2MnO \quad (6)$$

Reactions (4), (5) and (6) take place easily in the acid electric furnace because of the high temperatures commonly obtained. When bath temperatures exceed 3000 F, these reducing reactions are more difficult to prevent as time goes on, since the free oxygen content of both the bath and the slag decreases continuously at high temperatures. These reactions can be retarded by the judicious use of basic materials, such as ore and lime, but as the temperature increases, the reactions continue in rapid cycle.

The normal deoxidation procedure at the end of the refining period is usually accomplished by adding ferrosilicon and ferromanganese, or other deoxidizers, to the furnace. When steel is to be made into castings thorough deoxidation is essential, since the metal must solidify without the formation of gas inclusions. For this reason it is common practice to make "solidity" tests at the furnace to determine whether the metal has been properly "killed".

Temperature tests are then made, and with the previous adjustments assuring the proper composition and adequate deoxidation, the heat is ready to be tapped. Further and final deoxidation in the ladle is commonly conducted with additions of aluminum ranging from 2 to 3 lb per ton. Other deoxidizers, such as calcium and titanium alloys, may also be used. Final deoxidation in the ladle should always be performed with care to avoid reaction with the slag rather than with the metal. For this reason tap holes are usually constructed to permit the steel to enter the ladle before the slag when the furnace is quickly tilted. The metal is then ready to be cast into molds.

Slag Control. The control of slag during the various stages of the heat is effective in assuring consistent results.[1] Fluidity of the slag appears to be the most practical measure of the degree of oxidation during all stages of the process.[2] A modified Herty viscosimeter for the quantitative measure of fluidity has been successfully applied to many production furnaces.[3] A very fluid slag, common at the melt-down period and before the boil, may show a viscosity of 11 in. with a silica content of about 40% and an iron oxide content of about 41%. This may be considered an active oxidizing slag.

As the carbon boil continues, the fluidity decreases and

the acidity of the slag increases. A viscosimeter reading of about 4½ in. indicates a slag containing about 50% each of acids and bases. There is very little oxidizing or reducing power in such a slag from an operational viewpoint.

As the temperature increases and the metal is ready for final deoxidizing additions, the fluidity is further reduced. Slag viscosity readings of about 2 in. indicate a silica content of about 56%; the remainder is the basic constituents FeO, MnO and CaO.

Recovery of Alloying Elements. The recovery of alloying elements usually increases with increasing carbon content. A variable recovery is anticipated on account of the different degrees of initial oxidation and deoxidation normally occurring under actual operating conditions. With a complete oxidation process and a charge of 50% alloy-bearing scrap of the same type, average values for the recovery of manganese, silicon, and chromium at different carbon levels may be expected as shown below.

Carbon Content	% Recovery of Final Alloying Additions				
	Manganese		Silicon	Chromium	
	0.60%	1.35%	0.40%	0.50%	1.50%
0.15	72	65	87	90	88
0.30	75	70	98	92	90
0.45	80	74	110	93	92

Temperature Control. Many methods are used to indicate temperature and fluidity. Immersion pyrometers may be used but they are too costly for general control work. Optical pyrometers are reasonably satisfactory for control purposes when sighted on molten metal without interference of oxide film or smoke.

The spoon or set test is commonly used for estimating the temperature at the furnace. Test spoons are immersed in the molten bath and a representative sample is withdrawn. After the slag has been removed the sample is poured into a mold of standard size. A record is kept of the time in seconds required for the oxide film to cover the test sample completely and this information, correlated with other temperature readings, indicates the temperature. The immersion of low-carbon steel rods in the bath for a given period of time is also used to indicate temperature. As the metal temperature increases, an increasing amount of steel rod dissolves.

Fluidity is probably the best method of indicating temperature and is significantly important to the foundryman. This test requires that about 8 lb of metal be withdrawn from the furnace and cast into a standard mold for the fluidity test. The mold, developed at the Bureau of Standards, is of the spiral type and indicates the casting fluidity in inches. Further details of testing the fluidity of metals are covered in the article on page 199 of this Handbook.

The Induction Furnace Process of Steel Melting

By R. N. Blakeslee* and G. V. Luerssen*

THE coreless induction furnace, commonly known as the high-frequency furnace, was invented in 1916 by the late Edwin F. Northrup. Until about 1925, the furnace was confined to small sizes, used mostly in laboratories and for melting precious metal, for melting in small-scale production and for miscellaneous heat treatment of metals. However, in 1925 commercially large and efficient generators became available for production-size units, and in 1926 the first production steel-melting furnace was installed, utilizing 150 kw of 2000-c power. Since that time the use of these furnaces has increased rapidly.

Most of the furnaces installed by the steel industry have been used for melting tool steel, stainless steel and various special alloys. These installations have been supplied with power principally by 960 or 1000-c single-phase generators. Heating installations utilizing up to 7000 kw in a single plant, and melting furnaces ranging to ten tons in melting capacity have been built. To date (1946), some 250,000 kw of high-frequency melting furnace capacity has been installed throughout the world.

Application. Though the coreless induction principle of heating is being applied successfully to various fields, such as melting of both ferrous and nonferrous alloys, heating for hot forming, heating for surface hardening, and brazing, the present article is concerned primarily with the application of the induction heating principle to steel melting. In this field the high-frequency furnace is used both in the making of ingots and in the steel foundry. In ingot practice this furnace is well adapted to the melting of special tool steels such as high speed, and the high-grade nickel-chromium alloys used for electric-resistance and high-temperature applications. Because of the absence of carbon pickup and low melting losses, this furnace provides a good tool for the production of low-carbon stainless steel, since it makes possible the use of a high percentage of stainless steel scrap in the charge.

In the foundry the high-frequency furnace is valuable because of its flexibility in operation, particularly in the production of small alloy castings. Virtually all the magnet steels of the aluminum-nickel-iron type are made in the coreless induction furnace. Although it is not the only melting method adapted to centrifugal casting, it lends itself well to this practice, and it is interesting to note that probably all the centrifugally cast guns for World War II were made from steel melted by this method.

Construction of the Furnace. The coreless induction furnace is really an air-cored transformer, having the furnace coil as primary and the melt, or other conducting body to be heated, as secondary.

* Vice President, Ajax Electrothermic Corporation, Trenton, N. J.
* Chief Metallurgist, Carpenter Steel Company, Reading, Pa.
Prepared for the Subcommittee on Melting

The primary is a helical coil of copper tubing, insulated between turns, through which water is passed for cooling the copper. When high-frequency current is applied to the terminals of the helix, all the space inside the coil is subjected to a rapidly alternating electromagnetic field. Any electrical conductor inside the coil (in practice, the furnace charge) has currents induced in it, causing rapid and efficient heating. The essential parts of a commercial furnace are shown in Fig. 1, which represents a longitudinal center section. The outer shell *S* is made of asbestos lumber and carries the trunnions *T* on which the furnace pivots in tapping or pouring. The coil *C*, consisting of a helix of water-cooled copper tubing, is lined with a thin layer *L*, of refractory material—usually an air-setting cement, such as sillimanite, that acts to keep the dry refractory from leaking out between the turns and to protect the coil in the event of a metal leak. Some prefer to omit this thin lining and use asbestos cloth against the coil. This layer is continued above and below the coil against the asbestos support *R*, and the firebrick base *F*. The coil lining and the firebrick bottom provide a cavity into which the refractory lining of the furnace is built. This lining may take the form of a thin-wall crucible or supporting shell *M*, packed into the cavity with grain refractory *G*, or it may be in the form of a sintered lining. This lining holds the charge or bath of metal *B*, and is grooved out at the top on one side to form the pouring spout *D*.

Furnace Refractories. Small furnaces, usually up to 500 lb in capacity, are lined with preformed crucibles, either acid or basic, as required. After the coil has been protected with either the sillimanite cement or asbestos cloth, dry granular refractory, acid or basic, is poured into the bottom of the furnace and tamped to eliminate voids, to a level about even with the bottom of the coil. The prefired crucible is then placed in the furnace, centered, and the granular backing material is hard rammed into place. About 1 in. or so from the top of the crucible, the lining is finished off with an air-setting cement.

In the larger furnaces, the crucible is formed in the furnace. A thin composition-asbestos liner is commonly used as a form and the granular refractory material is rammed between it and the coil as before. During the first heating, the liner slags off and helps sinter the granular material, thus forming a crucible for the molten metal.

For acid linings in small furnaces, the crucibles are preformed of silica with a binder, and the backing between the crucible and coil is a high-grade silica sand. In large furnaces, the acid lining is formed around the composition asbestos liner and consists of 98% pure SiO_2 or ganister. Where a binder is used, this may be either silicate of soda or clay.

For basic linings in small furnaces, the crucible is preformed of electrically fused MgO and backed with electrically fused MgO of assorted grain size. For basic linings in large furnaces, where the crucible is formed in the furnace, a very popular mixture is 60% electrically fused magnesia and 40% electrically fused alumina.

The life of either basic or acid linings varies greatly. In general, acid linings have a shorter life and require more patching but are less costly.

Principle of Operation. In the operation of the furnace, high-frequency current is passed through the primary coil or helix *C* (Fig. 1), inducing a much heavier secondary current in the charge and thus heating it by resistance to the desired temperature. The charge may consist either of a single lump of metal or a quantity of loose pieces such as ordinary steel scrap. Even comparatively fine turnings can be melted successfully if a sufficient amount of heavier scrap is used to provide some conductivity through the charge. The current in the charge circulates in a path about its periphery in a direction parallel to and opposite to that of the coil. The higher the resistivity of the charge and the lower the frequency of the current applied, the greater will be the radial thickness of the current path. Though high-frequency heating is effective over a wide range, the most practical frequency in production steel melting is about 1000 cycles per second.

The heat is developed in the outer part of the charge and is quickly carried to the center by conduction, which is rapid through solid metals. After the charge has started to melt and a pool has formed in the bottom of the furnace, a stirring motion occurs. This not only carries heat to the center of the charge by convection, but accelerates melting by washing molten metal against solid metal. It also mixes thoroughly the elements in the charge, thus assuring uniformity. The vigor of the stirring can be controlled by varying the power input or location of the charge in relation to the coil.

Since the amount of heat generated in the charge is directly proportional to the power input, it follows that the speed of melting depends on the power input per ton of charge. Using an average scrap charge, a 350-kw generator is capable of producing 1000 lb of finished steel per hour. A 1000-lb furnace using 350-kw power will thus tap a heat every hour, while a 2000-lb furnace will tap about every two hours. On the other hand a 2000-lb furnace using 700-kw power will tap in about one hour. The choice of furnace size in relation to power input is governed by specific operating conditions in each individual plant.

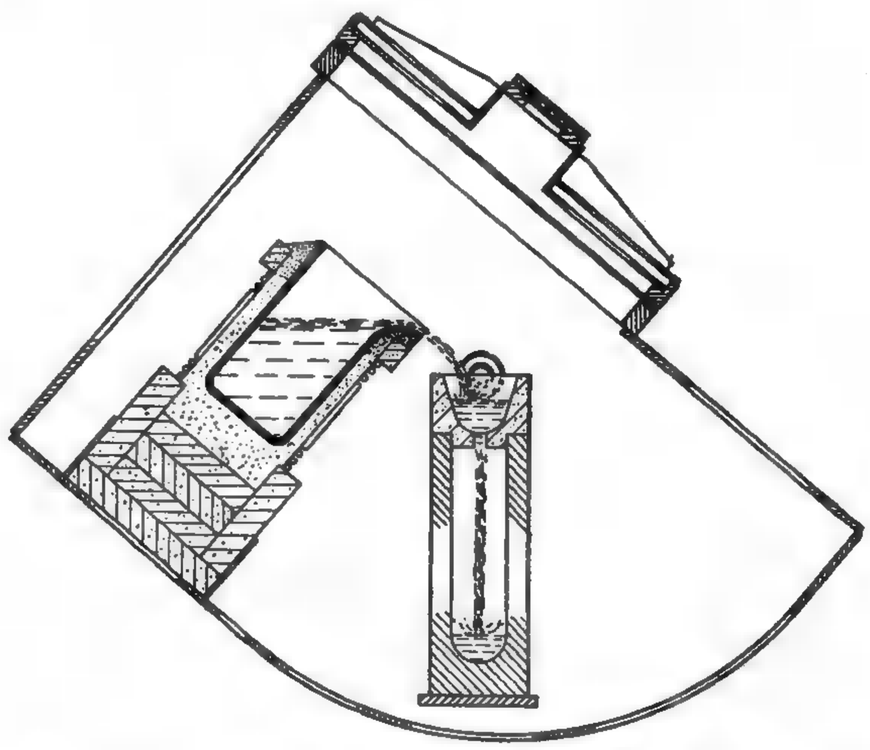

Fig. 2 Arrangement for melting and pouring in a vacuum or under pressure

Melting Procedure. In most steel plants using induction furnaces, the melting procedure is essentially a crucible process. Since the heat is generated entirely in the charge itself, melting is rapid and there is only a slight loss of the oxidizable elements. Furthermore, on account of rapidity of operation, preliminary bath analyses are seldom made. Consequently, the charge is usually made of carefully selected scrap and alloys which together will produce the composition desired in the finished steel without further additions, except possibly small amounts of ferromanganese, ferrosilicon or other final deoxidizers.

The heavy scrap is charged first and as much of the charge as possible is packed into the crucible. The current is turned on and, as a pool of molten metal forms on the bottom, the charge sinks and additional scrap is then introduced progressively until the entire charge has been added. In a 1000-lb furnace with an input of 350 kw, the charge will melt down in 45 min to 1 hr, depending on the character of the scrap. The additional time required to finish the heat depends on the amount of superheating and refining necessary.

Ordinarily no attempt is made in induction furnaces to melt under a slag cover, since it is difficult to keep a slag blanket on the metal because of the convexity of the bath, resulting from the stirring action. Fortunately, oxidation from the atmosphere is so slight that a slag is not considered necessary for protection alone. However, slags are being used successfully both during the melting-down operation and for refining. The degree of convexity of the bath is governed largely by the rate of power input to the melt and by the relative position of the charge with respect to the coil. A slag blanket on a one-ton furnace powered with 350 kw will be easier to maintain than on a one-half ton furnace with the same power input. The character and

effectiveness of such slags are, of course, governed by whether the furnace is acid lined or basic lined.

While it is common practice to operate the furnace with the top open, some melters prefer to cover the furnace with a refractory cap or roof as soon as the bath is melted down. This is said to reduce heat losses and to assist in controlling temperature and slag reactions.

As soon as the charge has been melted clear and refining has been completed, any further necessary additions of alloys or deoxidizers are made and the bath is superheated to the proper pouring temperature. The current is then turned off and the furnace is tilted to pour the metal over the lip, directly into the mold, into a funnel or pouring box placed over the mold, or into a ladle from which it is later poured into molds. In foundries making small castings it is sometimes the practice to pour into shank ladles. As soon as the heat has been poured, the furnace is scraped clean of adhering slag and immediately recharged for the next heat.

A variation of the usual melting procedure, adapted to the melting of certain special alloys, consists in melting either in a vacuum, or under pressure in the presence of inert gases. In these processes the entire furnace and mold are encased in an airtight container, which can be evacuated or put under pressure at will. Figure 2 shows a section of such an arrangement with the furnace in the pouring position.

Ingot and Pouring Practice

BY THE SUBCOMMITTEE ON MELTING

AFTER the furnace operations are complete, the next step in producing a heat of steel is to make a solid homogeneous casting. In foundry practice the casting will be of approximately finished size and shape; in ingot practice the casting will take the form of a chilled ingot to be rolled or forged into the final form. Regardless of the steelmaking process used, the procedure after the metal leaves the furnace consists of two distinct steps: (1) tapping the heat into a container called a *ladle*, and (2), pouring from the ladle into molds that have the size and shape of the ingot desired.*

* There are two possible exceptions, namely, in the crucible process, where it was sometimes customary to pour directly from the pot into the mold, by what is known as "single practice"; and in the high-frequency induction furnace, where it is sometimes the practice to pour from the furnace directly into the mold.

Ladle Practice. The function of the ladle is to serve as a container or reservoir for the molten steel after it leaves the furnace. From the ladle the molten steel is poured into the mold. Since steel practices and furnace capacities differ greatly, the character and size of ladles differ also to fit various operating conditions. Steel ladles vary in size from approximately 100 lb, typified by the small hand-shank ladles used in foundries, to 100 tons or more, employed in large open hearth plants. In type, they fall into two general classes: *lip-pour,* and *bottom-pour*.

Lip-Pour Ladle. This ladle, used in steel foundries and in some Bessemer plants, is constructed so that the metal is poured over the lip by tilting the ladle. It usually consists of a bucket-shaped shell of steel plate having trunnions on the sides for engagement with a crane bail. Small hand-shank lip-pour ladles are simply steel pots carried in suitable shank handles and must usually be tilted for pouring. The shell may be lined with a layer of special refractory firebrick, or a mortar of ganister and clay or other siliceous ramming mixture, or sometimes a magnesia-type base material.

In practice when the metal is tapped from the furnace, the slag is allowed to run on top to act as a cover. While pouring molten metal into molds, the ladle is tilted on the trunnions, usually by means of a worm and gear, and the metal runs over the lip, but the slag is held back. A modification of the lip-pour ladle is the so-called "teapot ladle", in which an independent spout or tube is built down through the lining so as to connect at the bottom. This allows lip-pouring in such a way as to draw the metal from the bottom of the ladle, thus avoiding contamination by the slag. This type of ladle is particularly adapted to high-manganese steel, which is notably corrosive on stoppers and nozzles, and in this instance is often used for transferring the metal to smaller shank ladles.

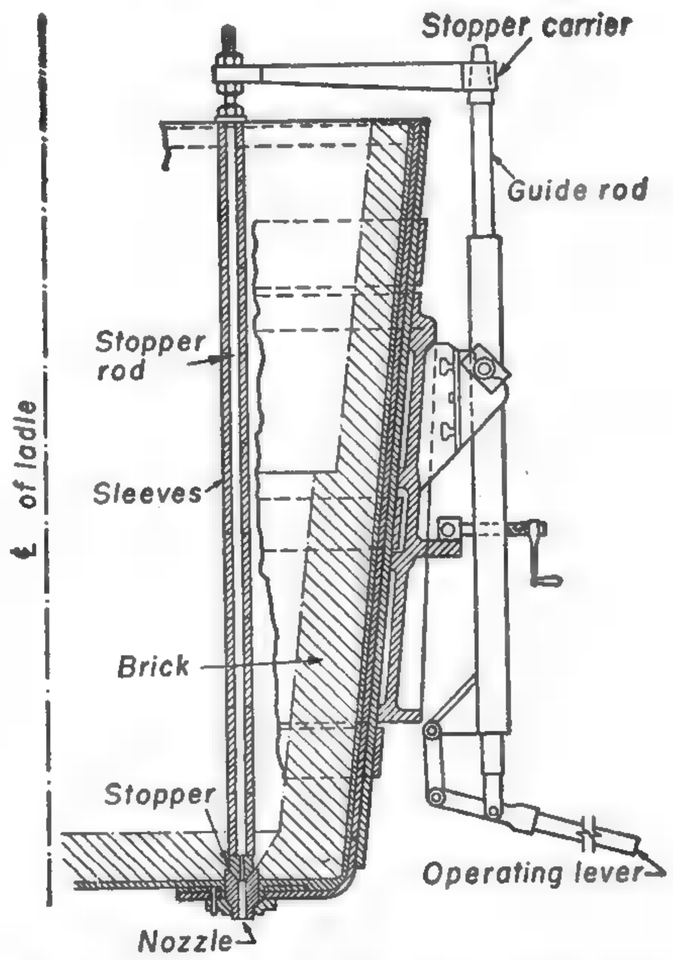

Fig. 1 Section of a bottom-pour ladle (Boylston)

Bottom-Pour Ladle. This has a steel shell of much the same shape as the lip-pour ladle. It has trunnions for either hanging on a crane by means of a bail or holding in a carriage or a buggy. Bottom-pour ladles are usually lined with brick, sometimes with an additional plaster of fire clay over the surface. In foundries, monolithic rammed linings are often made for the smaller ladles. Near the rim at the bottom, the shell has a hole in which is inserted a refractory *nozzle* made of clay, graphite-clay or magnesia. Into this nozzle fits a *stopper head* or *plug* made of a graphite-clay mixture. This stopper head is held on a steel stopper rod that is protected by clay sleeves and extends vertically through the metal in the ladle. The top end of the rod, protruding above the top of the ladle, is fastened to a gooseneck extending over the side of the ladle, which is raised and lowered by a lever. The flow of metal through the nozzle can be controlled by this arrangement. The sizes and types of nozzles and stoppers vary to suit specific purposes. The primary purpose is to deliver a smooth stream at the proper rate and temperature with the minimum amount of erosion of the stopper parts. Figure 1 shows the section of a bottom-pour ladle.

Operation. All ladles must be carefully dried before tapping the metal and in some instances, particularly with the smaller ladles, not only dried, but heated to a good red heat. In the bottom-pour ladle, the stopper is set when the ladle is cold, then unlocked from the rigging, and the ladle and stopper may be heated separately. When the steel is ready to tap, the stopper is keyed into the ladle, pulled tight into the nozzle, and held there with a set screw on the saddle of the stopper rigging. A handful of sand is then thrown around the stopper head to test the stopper for tightness. In open hearth and electric-arc practice, the ladle is carried by crane, and usually set on a steel and concrete stand under the spout of the furnace for tapping. Additions of deoxidizers or recarburizers are often made in the ladle during the tapping. Occasionally deoxidizers or alloying elements (such as lead, in making the leaded free-machining steels) may be added to the molds during pouring. In Bessemer practice, the ladle is brought to the converter by crane or buggy and the converter is tilted to tap into the ladle. The necessary recarburizing additions are made during the transfer.

When large heats of steel are to be poured into small molds, the ladle is often rigged with two nozzles and two stopper rods so that a double row of ingots can be poured simultaneously. In such an arrangement the ingot molds have to be placed very accurately, so that any given position of the ladle will find the two nozzles centered over the molds.

When the entire heat of steel has been tapped or transferred into the ladle, the metal is assumed to be at the proper temperature for pouring, or at a somewhat higher temperature, uniform throughout, and covered with a slag blanket as protection against oxidation and chilling by the air. If the temperature is too high, the ladle may be held for a length of time calculated to cool it to the proper temperature; then the steel is poured into the molds.

After pouring, the ladle is immediately dumped to clean out slag and residual metal, and is permitted to cool. When cold, the ladle is chipped free of slag and metal preparatory to repatching the lining. Sometimes when the heat of steel is tapped too cold, a shell of steel, known as a *skull,* is left in the ladle. This must be removed, and often requires extensive repairs because it tends to pull with it much of the refractory lining with which it is in contact. The amount of skull left in the ladle is often taken as an indication of the temperature of the metal.

When the ladle has been cleaned of slag and metal, it is patched with mortar and sometimes with brick, and a new nozzle and stopper are set. The ladle is then ready for drying for the next heat. With minor repairs after each heat, brick-lined ladles run a limited number of heats per lining, after which the inner course of brick must be entirely torn out and replaced.

Ingot Practice. Assuming that the heat of steel in the ladle is at the proper pouring temperature, the process of pouring into the molds to form a sound ingot may appear at first glance to be ■ very simple matter. On the contrary, the operation involves a great many complex reactions, the control of which is extremely important, since in pouring the ingot the steelmaker is virtually laying the foundation for every step that comes after. To comprehend this clearly, it is necessary to look briefly into the mechanism of the freezing of steel.

Freezing of Steel. In the molten condition, steel is virtually a uniform liquid with every part like every other part. The various elements in addition to iron, such as carbon, manganese, silicon, phosphorus, sulfur, chromium, nickel and vanadium, are all in uniform solution in the iron, or nearly so. However, after freezing, the steel no longer has this complete uniformity. The reason is that, like all other metals, steel crystallizes during freezing and, in so doing, solidifies selectively. Solidification begins with

the formation of crystals rich in the element that raises the freezing point of the alloy. The liquid left between the crystals is rich in the elements that lower the melting point of the alloy. If cooling is fast, they are quickly trapped between the original crystals, which are called *dendrites* because of their treelike form. In this condition the dendrites are not harmful, since they are well distributed and in a condition that can be broken up readily in hot working. However, if cooling is quite slow, the low-melting constituents will remain liquid for a length of time sufficient to allow them to gather in certain parts of the ingot, particularly the axis. The gathering of these low-melting constituents is called *segregation*. The extent and location of such segregations depend on the speed of freezing, which in turn depends on the sectional size of the ingot, pouring temperature, rate of pouring, and the design of the mold.

During freezing, steel contracts or shrinks, so if the mold is poured full of molten steel, it will no longer be full after the steel has solidified. It will be found that the steel has not simply settled down, leaving an air space above it, but that the location and shape of this air space or *shrinkage cavity* depend largely on the shape and design of the mold.

Mechanism of Freezing. The first metal that freezes against the mold wall shrinks slowly and this shrinkage is

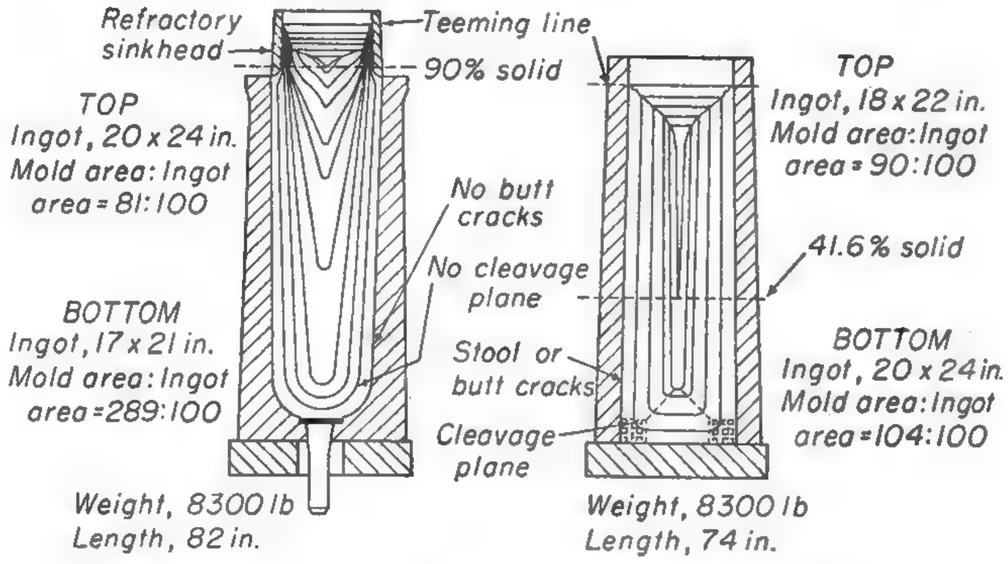

Fig. 2 Section of big-end-up and big-end-down molds

immediately filled by the molten metal in contact with it. Each succeeding layer freezing parallel to the mold surface shrinks similarly and robs molten metal from the center. In a cylindrical or prismatic mold, the steel freezes progressively from the walls. The molten pool in the center gradually sinks downward as it feeds these shrinking walls. This continues as long as the chilling effect of the mold wall is felt in the molten pool. When this effect is no longer felt, the molten metal freezes slowly throughout and shrinks downward. The net result is an ingot with sound walls, and with an axial cavity, or pipe, extending a considerable distance downward. This pipe can be made to extend deeper into the ingot by designing the mold large at the bottom and small at the top (big-end-down), and it can be made much shallower by reversing the procedure and designing the mold big-end-up. Figure ■ shows sections of big-end-up and big-end-down molds and the difference in freezing behavior.

Another result of the shrinkage of steel during freezing is the behavior of the surface metal. The first molten metal coming in contact with the mold wall freezes instantly. As it does so, it also shrinks and the surface metal pulls away from the mold wall, leaving an air gap. Therefore, the shell of metal is now supporting the molten metal inside and is no longer in direct contact with the mold wall. This has two disadvantages: (1) it greatly reduces the chilling effect of the mold, and (2) it introduces the danger of the molten metal rupturing the shell, with consequent bleeding and a rough or cracked ingot as a result. The round-sectioned mold introduces the greatest hazard in this respect. The square mold is a considerable improvement over the round; and the fluted or corrugated mold is an additional improvement over the square.

Therefore, the design of the mold is a very important factor in the production of sound ingots. It should be mentioned, however, that the conditions described can be modified by adjustments in the pouring temperature and pouring rate, factors that must not be overlooked when shrinkage and segregation are being discussed.

Another characteristic of steel is that it liberates absorbed gas during freezing; the amount depends on the method of manufacture. Killed steel liberates a comparatively small amount but open or rimming steel evolves large quantities of gas. The evolution of this gas must be controlled by proper deoxidation methods and a suitable amount of chill to keep the resulting blowholes deep under the surface where they will be comparatively harmless.

Thus far the conditions considered affect the internal structure of the ingot. The surface condition is of equal importance, since this determines the amount of expensive chipping or grinding that must be done on the resulting billet to insure a finished bar or forging free from surface defects. To produce a good ingot surface requires a good mold surface and a minimum of splashing during the pouring of the ingot, controlled largely by proper nozzle size and pouring rate. The production of good ingot surface is sometimes accomplished by pouring the ingots from the bottom by means of a gate or runner, often in groups. This practice, called "bottom-pouring", is used principally in the production of forging ingots. The use of mold washes also improves ingot surface.

Mold Design. Ingot molds are ordinarily made of cast iron, although a few steel molds have been used with indifferent success. Water-cooled molds have also been used to a limited extent, although these are still in the experimental stage. The small molds ranging from 3 to 6 in. sq are often of the split or two-piece type to facilitate stripping. Molds larger than 6 in. are usually of the one-piece type, although some larger split molds are used. Molds fall into two general classes: big-end-up and big-end-down. Big-end-down molds have the advantages of lower first cost and easier stripping; big-end-up molds have the advantage of higher yields and sounder steel. Molds may be of various shapes—square, rectangular, corrugated round, 8 sides fluted, or 12 sides. Big-end-down molds are open at both ends and are set upon a cast-iron or copper stool, which forms the bottom of the mold. Big-end-up molds usually have a round hole in the bottom which is closed with a tapered plug, as in the Gathmann type. Such plugs are usually cast iron but other materials, such as copper, refractory or graphite, are being used successfully.

Setting the Molds. The method of setting the mold preparatory to pouring varies in different plants. In most open hearth plants, molds are set on buggies—three to each car—and are spotted along a pouring platform from which the ladleman operates. In some plants the molds are placed on the floor; in others they are set in pits so that the ladleman needs no platform.

Before they are set up, molds are carefully cleaned and if they do not retain some heat from the previous cast, they should be preheated. The mold coating is then applied. Coatings include tar, whitewash and aluminum. Sometimes the molds are coated with rosin smoke. In open hearth practice, molds may be either coated with tar by dipping, or sprayed with powdered pitch or graphite.

In many plants making killed steel, a *hot top* is placed on the top of the mold to control the depth of the pipe. In small ingot practice these hot tops usually take the form of fire clay shells, which are heated as much as possible before being placed on the molds. In large ingot practice, hot tops may be sectional pieces of fire clay, brick, or even lined steel castings; and the preheating is not so important because of the volume of hot metal they will contain. These hot tops are smaller in section than the mold and are shimmed up above the mold top so that they can float on the metal in the filled mold, thus giving ample space for shrinkage to take place without binding the hot top to the top of the mold. If such binding should occur on various types of high-carbon, alloy and high speed steel, ruptured ingots might result. The space thus exposed between the mold and the hot top may be sealed with wet sand to prevent leakage as the metal rises in the hot top, or leakage may be prevented by delaying the pouring

for a short time at the joint. Hot-top volume, depending on the type of steel, will vary from 10 to 18%; but this does not mean that an equivalent weight of metal remains after the ingot solidifies, because the steel in the hot top will feed into the ingot pipe as it develops, and will thus reduce in volume during the process of solidification.

The metal in the hot top may be kept molten by several methods: by replenishment at a stated interval after the first pouring, or by the use of "pipe eliminators" which are placed on the top of the hot-top metal and either burn to generate heat or enter into exothermic chemical reactions to keep the metal liquid. Some of these reagents are carburizers, so they must be selected according to the type of steel being made. Lastly, single-arc electrodes or even induction coils are sometimes used to keep the hot-top metal fluid.

In pouring "rimmed" steel or "effervescing" steel, hot tops are not used; but at the proper time, the ingot top is "capped" to cut off the flow of escaping gases and allow the metal to solidify with the gases trapped in the steel. Such ingots do not have pipe or shrinkage cavities in the usual sense.

In bottom-pouring, the stools are especially designed with a hole in the center into which a brick cup is inserted. This cup is connected to a built-up tube of brick, known as a "runner", which is elbowed in turn to a vertical brick runner into which the metal is poured.

Pouring Operation. The ladle is spotted over the properly set mold, or over the "runner" or "fountain" in bottom-pouring. The steel is carefully poured at the proper rate, which is controlled chiefly by nozzle size and often timed by watch. Sometimes instead of being poured directly into the mold, the steel is poured into a pouring box which has one or more nozzles in the bottom. This pouring box is used to reduce pressure and thus eliminate splashing.

When the ingots are entirely frozen or *set*, they are removed from the mold or *stripped*. For car-type molds, special stripping cranes are in use, adapted either to big-end-up or big-end-down practice. In small mold practice, stripping is done by hand with the assistance of the crane.

The cooling of the ingot after stripping, particularly in the higher alloy steels, is of considerable importance and must be done carefully to prevent cracks. Usually when the hot ingots are not taken directly to a soaking pit, they are buried in ashes or other insulating material to insure slow cooling.

Metals and Ferro-Alloys Used in the Manufacture of Steel

By G. K. Herzog*

Howe's classical definition of a ferro-alloy as "iron so rich in some element other than carbon that it is used as a vehicle for introducing that element in the manufacture of iron or steel" is still about the best short definition that has been devised. Common usage, however, has made the term "ferro-alloy" mean somewhat more than this; it now includes a number of alloys so low in iron that they cannot properly be called "iron". For example, calcium-silicon, generally containing a maximum of 6% Fe, is usually classified as a ferro-alloy.

A number of ferro-alloys and metals are in common use in the manufacture of steel. Some are used for the special properties they impart to steel when in solid solution with the iron or when they combine, either wholly or partially, to form carbides; others are used for the beneficial effect they have on the impurities in the steel; and still others are employed to counteract harmful oxides or gases, and do not remain in the steel to any great extent after solidification, but merely act as fluxes or scavengers of objectionable impurities.

The melting points of the ferro-alloys used are generally of only minor importance in the manufacture of steel. The solubility of ferro-alloys in molten steel is of much greater significance. Throughout this chapter, the melting "ranges" of the various alloys are given. In general, the lower figure indicates when the alloy begins to melt, while the higher figure shows when it is completely molten. In a few instances, the lower figure gives the temperature at which the alloy having the highest carbon content of a series begins to melt, and the higher figure gives the temperature at which the alloy having the lowest carbon content is completely molten.

Standard Ferromanganese. Manganese is generally added to the molten steel in the form of ferromanganese. The standard or high-carbon grade has approximately the following composition:

Manganese	78 to 82%
Iron	12 to 16%
Carbon	6 to 8%
Silicon	1.00% max
Phosphorus	0.30% max
Sulfur	0.05% max

This alloy is furnished in various crushed and ground sizes. A common form ranges in size from lumps weighing 75 lb each to pieces about ½ in. in diam. When made under favorable and closely controlled conditions, standard ferromanganese will not disintegrate or crumble. It is used in all grades of steel, including Bessemer, open hearth and electric, for forgings, rolled products and castings.

The melting range of standard ferromanganese is between approximately 1960 and 2310 F.

Low-Carbon Ferromanganese. This alloy is used for adding manganese to steels so low in carbon content that the required manganese cannot be added either as standard ferromanganese or as medium-carbon ferromanganese. Low-carbon ferromanganese is particularly suitable for adding manganese to the austenitic chromium-nickel steels of the 18% Cr, 8% Ni type in which the carbon content must frequently be kept below 0.10%.

Low-carbon ferromanganese is available in several grades with maximum carbon content ranging in steps from approximately 0.06 to 0.75% and phosphorus content as low as 0.06%, as follows:

	(1)	*(2)*	*(3)*
Manganese	90.00%	80 to 85%	80 to 85%
Carbon	0.07% max	0.10% max	0.15% max
Silicon	1.00% max	1.00% max	1.00% max
Phosphorus	0.06% max	0.20% max	0.20% max

	(4)	*(5)*	*(6)*
Manganese	80 to 85%	80 to 85%	80 to 85%
Carbon	0.30% max	0.50% max	0.75% max
Silicon	1.00% max	1.00% max	7.00% max
Phosphorus	0.20% max	0.20% max	0.25% max

This ferro-alloy is furnished in several sizes ranging from 50-lb lumps to a ground size of 80-mesh and smaller.

The melting range of low-carbon ferromanganese is 2190 to 2220 F.

Medium-Carbon Ferromanganese. This alloy is generally used for making low-carbon steels. It is sometimes used in the manufacture of Hadfield (13% Mn) austenitic steel when large quantities of returned scrap are being melted.

Medium-carbon ferromanganese is available in one grade, as follows:

	(1)
Manganese	80 to 85%
Carbon	1.50% max
Silicon	1.50% max

*Metallurgical Engineer, Electro Metallurgical Company, New York

This ferro-alloy is available in a number of crushed and ground sizes. For furnace additions, the preferred material ranges in size from 50-lb lumps to pieces 2 in. in diam, while for ladle additions, material crushed to 2 in. or 1 in. and smaller is found most satisfactory. The melting range of medium-carbon ferromanganese is about 2220 to 2230 F.

Spiegeleisen or Spiegel. Spiegeleisen is virtually a high-manganese pig iron used in both Bessemer and basic open hearth practices. It is made in either the blast furnace or the electric furnace; the more important grades include the following:

	(1)	(2)	(3)
Manganese	16 to 19%	19 to 21%	26 to 28%
Carbon	6.50% max	6.50% max	6.50% max
Silicon	3.00% max	3.00% max	1.00% max

Since spiegeleisen is generally used as a furnace addition, it is furnished either in pigs weighing as much as 100 lb or in large lumps. The melting range is from 1950 to 2265 F.

Silicospiegel. Silicospiegel is used in much the same manner and for much the same general purposes as spiegeleisen. When made in the electric furnace silicospiegel usually contains 25 to 28% Mn, 5 to 6% Si, and approximately 4% C.

Silicomanganese. Because of the low ratio of carbon to manganese, this alloy is particularly suitable for introducing manganese into low-carbon steels in which the added silicon is not objectionable. Many producers of high-grade steels prefer silicomanganese to other alloys for the blocking of heats, because of the saving of time from block to tap and the improved cleanliness of the steel produced.

Silicomanganese can be made in various grades, but the grade that satisfies almost any requirement contains 65 to 70% Mn, 17 to 20% Si, 1.50% C (max). This alloy is available in various sizes. For furnace addition, lump material is preferred, having a maximum size of 75 lb and a minimum size of 2 in.; for ladle additions, material crushed to ½ in. and smaller gives best results.

The melting range of silicomanganese is from 1960 to 2400 F.

Ferrosilicon. Ferrosilicon is furnished in a number of grades, depending on the purpose for which it is to be used.

Fifteen Per Cent Ferrosilicon. Fifteen per cent ferrosilicon is available as a product both of blast furnaces and of electric furnaces. A number of grades range in silicon content by steps from 14 to 18%.

The electric-furnace grade will usually meet the following specification: 14 to 18% Si, 1.00% C (max), 0.05% P (max), 0.04% S (max). Because of its low phosphorus and sulfur contents, the electric furnace product is generally preferred for the production of quality steels. It is used for blocking heats, and as a deoxidizer and cleanser prior to the addition of more expensive alloys. Since this grade of ferrosilicon is used only as a furnace addition, it is ordinarily supplied in the form of pigs or half-pigs, ranging in weight from about 50 to 100 lb.

The melting range of 15% ferrosilicon is from 2220 to 2280 F.

Twenty-Five Per Cent Ferrosilicon. This grade is used for the same general purposes and in about the same manner as the 15% grade. It contains 25 to 30% Si and is available in lump and crushed form.

The melting range of this alloy is from 2200 to 2400 F.

Fifty Per Cent Ferrosilicon. This is the grade of ferrosilicon most widely used in the steel industry as a deoxidizer in the production of most grades of killed or semi-killed steel. It is also used for adding silicon to the high-silicon steels, such as those used for the production of springs, electrical sheets and various other products.

Fifty per cent ferrosilicon contains approximately 46 to 52% Si and is available in lump form as well as in various crushed sizes suitable for different purposes. If it is made under the correct manufacturing conditions, 50% ferrosilicon will not disintegrate or crumble when exposed to the air. The melting range is from 2210 to 2230 F.

Seventy-Five Per Cent Ferrosilicon. Some melters prefer this grade for the production of high-silicon spring and electrical sheet steels because it contains a higher percentage of silicon and, consequently, smaller additions of alloy to the ladle obtain the desired final silicon content. Furthermore, when ferrosilicon containing more than approximately 75% Si is added to molten steel, heat is generated, so instead of chilling the bath, the addition actually heats it somewhat. This is a great advantage in producing steels that contain more than 2% Si.

This grade of ferrosilicon, containing about 74 to 79% Si, is furnished in lump form as well as in various crushed sizes. The melting range is from 2200 to 2400 F.

Eighty-Five Per Cent Ferrosilicon. This grade is used for the same general purposes and in much the same manner as the 75% grade. Because of its still higher silicon content, even smaller amounts of cold alloy are added to the ladle in order to introduce the desired amount of silicon. Also this grade generates more heat when added to molten steel and thus enables the melter to add higher percentages of silicon without chilling the steel.

This alloy may contain from 80 to 90% Si and is frequently furnished in two ranges of silicon content, 80 to 85% and 85 to 95%, available in lump form and various crushed sizes. The melting range is from 2200 to 2460 F.

Ninety to Ninety-Five Per Cent Ferrosilicon. The remarks about the 75% and 85% grades of ferrosilicon apply with greater emphasis to the 90 to 95% grade. It is available in lump size as well as in various crushed sizes. The melting range is from 2200 to 2520 F.

Ferrochromium. Chromium is added to steel as ferrochromium, and because the types of chromium-bearing steels differ widely in carbon and chromium contents, a number of grades of ferrochromium are required to fill industrial needs properly. The ferrochromiums are divided into two broad classes—low-carbon ferrochromium and high-carbon ferrochromium.

Low-Carbon Ferrochromium. This is used in producing chromium steels of low carbon and frequently high chromium contents, such as the various types of steels resistant to corrosion and heat and commonly known as "stainless". Low-carbon ferrochromium is available in a number of grades having different carbon contents, but all contain from 67 to 72% Cr. The maximum carbon contents of the various grades are 0.03%, 0.04%, 0.05%, 0.06%, 0.10%, 0.15%, 0.20%, 0.50%, 1.00% and 2.00%.

This alloy is available in various crushed sizes and in lump form. The largest lumps weigh about 50 lb. The melting range of low-carbon ferrochromium varies inversely as the carbon content, being from 2500 to 3110 F for the 0.03% C grade, and from 2340 to 2460 F for the 2.00% C grade.

High-Carbon Ferrochromium. For making medium- or high-carbon steels of relatively low chromium content, high-carbon ferrochromium is commonly used. This alloy is available in several grades, ranging from 65 to 70% Cr, and from 4 to 9% C.

This ferro-alloy is furnished in various crushed sizes and in lumps weighing as much as 75 lb. The melting range is from approximately 2230 to 2790 F.

High-Nitrogen Ferrochromium. Ferrochromium with a nitrogen content equal to approximately 1% of the chromium content is available in both the high-carbon and low-carbon grades.

Special Ferrochromiums. Ferrochromiums especially designed for ladle additions are also available. Among these are SM low-carbon ferrochromium and SM high-carbon ferrochromium, with the following chemical compositions:

	Low-Carbon	*High-Carbon*
Chromium	62 to 66%	60 to 65%
Silicon	4 to 6%	4 to 6%
Manganese	4 to 6%	4 to 6%
Carbon	1.25% max	4 to 6%

Both the low-carbon and the high-carbon grades, furnished in lump form and in various crushed sizes, are distinguished by the readiness with which they dissolve in liquid steel.

Foundry Grade Ferrochromium. This grade is especially

designed for the ladle addition of chromium to cast iron, but may be used for steel as well. The chemical composition ranges from 62 to 66% Cr, 6 to 9% Si and 4 to 7% C. This ferro-alloy is furnished in lump size and in a number of crushed and ground sizes suitable for furnace and ladle additions.

Alsifer. This alloy is used for final deoxidation and for control of grain size. In open hearth practice it is ordinarily added to the ladle; in electric furnace practice it is added preferably in the furnace. The approximate composition is 20% Al, 40% Si and 40% Fe. Alsifer is furnished in lump form as well as in various crushed sizes.

Simanal. This combined deoxidizer and grain refiner has the following approximate composition: 20% Si, 20% Mn, 20% Al and 40% Fe. It is available in lump form as well as in various crushed sizes.

Calcium-Silicon. Calcium-silicon is used as a deoxidizer and degasifier in the production of steel. Both calcium and silicon are active deoxidizers and their reaction products form a low-melting-point slag that frees itself readily from the metal. Calcium-silicon also improves the fluidity of liquid steel. In open hearth practice this alloy is added in the ladle; in electric furnace practice it is added preferably in the furnace.

The composition ranges from 28 to 35% Ca, 60 to 65% Si and 6.0% Fe (max).

The melting range of calcium-silicon is from 1800 to 2030 F. This ferro-alloy is furnished in lump form and in various crushed sizes suitable for ladle additions.

Calcium-Manganese-Silicon. This alloy is used for the same purposes and in the same manner as calcium-silicon. The range of composition is as follows: 16 to 20% Ca, 14 to 18% Mn, and 53 to 59% Si. The melting range of calcium-manganese-silicon is from 1800 to 2020 F. This alloy is furnished in lump form and in various crushed sizes suitable for ladle additions.

Ferromolybdenum. The molybdenum added to engineering steels rarely exceeds 1%. In tool steels the amount may be as high as 10%, while in stainless steels of the austenitic chromium-nickel variety, as much as approximately 3% Mo is frequently added. Ferromolybdenum is available in several grades, containing from 55 to 75% Mo and either 0.10, 0.60 or 2.50% C (max). This ferro-alloy is generally crushed to 1 in. and smaller, and is usually added in the furnace, since molybdenum does not oxidize under steelmaking conditions. The approximate melting point is 2965 F.

Molybdenum Silicide. This ferro-alloy, containing about 60% Mo, 30% Si and about 1% Fe, is produced for those who wish to add molybdenum and silicon simultaneously. It is furnished crushed to a size suitable for either furnace or ladle addition.

Calcium Molybdate. Calcium molybdate contains 40 to 48% Mo, 10 to 25% calcium oxide and is virtually free from carbon. It is usually packed in containers holding an exact amount of molybdenum. This material is added in the furnace at any time during the progress of the heat, preferably after the charge is melted. As much molybdenum is recovered from additions of calcium molybdate as from additions of ferromolybdenum.

Molybdic Oxide. Molybdic oxide can be used in much the same manner as calcium molybdate. It can be obtained packed in cans containing definite and exact weights of molybdenum or in briquets weighing approximately 5 lb each and containing 2½ lb Mo.

Ferrovanadium. The amount of vanadium added to engineering steels is generally 0.10 to 0.25%. In high speed steel, the amount ranges from approximately 1.00 to 2.50%, although some steels are made with a still higher vanadium content. Ferrovanadium is available in several grades that have the following approximate composition: 35 to 55% V, 1.50 to 12% Si and 0.20 to 3.50% C. This ferro-alloy is produced in lump, crushed and ground sizes. Because vanadium oxidizes readily it is usually added to the ladle in open hearth practice. In basic electric practice it is ordinarily added to the furnace. The melting range of ferrovanadium is from 2700 to 2770 F.

Ferrotitanium. Several grades of ferrotitanium are used in steelmaking. The low-carbon variety is available in a number of grades having the compositions given below. These are used largely in the production of the so-called "stabilized" austenitic chromium-nickel steels.

	(1)	*(2)*	*(3)*	*(4)*	*(5)*
Titanium	20 to 25%	24 to 26%	38 to 42%	38 to 42%	40 to 45%
Aluminum	3.00% max	5 to 6%	6 to 9%	2 to 5%	7.00% max
Silicon	4.00% max	3 to 4%	3 to 5%	9 to 13%	4.00% max
Carbon	0.10% max	0.10% max	0.10% max	0.10% max	0.10% max

The high-carbon variety of ferrotitanium, frequently known as ferrocarbon titanium, is available in two grades —high-carbon and medium-carbon—having the following approximate compositions:

	High-Carbon	*Medium-Carbon*
Titanium	15 to 16%	17 to 20%
Aluminum	1 to 2%	1 to 2%
Silicon	2 to 3%	2 to 3%
Carbon	6 to 8%	3 to 5%

These grades are used as deoxidizers and scavengers in steel in such amounts that only a barely appreciable percentage remains in the solid steel. In medium- or high-carbon killed steels, ferrocarbon titanium is used as a final deoxidizer to prevent segregation and the occurrence of objectionable inclusions, and occasionally to control grain size.

One grade of ferrotitanium contains 25 to 27% Ti, 20 to 24% Si, 1.00% Al (max) and 1.00% C (max). All the titanium alloys are available in various lump, crushed and ground sizes suitable for different purposes.

Tungsten. The principal use of tungsten is for the manufacture of high speed tool steel, in which tungsten may range from about 2% to 22%. It is used also in the production of steels for hot working dies for certain high-temperature alloys and is used to a limited extent in permanent magnet steels. The various tungsten steels are ordinarily made in the electric furnace.

Ferrotungsten is the alloy commonly used for adding tungsten to steel, although tungsten metal powder is sometimes used, as well as some tungsten compounds such as calcium tungstate. The range of tungsten contents of standard ferrotungsten is from 70 to 80% with a maximum of 0.60% C. A number of grades falling outside these limits are, however, commercially available as follows:

	Special	*Grade B*	*Grade C*
Tungsten	65 to 72%	78 to 82%	78 to 82%
Carbon	2.50% max	0.25% max	1 to 2%

Ferrotungsten is furnished in various crushed and ground sizes; the largest is about 1 in. The melting range of standard ferrotungsten is relatively high, from approximately 3000 to 5000 F. However, this alloy dissolves quite readily in molten steel, so that an addition of as much as 20% W involves no particular difficulty.

Tungsten metal powder, like ferrotungsten, is available in a number of grades suitable for the production of tungsten steels, as well as in grades of very high purity with closely controlled, extremely fine particle sizes suitable for the production of tungsten carbide tools and similar applications.

Zirconium. Zirconium is added to steel in amounts ranging from less than 0.05 to approximately 0.20%. This element acts as a deoxidizer and scavenger, combining readily with oxygen, nitrogen and sulfur, which are thus either eliminated from the bath or rendered harmless. The reaction with nitrogen, resulting in the formation of zirconium nitride, reduces age hardening in the deep-drawing steels. In high-sulfur steels formation of zirconium sulfide diminishes the hot shortness. Additions of more than 0.10% Zr will usually give a fine-grained steel, but smaller additions, such as approximately 0.05% Zr, will give thorough deoxidation without grain refinement.

Two zirconium alloys are used for the majority of the

zirconium additions made to steel. The approximate compositions of these alloys are as follows:

	(1)	(2)
Zirconium	12 to 15%	35 to 40%
Silicon	39 to 43%	47 to 52%
Iron	40 to 45%	8 to 12%

Zirconium alloys, available in a number of lump, crushed and ground sizes, begin to melt at about 2300 to 2450 F.

Nickel. Nickel is used in a wide range of percentages in many types of steel. In engineering steels the percentage of nickel may vary from about 0.40 to 6.00% and is occasionally somewhat higher. When it is used in combination with chromium in steels resisting corrosion and heat, nickel may be present from about 1% to about 40% or even higher. Some of the alloys still higher in nickel contain so little iron that they cannot be listed properly as steels. The same remark would apply to some of the special nickel alloys used for magnetic and other purposes.

Because nickel is not oxidized in a molten steel bath, it may be added to the furnace charge at any time during the progress of the heat. Nickel is supplied in the form of electrolytic cathodes sheared to a convenient size. It is also available in the form of shot and ingots made of remelted cathodes. The approximate composition and melting point of these grades is as follows:

	Electrolytic Cathode	Remelted Cathode
Composition, percentage nickel plus cobalt	99.95	99.60
Melting point, deg Fahr	2650	2600

Columbium. Columbium is used mainly in the production of "stabilized" austenitic chromium-nickel steels. It is used also to reduce the air-hardening characteristics in the plain chromium steels of the corrosion-resistant type. For these applications the columbium seldom exceeds 1%; the amount added is from 5 to 10 times the carbon content. Columbium (as much as several per cent) is also a constituent of some of the alloys developed for use at high temperatures, since it increases their creep strength.

Columbium is available as ferrocolumbium containing 50 to 60% Cb and having 5% Mn (max), 8% Si and 0.40% C. When this ferro-alloy is added to a deoxidized steel bath 12 to 15 min before tapping, 80% may be recovered. Ferrocolumbium is available in a number of crushed and ground sizes. The melting range is from 2550 to 2750 F.

Cobalt. Cobalt resembles nickel in appearance and chemical properties; however, its effects on steels and other ferrous alloys are quite different from those of nickel. Cobalt is the only metal that is known to reduce the hardenability of the steel in which it is present. It is added to high speed steels in amounts from 5 to 12%, to permanent magnet steels in amounts from 5 to 40%, and in various percentages to steels and alloys for high-speed cutting tools and for use at high temperatures. Cobalt is ordinarily added to steel as cobalt metal, in the form of rondelles and shot containing 97 to 99% Co. The melting point of pure cobalt is about 2720 F.

Aluminum. Because it is an extremely active deoxidizer and degasifier, aluminum is used in virtually all steelmaking processes, either as a mold addition for quieting turbulent steel, or as a ladle addition for obtaining a fine grain size and preventing porosity in steel castings. Aluminum is a constituent of a majority of the nitriding steels. It is available in several forms, such as shot, sticks and small ingots. The amount used—ordinarily only a few hundredths of a per cent—depends on the steelmaking practice and the intended application for the steel. The nitriding steels may contain as much as 1.50% Al. The melting point of aluminum is 1220 F.

Copper. Copper is added to steel in various amounts ranging from a few tenths of a per cent to several per cent. The greatest tonnage of copper steels consists of those containing 0.20 to 0.50% Cu, in which copper increases corrosion resistance without greatly affecting the mechanical properties. Low-alloy high-strength structural steels may contain as much as 1% Cu. Some of the high-chromium, corrosion-resistant steels contain as much as 1 to 4% Cu, and many cast steels as much as 2.50% Cu.

Copper for addition to steel is available in several forms. Virgin copper is best used in the form of pigs. However, scrap material of almost any kind may be used. Because copper does not oxidize in the steel bath, it may be added at any time during the production of the heat. The melting point of copper is 1981 F.

Boron. Boron is used in steel for one purpose only—to increase the hardenability; that is, to increase the depth to which the steel will harden when quenched. Only a few thousandths of a per cent is ordinarily added. Several alloys available for adding boron to steel, range in boron content from about 0.20 to as much as 24.00%. At least four grades of ferroboron can be obtained, having the following approximate compositions:

	(1)	(2)	(3)	(4)
Boron	10 to 14%	14 to 19%	19 to 24%	17.50% min
Carbon	3% max	3% max	3% max	0.50% max
Silicon	4% max	4% max	4% max	1.50% max

Also available are manganese-boron, containing 15 to 20% B, the remainder mainly manganese; and nickel-boron, containing 15 to 18% B, the remainder mainly nickel. Because of the extremely small percentages of boron that are added, and because boron itself is readily oxidized at steelmaking temperatures, some operators prefer an alloy relatively low in boron but containing substantial percentages of other elements that serve to protect the boron from oxidation in the steel bath. Some of these special boron alloys, occasionally referred to as "intensifiers", contain elements that impart desired properties to the steel in addition to protecting the boron. The more important of these alloys, all sold under trade names, have the following approximate compositions. The various boron alloys are available in a number of crushed and ground sizes.

Boron	0.20%	0.20%	0.50%	0.70%	0.70%	1.00%	1.75%	3.50%
Aluminum	10.00%	12.00%	13.00%	6.00%	7.00%	1.50%	14.00%	....
Titanium	15.00%	20.00%	20.00%	10.00%	10.00%	16.00%	17.00%	....
Vanadium	25.00%	13.00%	....	10.00%	....	....	....	....

The Use of Aluminum for Deoxidation and Control of Grain Size in Steel

By H. W. McQuaid* and John Chipman*

THE importance of the control of grain size in commercial steels has become so widely recognized that the method used in obtaining this control is of interest to everyone responsible for the treating and application of commercial steel. "Grain size" refers here to the austenite grain as indicated by the McQuaid-Ehn carburizing test[1] (*see* page 407) or by other suitable measures of austenitic grain size (*see* page 399) and is rated usually according to the chart of the ASTM. Virtually every heat of carbon and alloy steel specified in this country for heat treated parts is made according to a certain melting practice designed to provide properties in the steel that will make it most suitable for the part in which it is to be used. The grain size serves as an indicator of the characteristics of the particular steel in its response to heat treatment, machining and other processing. Grain size is now recognized to be as important, in many instances, as the chemical specification, in the results obtained from the commercial heat treatment of steels.

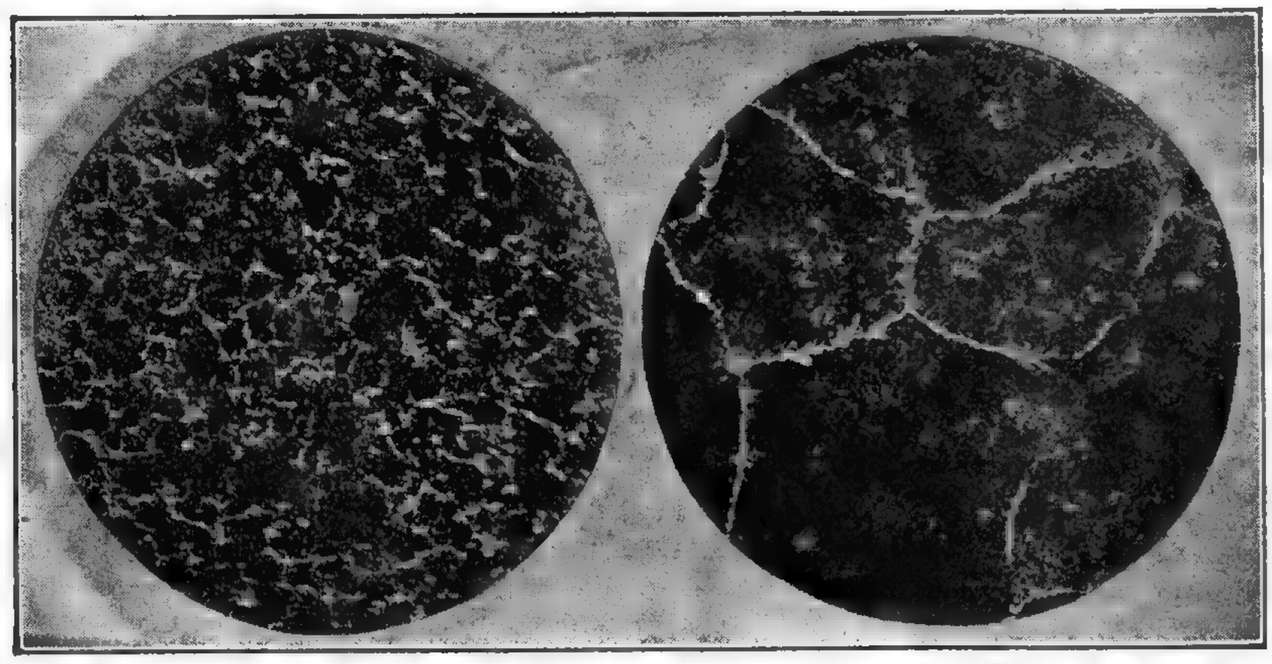

Fig. 1 The fine grain obtained by aluminum deoxidation as contrasted with the coarse grain obtained by deoxidation with manganese. (× 200)

The most important single factor in the control of grain size today is aluminum. Experience has shown that the amount of aluminum required to produce the properties characteristic of the fine-grained steels varies from a few ounces to as much as 4 lb per ton, depending on the condition of the steel to which it is added.

The production of steel within a definite range of grain size is commercially possible only when the specifications cover either a coarse-grained type or a fine-grained type. Although steel can be made that will show an intermediate grain-size range and specifications call for it at times, steel of this type requires very careful control of every factor and is not ordinarily considered "commercial".

One of the earliest published evidences of the effect of aluminum on grain size is reproduced in Fig. 1.[1] The first active work in connecting the aluminum addition with grain size was done hardly more than 20 years ago. As soon as the first chart appeared in 1924 and some steel users insisted on obtaining steel of a definite grain size, it was found necessary to develop a melting technique that would make it possible to meet these specifications commercially.

In a recent paper, J. H. Whiteley[3] has pointed out that at least eight factors influence grain size. These are the temperature, time and rate of heating, the initial grain size, hot work, the rate of cooling after solidification, the aluminum content of the steel, and the state of the carbide.

In the coarse-grained type of steel, a relatively gradual grain coarsening occurs when the steel is heated above the transformation range. In steels that have been made fine-grained by proper addition of aluminum, there is little evidence of grain coarsening until a temperature has been reached several hundred degrees above the transformation temperature. Further heating causes pronounced grain growth and the rate increases with rising temperature. A steel that is cooled during this period of growth invariably shows a duplex structure of fine and coarse grains, rather than an intermediate grain size. The final state of the fine-grained steel, after heating above the coarsening range, may be even coarser-grained than a similarly treated coarse-grained type of steel. Figure 2, taken from the work of Bain,[4] illustrates the effect of heating temperature on the ASTM grain size of typical steels of the two types.

Aluminum as a Deoxidizer. Of the elements commonly used as deoxidizers, aluminum is the most potent and affords the most nearly complete removal of dissolved ferrous oxide. The reaction in its simplest form is written as follows:

$$FeO \text{ (dissolved)} + Al \text{ (dissolved)} = Fe \text{ (liquid)} + Al_2O_3$$

When an excess of aluminum is employed, the inclusions formed in the reaction consist of Al_2O_3 more or less contaminated by other oxides. When a deficiency of aluminum is used, the resultant inclusions are mainly ferrous aluminate with exact composition unknown and probably variable.

The completeness with which aluminum removes dissolved FeO from the steel bath is shown in Fig. 3, obtained from the calculated equilibrium constant of the reaction. This diagram shows, for example, that in a bath at 2910 F, if enough aluminum is added to react with the other oxides present, and to leave a residual of 0.01% metallic aluminum dissolved in the steel, the content of dissolved FeO will be reduced to 0.002%. Similarly, if the bath temperature is 3090 F, and the residual metallic aluminum 0.02%, the dissolved FeO will be less than 0.005%. It should be emphasized that these figures are based on calculated

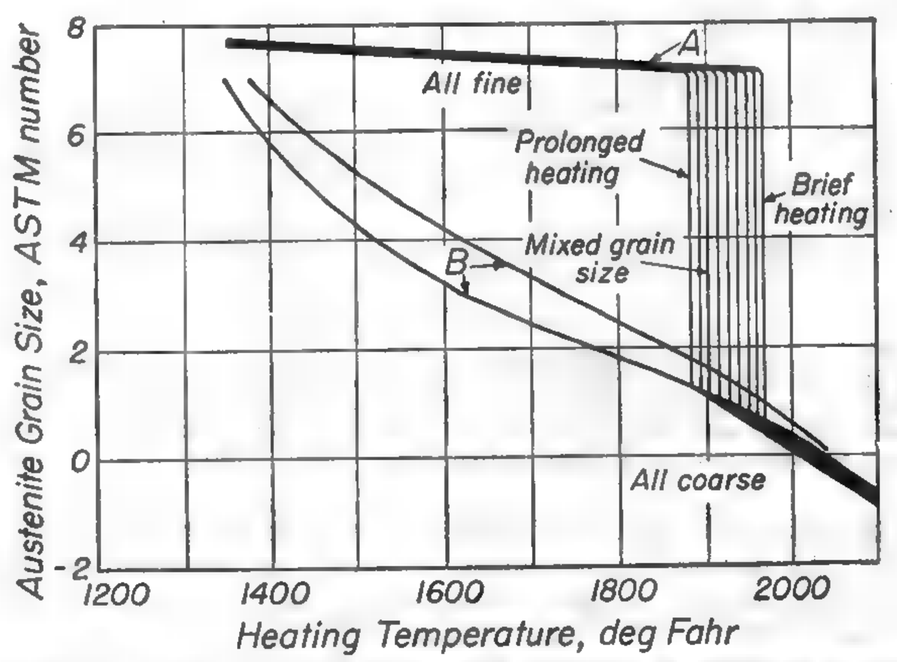

Fig. 2 Comparison of the coarsening behavior of steels of the fine-grained type (Curves A) with those of the gradually coarsening type (Curves B). Note that in general 1700 F is a satisfactory temperature for distinguishing between types. (Schematic, after Bain[4])

* Professor of Metallurgy, Massachusetts Institute of Technology, Cambridge, Mass.

rather than experimental values of the equilibrium constant. However, in view of the limitations of present experimental methods when applied to small amounts of aluminum and oxygen at high temperatures, these calculations are probably more dependable than direct determinations.

Aluminum Requirements. The amount of aluminum that must be added to produce a fine-grained heat depends on the amount of (1) aluminum losses by reaction with air, slag, refractories and the like, (2) aluminum consumed in the deoxidation reaction, and (3) residual aluminum desired in the steel.

The first of these factors depends largely on the individual steelmaking practice and therefore no quantitative

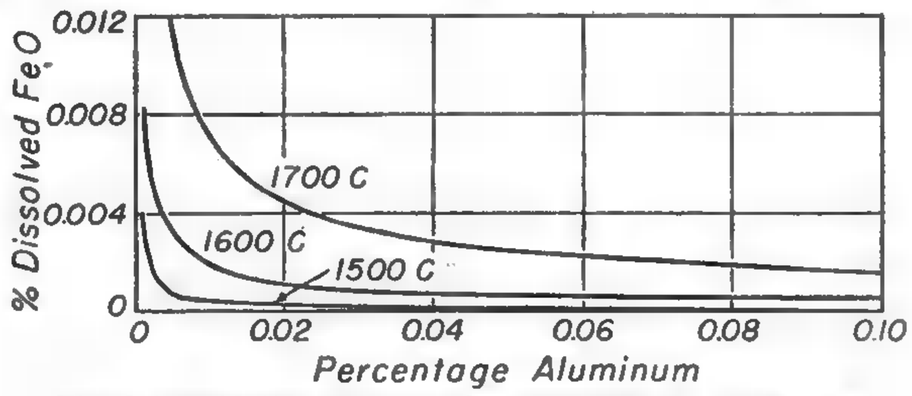

Fig. 3 Deoxidation diagram for aluminum in liquid steel

statement can be made that will be widely applicable. The efficiency of the addition is greatest when added to the molds and least when added to the furnace. Furnace additions are not ordinarily used for control of grain size, except in certain electric furnace practices.

The amount of aluminum required for actual deoxidation of the bath depends on the oxygen content of the metal. In the open hearth this oxygen content is determined principally by carbon content and other deoxidizer additions and, to a smaller extent, by slag composition. The calculated requirement, based on the highest oxygen content normally found in the open hearth bath at any given carbon level, is shown in Curve A of Fig. 4. The addition of silicon reduces the aluminum requirement, especially in low-carbon steels. When substantial quantities of silicon are present, the aluminum requirement in low-carbon steels may differ little from that of the higher carbon grades.

The minimum amount of residual aluminum required to produce a fine-grained steel has not yet been determined

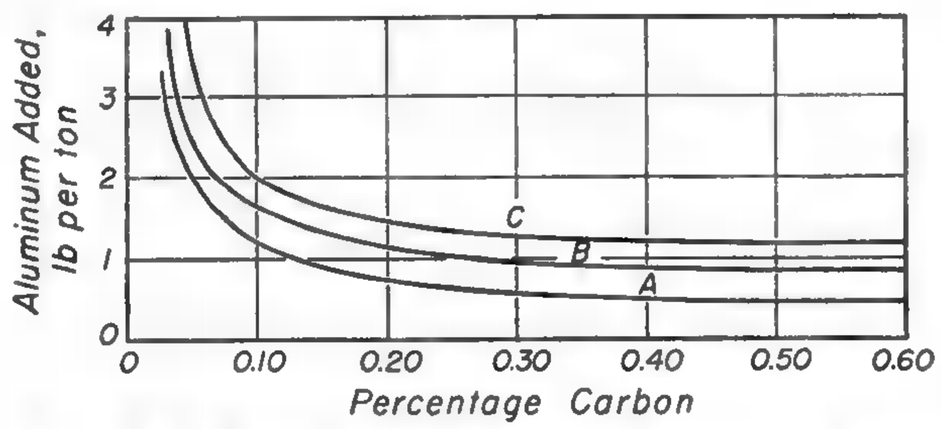

Fig. 4 Effect of carbon content on the normal aluminum requirement for fine-grained open hearth steel (calculated). Curve A shows amount required for deoxidation only. Curve B provides for an excess of 0.02% above the amount required for deoxidation. The normal commercial range of additions is generally between Curves B and C.

with accuracy. Fine-grained steels containing as little as 0.01% Al have been reported. The grain-coarsening temperature reaches a maximum at 0.02 to 0.03% Al,[5] decreasing somewhat with larger percentages, as shown in Fig. 5.

For purposes of comparison, Curve B of Fig. 4 shows the aluminum addition to yield a residual of 0.02%, neglecting losses. Since the efficiency of the addition is never perfect, a somewhat greater amount is required in practice, and the band between B and C represents approximately the addition required in open hearth steel containing little or no silicon.

Additions of Aluminum to Molten Steel. Aluminum must be carefully added to liquid steel, if the losses caused by oxidation are to be within reasonable limits and also if the aluminum is to be effective in its role as agent for control of grain size.

Because of the great affinity of aluminum for oxygen, the addition of stick aluminum to the ladle will result in high losses from oxidation at the surface of the steel. A special effort must be made to keep the aluminum completely submerged in order to prevent both the high loss of aluminum in the slag and the formation of large masses of aluminum oxide in the steel itself.

The common practice in this country is to add aluminum in the ladle whereas, according to Ohman,[6] the Swedish practice is to add it in the mold. Epstein and co-workers[7] show that the mold addition is apparently more effective than the ladle addition in producing fine grain, and theoretically the mold addition should be the more economical. Experience has shown that in large basic open hearth heats more uniform results are obtained by a ladle addition.

In the basic electric furnace, the FeO in the finishing slag and in the bath itself is relatively low. Thus less

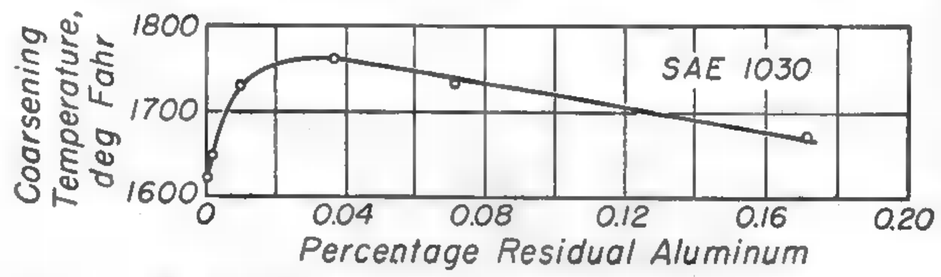

Fig. 5 Effect of residual aluminum on the grain-coarsening temperature of SAE 1030 steel. (Washburn[5])

aluminum is required than when steel is made under a basic open hearth slag, and frequently the aluminum addition is made in the furnace. The additions of aluminum required for obtaining a fine-grained steel are usually smaller than in the open hearth, depending on the character of the charge and the type of slag used. It is difficult to give any hard and fast rule as to the exact amount of aluminum that must be added to produce a fine-grained heat in basic electric furnace practice, but usually from 1 to 1½ lb per ton is sufficient.

Aluminum is commonly added in the furnace by the use of cast aluminum blocks or rods, which should be carefully handled to insure lower losses from oxidation. Aluminum alloys, such as silicon-aluminum-manganese, iron-aluminum-silicon, and iron-aluminum have all been used for better control of the aluminum addition. However, the common practice is still to use metallic aluminum, which is thrown by hand into the ladle while it is being filled.

Aluminum is added to rimming and semikilled steels to diminish the content of active FeO and to control the action in the molds. The amount used in rimming steels ranges from 0 to 0.4 lb per ton in the ladle; for semikilled, 0 to 0.7 lb per ton, and as much as half this amount in the molds. The amount will vary with the carbon and manganese content of the steel, the composition of the slag, the size of the heat and the size of the mold. In general, the rimming action contributes to the removal of the products of deoxidation, and the use of aluminum in the molds does not necessarily lead to the presence of nonmetallic inclusions. The amount of aluminum added is never sufficient to react with more than a small fraction of the ferrous oxide present. Reference to the deoxidation diagram shows that the residual metallic aluminum is virtually nil, in rimming and semikilled steels.

Hot Mechanical Working of Steel

BY THE SUBCOMMITTEE ON HOT MECHANICAL WORKING OF STEEL*

STEEL cast from the melting furnace into ingot molds must be reduced from the ingot by mechanical force through the intermediate stages of bloom and billet to bar, structural shape, plate, sheet, strip, coil or forging, which are the common hot finished forms of steel. For several essential reasons this mechanical force is applied to the steel while hot.

The ingots into which the steel is cast from the melting furnace usually represent a considerable mass of metal that is slow to solidify and cool to room temperature; hence its structure, by virtue of the natural laws that govern the solidification of liquid metal, is a disorderly arrangement of very coarse crystals and incidental impurities with varying chemical composition. Ingot metal in this condition is deficient in ductility and is highly stressed. The stresses can be of sufficient magnitude to cause rupture if the mass is subjected to unequal or sudden temperature changes; hence such ingot metal is unsuited for safe use as an engineering material. Consequently, one of the primary reasons for the hot mechanical working of steel is to bring about as complete a reconstruction and refinement of this crystalline structure as possible. When steel is heated to its plastic state and mechanically worked, the coarse crystallinity of the steel ingot is progressively fragmented and rearranged, and the metal is made to flow in the desired directions. This results in a reduced section of a more homogeneous character and finer crystalline structure. By proper selection of temperature and by mechanical working through rolls, dies and the like, the physical properties of the steel may be improved both statically and dynamically, as compared with those of the original cast ingot.

Hot Working Range and Effects. Heating steel above the so-called "blue-heat range" near 700 F constantly decreases the strength and increases the plasticity until, at a temperature where the lowest melting constituent of the steel starts to melt, the strength is greatly decreased and the mass also loses plasticity and tends to crumble under applied stress. When this point is reached, mechanical work cannot be performed, since the steel will crumble rather than flow.

The optimum hot working temperature is therefore a balance or average between decreasing strength and increasing plasticity. This temperature, varying with different compositions of steel, is covered by a range called the hot working range. The top of the range is limited by a margin of safety below the melting point of the lowest melting constituent; the lower end is limited by the temperature at which strength increases and plasticity decreases to such an extent that excessive pressures are required to cause flow, thus limiting the efficiency of the process and possibly causing ruptures in the metal.

Finishing Temperatures. Although the final properties of the finished steel are often determined by heat treatments applied subsequent to the hot mechanical working, the temperature at which the mechanical work is finished (known as the "finishing temperature") is important in governing the final treatments necessary and the properties obtained. It is generally conceded that the lower the finishing temperature, the finer the structure of the piece when mechanically worked and the more amenable it will be to simple heat treatments. However, the actual temperature is limited by mass, shape, process and other considerations. A special application of this principle is illustrated by the austenitic steels, wherein certain desirable physical properties can be obtained only by closely controlled finishing temperatures. Large forgings and intricate shapes to be flowed into dies require relatively high finishing temperatures, and the required refinements of structure must be taken care of by subsequent heat treatment. For small and simple pieces, the finishing temperatures can be at or near the lower transformation point, which produces refined structures that respond readily to simple heat treatment. A good example of the latter is the Damascene swords, which received repeated light workings at critical and subcritical temperatures. The extremely refined structure thus produced responded to subsequent hardening, and a blade of remarkable properties was obtained.

Cooling Practice. Certain grades of carbon and alloy steel must be slowly cooled immediately after the mechanical working has ceased and while the metal is still hot, to avoid internal as well as external ruptures. Some alloy steels are so sensitive that they require program annealing before they can be removed from the furnace; refer to articles on "Heating Steel for Forging" and "Hot Working of Large Sections", pages 348 and 350.

Ingot Structure. The ingot of cast steel is composed of a mass of grains of various sizes. The central portions of these grains are comparatively pure iron or ferrite, whereas the portions near the grain boundaries are higher in the alloying elements and impurities. The resultant chemical heterogeneity is not entirely destroyed by diffusion or by mechanical hot working. Mechanical hot working causes these nonhomogeneous grains to be elongated in the direction of the working. The macro-etching of a section parallel to the direction of working shows laminations or lines resulting from the chemical heterogeneity. Such

*The members of this subcommittee are S. C. Spalding, *Chairman* (The American Brass Company), A. O. Schaefer (The Midvale Company), J. S. Worth (Bethlehem Steel Company), and J. P. Bindyke (Heppenstall Company).

lines are known as "flow lines" because they indicate the direction in which the metal "flowed" or was worked.

Steel may differ markedly in mechanical properties, especially in ductility and resistance to shock, in a direction parallel to the flow lines and perpendicular to them, particularly if the metal is not clean. In forging practice, consideration must be given to the service for which the forging is intended. As an example, if rings are forged from a slab produced by elongating the ingot into a long block of rectangular section and subsequently trimming it to shape, certain sections of the rings will show radial flow lines and will probably have less ductility than the portions 90 deg away, which have tangential flow lines. For this reason, rings and forgings subject to tangential stresses during service are best upset or expanded in such a direction as to increase the physical properties in the desired way.

In general, the amount of mechanical hot working, or of reduction from the ingot, is regulated by the ultimate use of the steel product and the type of stress involved.

The conditioning of ingots, as well as blooms, billets and slabs, is vitally important in the production of high-quality steel products and should be given careful consideration at all times. Conditioning may be accomplished by chipping, scarfing, swing-grinding, blasting and pickling. (*See* page 346.)

Mechanism of Hot Mechanical Working. The mechanism of the hot mechanical working of steel may be either rolling or forging. Rolling, as the term implies, works the metal by rolls; forging works the metal by hammers, presses and forging machines.

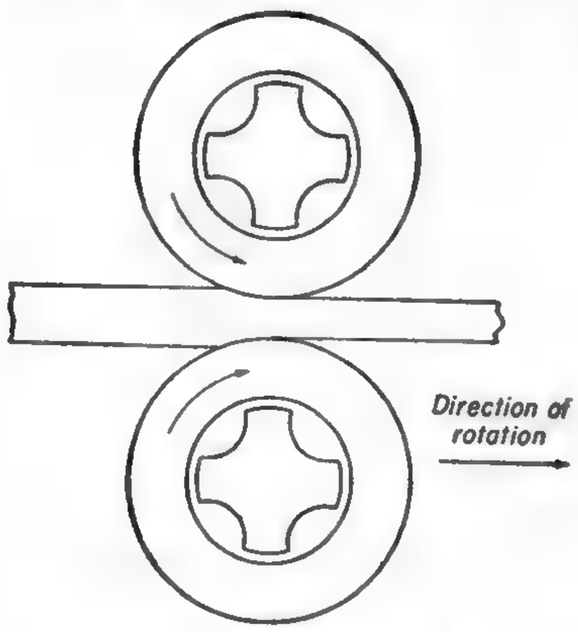

Fig. 1 Action of rolling

Hot Rolling. In this method of hot working, the hot metal is fed between two rolls rotating in opposite directions. Hot rolling accomplishes three main purposes: (1) reduction of cross-sectional area, (2) refinement of structure, and (3) shaping of the metal into desired forms, such as bars, sheets, plates, rails, angles and I-beams. The flow of metal in the rolling operation is continuous and almost entirely in a longitudinal direction (Fig. 1).

Blooming Mill. Except for some flat rolled products, the rolling mill in which the first hot mechanical working of the cast ingot is done is known as the "bloomer" or "blooming mill". The function of the bloomer is to take the hot ingot as received from the soaking pit and break it down or reduce it to a smaller size called a bloom or billet. This bloom is a semifinished product to be rolled subsequently on a billet mill or finishing mill, or used for forgings. The sizes of the majority of blooming mills range from 28 to 54 in. The size is based on the distance from center to center of the pinions. Most bloomers are of the two-high reversing type, which consists of two rolls mounted one above the other and reversible in the direction of rotation to allow for the passage of the metal back and forth through the rolls. Grooves or passes cut in the rolls are of a size and shape to accommodate the ingot and the various reductions desired. The most frequent procedure is a flat center pass called a "bull head", used for breaking down the ingot to the size of the first pass, which is usually 13 to 14 in. wide. In addition, the blooming rolls contain several small passes, usually 8, 6, or 4 in. wide, depending on the finished bloom sizes required.

Operations on Blooming Mill. For example, in rolling a 24-in. corrugated ingot to a 4 by 4 in. bloom on a reversing bloomer, the following method, requiring about 27 passes, is used for alloy steels: The ingot is broken down to 18 by 13 in. under the bull head, by giving light drafts and turning the ingot each pass for the first four passes; then two passes each way are given while the metal is being slabbed to 18 by 13 in. Then it is turned and entered into the 14-in. pass, given two passes and turned; then two passes to 14 by 8 in.; turned and entered into the 8-in. pass, given one pass and turned; then one pass to 5 by 8 in.; turned and entered into the 6-in. pass to achieve 6 by 6 in.; turned and given one pass to 6 by 4 in.; then turned and entered into the 4-in. pass, and finished to 4 by 4 in.

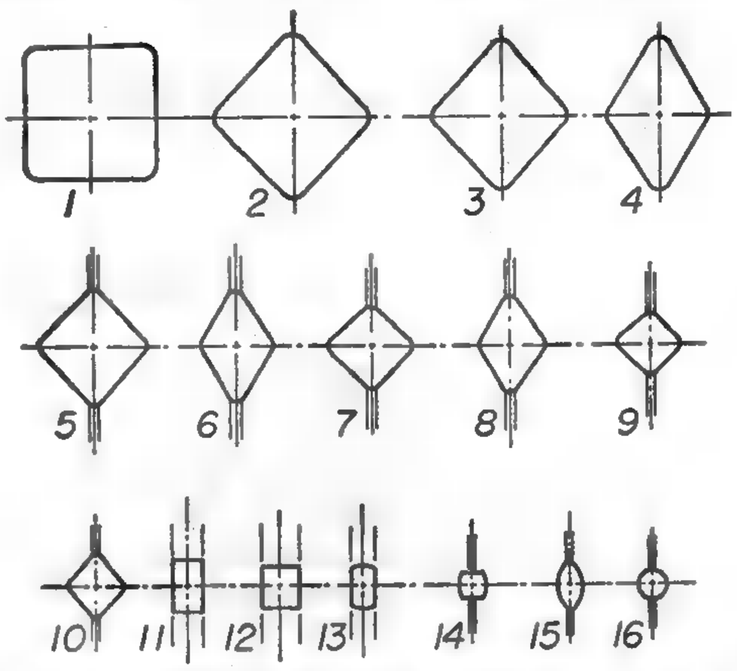

Fig. 2 Passes and reductions of a 4 by 4-in. billet to a ¾-in. round bar

Billet Mill. In order to produce the size of billet necessary for use in the smaller finishing mills, it is customary to reroll the blooms, either with or without reheating, in some type of billet mill. The billet mill may be of the 3-high type, or may be continuous.

Finishing Mill. The billets or blooms, if not used for forging purposes, are rolled on smaller mills into bars of varying shapes and sizes. They may be rounds, hexagons, flats or special shapes. Round bars are generally rolled in open-pass rolls. Figure 2 shows the passes and reduction of a 4 by 4 in. billet to a ¾-in. round. For special steels more passes may be required and the shape of the passes may not be the same as shown.

Flat bars are sometimes rolled in open-pass rolls and many times are rolled in tongue-and-groove rolls.

Sheets. The practice covering the rolling of sheet and strip is given on page 352.

Plates. Plates are produced either from slabs or directly from ingots by hot rolling. They are termed "sheared plates" or "sheared mill plates" when rolled between straight horizontal rolls only and trimmed on all edges. They are termed "Universal plates" or "Universal Mill plates" (abbreviated "U M" plates) when rolled between straight horizontal and vertical rolls and trimmed on the ends only. Universal plates are sometimes rolled in grooved rolls.

There are various types of mills for producing sheared plate, such as two-high, three-high, four-high and tandem. The two-high mill has two horizontal rolls propelled in opposite directions. In one type of mill the material is passed one way and then returned overshot for repeating operations until finished. In another type, the direction of the rolls is reversed after each draft, so the material passes back and forth through the mill as in a blooming mill.

The three-high mill has one top and one bottom power-driven roll of the same diameter, and one middle or floating roll of smaller diameter. The middle roll rotates by friction and is lowered or raised as the material passes back and forth through the rolls. This type of mill is fitted with tilting tables both in front of the rolls and behind them, and these tables are raised or lowered in order to re-

ceive and return the material through the top and bottom passes. The direction of rotation of the rolls is constant.

The four-high mill consists of one or more stands of rolls in which the top and bottom, or backing-up rolls, are larger in diameter than the two work rolls in the center. The material being rolled passes between the two center rolls, and the top and bottom rolls act as "stiffeners" to back up the center rolls. In one-stand mills, the direction of the rolls is reversed between passes so that working takes place as the material is passed back and forth through the mill. In the case of mills having several stands in tandem, the rolling is the same as that for hot rolled strip described on page 352.

Tandem mills have two or more stands of rolls so arranged on a straight line as to permit the product to be run continuously from one to the other. The first stand in this arrangement is called a "roughing mill" and may be either a two-high, three-high or four-high mill. The other stand or stands may be either three-high or four-high and are usually called "finishing mills".

It is customary to cross-roll in producing sheared mill plates; that is, to roll the ingots or slabs in both directions so that tension and bend tests taken both parallel and transverse to the greatest dimension give quite similar results.

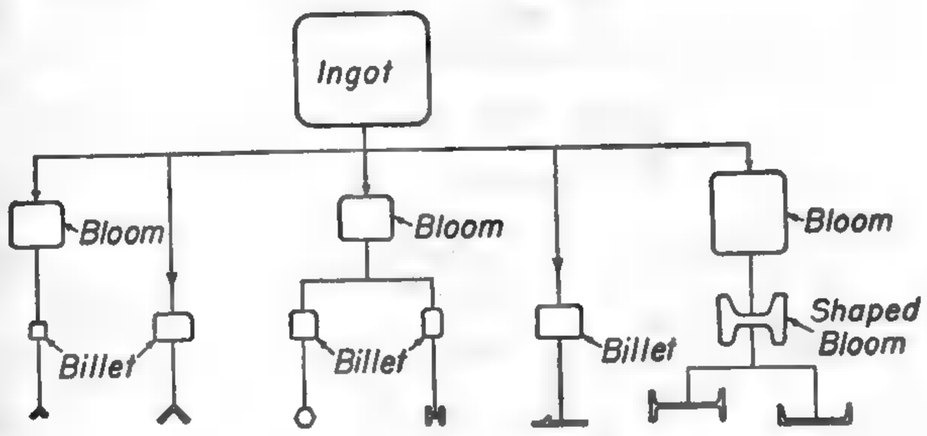

Fig. 3 Bar and structural shapes

The Universal Mill is usually a reversible mill consisting of two horizontal and four vertical rolls, the latter being so placed that they can be manipulated for side rolling, one in front and one behind at each end of the horizontal rolls. This arrangement produces a straight, almost parallel "mill" edge. By this method of rolling, the slab or ingot does not receive cross-rolling, but is merely elongated in one direction. Therefore, this product cannot be expected to have ductility as great as that of sheared mill plates when tested in tension transversely to the direction of rolling, or when bent parallel to the direction of rolling.

Shapes. Steel can be rolled into many different shapes, and special passes are made in rolls, depending on the specified shape of the finished product. In the majority of cases, these shapes are rolled from a square or rectangular bloom or billet; all the shaping is done in the intermediate passes of the mill.

Forging. The term "forging" may be used to describe all mechanical hot working of metal, but it is usually applied more specifically to the mechanical working of metals by the application of an intermittent force rather than of a continuous one, as in rolling. Thus a forging hammer works the metal by successive blows, while a forging press applies a kneading or squeezing action. These typify the simplest tools for forging. There are numerous other forging devices in addition to these, including drawbenches, which form objects by forcing them through dies; forging machines that can be made to perform a series of varied operations by the mechanical action of a series of dies; forging rolls that apply intermittent action by the cam principle; extrusion presses and the like. Many of these are described in other articles in this Handbook, pages 33 to 43.

Hammering. The simplest and oldest of forging operations is performed by the blacksmith in forming metal objects by hammering the hot metal on his anvil.

Early mechanical hammers consisted of means for raising a heavy upper die and then allowing it to fall on the object to be forged. In the so-called "helve" hammer, the falling weight was attached to a long beam or lever, having the fulcrum in the central portion. A cam or similar device on the farther end forced the weight to be raised, and then released it.

Early steam hammers utilized a steam cylinder for raising the ram, which was then allowed to fall by its own weight on the object to be forged. Modern board drop hammers still use this principle. The upper die or falling weight is attached to a board or boards, and is raised by the action of rollers on this board. At the top of the stroke, the rollers release the boards, and the upper die assembly falls by its own weight.

Most modern steam hammers are "double acting"; that is, steam is applied on both sides of the piston, and the upper die is driven down upon the work metal by power, in addition to the force exerted by the falling weight.

The steam hammers used for "open-die work", as described in this section, usually have anvils mounted on foundations separate from the one supporting the hammer frame, with consequent reduction of vibration in the working parts. The hammers used for "closed-die work", variously called "hot die forging" or "drop forging", must be more rigidly constructed to insure alignment of the dies during the striking. In hammers of this type the ram that supports the upper die, slides in a series of parallel grooves in the hammer frame. The anvil must be part of the same rigid structure; one block supports both the anvil and the columns of the hammer. This type of structure requires massive parts for rigidity and strength.

Drop forging is discussed on page 36.

Pressing. Hot mechanical working may also be applied to metal objects by presses, which differ from hammers in that they subject the metal to a series of squeezing actions, rather than to a series of blows.

Forging presses may be mechanical, hydraulic or steam-hydraulic.

Mechanical presses* are most widely used for nonferrous metals. They find special application, however, in the production of quantities of identical forgings, such as artillery shells. Presses of both toggle and screw types are used. They have somewhat different action; the toggle press gives more of a squeezing and the screw press gives a sudden pressure or bump approaching that of a hammer. The screw press consists essentially of an enclosed frame similar to a drop hammer with lower die mounted on the anvil. The upper die is carried on a double- or triple-thread screw, which is turned through a large wheel by two friction disks rotating on opposite sides of the wheel. When in contact with one disk, the screw is rotated rapidly in a direction to drive the die down onto the anvil; then the other disk is thrown into contact, reversing the screw and raising the die. The operation of the toggle presses is similar to that of forging machines, as described in another article in this Handbook (page 38).

Hydraulic or steam-hydraulic forging presses are used principally for the production of steel forgings, usually of the larger sizes. The purely hydraulic type is driven by pumps, usually acting through an accumulator. The steam-hydraulic type uses a steam-hydraulic intensifier to supply the water at high pressure for the press cylinders. Such presses consist essentially of one or more cylinders, usually mounted on the top of the press, to which water at high pressure is admitted. The admission of water into the cylinder pushes down a ram to which is attached the crosshead, which is guided by the press columns. The upper die is attached to the lower face of the crosshead. The lower die is supported on a base plate to which the columns are also attached. Thus the whole unit is self-contained, and only a simple foundation is required. For lifting the crosshead, auxiliary cylinders supplied with either steam or water are usually attached to the main cylinder or its entablature.

The largest forgings ever produced have been made in forging presses of the hydraulic or steam-hydraulic type.

Tools for Hammers and Presses. The tools used in connection with forging hammers and forging presses find their counterparts in the blacksmith's hand tools.

Auxiliary equipment on the forging hammer must with-

* *See* "Mechanical Press Forging", page 41 in this Handbook.

stand the vibration or impact of the forging blows. Because of this, manipulators have not been developed and used on hammers as extensively as they have been applied on presses. Smaller forgings are held in tongs, sometimes supported by chains from overhead. Occasionally the shape and dimensions of a forging are such that it need not be held in tongs or similar equipment, but is kept in place on the die by lever bars. Larger forgings are held by porter bars that have an enlarged end or chuck for holding the piece to be forged, and a counterweight on the opposite end. Manipulators or charging machines may be used to charge and remove pieces from the heating furnace and to place them on the die where they may be grasped by tongs, porter bars or similar holders.

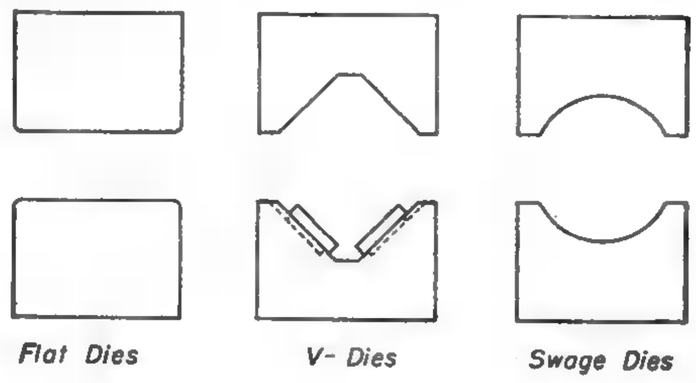

Fig. 4 Simple forms of forging dies

Manipulators for forging presses have been so far developed that now virtually all but the larger forging presses have such equipment. Because of the absence of shock, manipulators are used to hold the piece on the die, to feed it between the dies between squeezes, to rotate it and so on. The selection of the proper manipulators for a press plant is important because it has a vital effect on the efficiency and production of the shop. Manipulators may be suspended from an overhead crane, but are more frequently operated on the shop floor, often on rails. They utilize power-operated grip jaws to hold the forgings.

The largest forgings are held on presses by means of chains actuated by power-operated sprockets for turning.

Auxiliary tools for hammers and presses include slicing bars for cutting forgings to length, pegs for gages or spacing blocks used in bringing forgings down to size, V-tools to initiate setdowns or changes in section on forgings, and swages for finishing rounds.

Forgings are frequently cut to length at the hammer or press with a gas torch. Burning equipment is also frequently employed for hot scarfing or the removal of surface defects. Availability of such equipment at the forging tool makes it possible to remove defects with a minimum delay, without need for controlled cooling and removal by machining, chipping or grinding.

Dies. Dies may be considered the most important tools used on hammers and presses. The dies for closed-die or drop forging must be most carefully designed, made and treated. These dies are described in another article in this Handbook (page 36). Dies for open work are of three basic types, as shown in Fig. 4.

Flat dies are most commonly used for hammer work. Even round forgings, such as those used for the manufacture of round bars or shafts, may be forged down in flat dies as hexagons or octagons, and the corners may or may not be knocked off subsequently, or the forgings may be rounded in swage dies.

The use of V-dies, either for both upper and lower dies or for the lower die alone with a flat upper die, is most common for press operations. The greater the power that can be exerted by the press, the larger the die surface that can be used, and therefore the more effective the press can be in working the central portions of large masses.

Mandrels, both supported and unsupported at the ends, are used for hollow forgings. Punches are used for opening holes in or through forgings. Coring tools are also used for the same purpose.

Hammer and Press Operations. The principal forging operations, performed either by the hammer or the press, are as follows:

1 *Rounding up, cogging or roughing.* These first operations on the ingot are meant to refine and rearrange the surface crystals and to consolidate the central portion of the ingot.

2 *Cutting or slicing.* This operation cuts blocks, billets or forgings to length.

3. *Forging down or drawing.* This operation increases the length and decreases the diameter of the piece.

4 *Upsetting or forging* so as to change the major axis of the forging through an angle of 90 deg. Thus bars are upset to form disks.

5 *Setting down.* This reduces the cross-sectional area of a portion of the forging, as the journals of a shaft are forged down. Large "setdowns" are accomplished under the press, using a V-tool to start the reduction. Large fillets should always be allowed.

6 *Punching or coring.* Punches are used to pierce or open a hole through a forging. The hole is usually carried almost all the way through; then the forging is turned over, and the punch is started from the opposite side. Only a very small portion of the metal is removed. Coring utilizes a hollow punch to cut out the central portion.

7 *Hollow forging on mandrels.* After holes have been punched or cored, mandrels may be inserted, and the forging is then continued on the mandrels to produce hollow cylinders or rings. Mandrels are supported at the ends for expanding the piece by forging between the upper die and the mandrel. The forging down or drawing of hollow forgings is carried out on the unsupported mandrel.

Conditioning of Semifinished Steel

BY THE SUBCOMMITTEE ON CONDITIONING OF SEMIFINISHED STEEL*

IN the fabrication of steel, rejections of product are occasionally caused by steel imperfections, such as pipe, segregation, porosity, seams, laps, scabs, slivers, and the like, that are developed in the casting, heating and rolling of ingots into blooms, billets and slabs. Semifinished steel is inspected and conditioned to remove defects that are considered injurious for the intended application, in order to avoid the shipment of steel of unsatisfactory quality.

Inspection Prior to Conditioning. As a preliminary to conditioning for surface imperfections, steel is inspected for internal defects. Methods of inspection consist of:

1 *Examination of Sheared Ends for Piped Steel.* Pipe will usually show as a fairly distinct lip on the sheared end.

2 *Fracture Testing.* (*a*) To fracture, only shallow nicking or cutting is required, so most of the fractured cross section may be examined for pipes, cooling cracks, and injurious porosity or segregation. (*b*) Hardened disks are fractured in the inspection of certain steels to evaluate the results of deep etching. A hardened disk of full cross section is broken under a hammer or special fixture and longitudinal surface or surfaces are exposed. In some instances the piece is nicked in order to localize the break.

3 *Etch Testing.* A cross section is sawed from the billet and etched in hot acid, a test that will reveal any pipe condition present, and also segregation, blowholes, and general unsoundness of the interior, if present to an injurious extent. (*See* the article on page 389.)

Because internal defects cannot be removed after the steel is made, unfit material must be rejected. Accordingly, any internal inspection or testing is usually completed and rejections are disposed of before surface conditioning.

Extent of Conditioning. The extent of conditioning work performed depends on the final application of the steel.

*The members of this subcommittee are J. H. Flaherty, *Chairman* (Jones & Laughlin Steel Corporation), J. B. R. Anderson (Carnegie-Illinois Steel Corporation), E. V. Bennett (Bethlehem Steel Company), L. Fogg (Youngstown Sheet and Tube Company) and H. J. Weigel (Republic Steel Corporation).

When the surface requirements of the finished product are nominal, the conditioning is merely sufficient to remove scabs, tears, or heavy slivers, in order to permit passage of the billets through the rolling stands without damage to guides or rolls.

The majority of commercial products, including bars for cold finishing, bending, machining, welding, or common forging purposes, require somewhat better conditioning. This involves the removal of open and deep seams, cracks and slivers, but not the removal of light surface seams.

The most severe trade requirements, where a minimum of seams is essential in the finished part, necessitate extra processing and conditioning and make mandatory the removal of all visible defects. In order to reveal small defects, mill scale may be removed by high-pressure water jets, pickling, shot blasting or torch descaling.

Although surface conditioning is largely confined to semifinished steel, frequently forging ingots, castings, forgings and finished bars are conditioned for removal of similar defects.

Methods of Surface Conditioning. In early practice, surface conditioning was performed rather roughly with hand hammers and chisels. When that method was found inadequate, special beds were provided where the steel could be inspected closely and defects could be removed with pneumatic chipping hammers. Chipping involves a great deal of manpower and has led to the successful development of other methods. Some of these new methods employ machine tools, variously referred to as billeteers, deseamers, or gougers (which, in principle, are flexible-head planers or millers). Such tools are capable of cutting larger and deeper chips of metal more quickly than the pneumatic hammer. They are useful where the entire surface is to be removed or where deep defects are involved, and are particularly applicable to billets and blooms more than 4 in. sq.

Currently, torch scarfing is perhaps the most widely used conditioning method. The oxyacetylene torch has been progressively developed until today, in the hands of a competent operator, it will remove a great deal more metal per hour than a chipping hammer. Since the cost of fuel is a major factor, natural gas and other substitute fuels are often used. One of the main disadvantages of torch conditioning lies in the reaction of hardening grades of steel to the high temperature of the torch, and the quenching action of the adjacent cold steel. Steel of such grades is preheated before scarfing or torch cutting operations, to avoid the quenching action and residual stresses.

Turning or peeling steel on special lathes is another means of conditioning. This method is used for the most part on round billets for piercing into seamless tubes. It is necessary to inspect turned rounds to detect seams not removed by the arbitrary cut, and their removal by chipping or scarfing is a supplementary operation. The advantages of the method are that less prior conditioning is required and complete removal of the surface metal is effected rapidly.

Grinding is still another conditioning method, used on extremely hard alloy steels where other methods are not applicable. It is usually employed where seams or defects are fairly shallow. The billets are placed in position under a grinder track, which relieves the operator of the load of the wheel, and makes it necessary for him to apply his weight only at the spots to be conditioned.

Methods of Quality Control.* One of the duties of the steel works metallurgist is to minimize steel defects through quality controls in the melting, pouring, heating and rolling operations. Such controls are exerted through designation of the chemical limits, deoxidation, pouring, mold preparation, ingot handling schedules, heating and rolling practices.

To hold down conditioning costs, rejections and losses, many methods are employed, including hot topping, improved mold design, mold preparation, reheating, rerolling, hot scarfing in the mill, and slow cooling.

For certain grades or qualities, the use of a refractory top on the ingot mold is primarily to concentrate all the contraction cavities, porosity, slag enclosures and excessive chemical segregation within the hot top portion, and to eliminate such defects from the main body of the ingot.

Mold preparation involves proper mold surfaces, temperature, cleaning and coating, to avoid defects caused by splash, spray, hanger cracks, bleeding or pits.

"Saddening" is the taking of two to eight light passes on a heated ingot and then recharging into the soaking pits in order to toughen the skin. Reheating at some intermediate stage in the rolling also permits scaling and makes possible higher temperatures and greater plasticity in the finishing passes. This is known as "double conversion" and tends to minimize surface defects. Conditioning may be resorted to at the intermediate stage in conjunction with the double conversion.

In recent years, scarfing torches have been set in some mills for the removal of the original surface of the bloom or slab during the rolling operation. These torches remove from $\frac{1}{32}$ to $\frac{3}{16}$ in. of surface metal and have the advantage of working on hot steel. However, they are not selective in their operation; they remove the entire surface under the torches and not merely localized defects. Deep defects that will not be removed in this way require further conditioning.

Some grades of steel are air hardening; that is, they will harden during cooling in still air. When that occurs, enough stress may be developed to crack the billet or to emphasize cracks or seams already present. In order to avoid this, the semifinished steel is piled hot in pits, buried in ashes or set in covered cars and cooled slowly. More recently, furnaces for controlled cooling (gas- or oil-heated) have been installed in some mills, to enable suitable control of temperature for each grade of steel. Such a procedure has the advantage of increasing cooling capacity, because of better control of cooling cycles, and gives greater assurance of freedom from flakes.

Internal Defects. The more common types of internal defects found in semifinished steel are the following:

1 *Pipe.* A cavity formed in metal (especially ingots) by contraction during solidification.

2 *Porosity or Blowholes.* These terms describe unsoundness produced, during the solidification of the metal, by evolved gas failing to escape and being held in pockets which elongate in rolling.

3 *Segregation.* This is the variation of chemical composition throughout the ingot, caused by selective freezing of the various soluble constituents of steel. Segregation may be negative as well as positive, as expressed in variation from the average composition of the heat.

4 *Inclusions and Stringers.* Nonmetallic particles caused by deoxidation products or slag, which become entrapped during solidification. They are present in greater size and number in sulfurized steel.

5 *Flakes or Cooling Cracks.* Two theories exist as to the cause of these internal cracks or discontinuities which may occur in steel that has been improperly cooled: (*a*) Cooling stresses are occasioned by difference in temperature between the inside and outside of an ingot, bloom or billet, and hydrogen content. (*b*) Hydrogen is assumed to come out of solution at subcritical temperatures and to build up pressures that cause ruptures.

Factors promoting flakes or cooling cracks are: rapid rates of cooling, large sections, high carbon content, high alloy content, and cold weather.

Cooling cracks present in large sections can sometimes be welded completely by a reheating and rerolling operation, assuming that there is a sufficiently large reduction in cross section.

Surface Defects. The principal types follow:

1 *Seam.* A crack in the metal surface, which has been closed but not welded. These are caused by cracks in ingots, which have been elongated during rolling.

2 *Scab.* A flat bead of metal caused by a rolled-in splash on the ingot surface.

3 *Sliver.* An elongated layer of metal loosely adhering to the billet and usually caused by elongation of surface tears in rolling.

4 *Spongy, Burnt or Feathery Surface.* A condition attributed to insufficient deoxidation, chemical composition, excessive flame impingement in blooming-mill heating, or improper rolling temperatures.

* For information concerning the application of statistical methods to quality control, see the article on page 187.

5 *Corner Cracks.* A crack in bloom or billet, resulting from planes of weakness developed at mold corners or corrugations during solidification of the ingot.

6 *Lap.* A surface defect that has the appearance of a seam, caused by folded-over hot metal, fins or sharp corners, rolled or forged but not welded into the surface.

7 *Overfill.* Excessive metal on the corner of rolled steel, resulting from improper rolling temperature or incorrect setting of rolls. *Underfill,* or incomplete filling of corners, is a defect of an opposite nature.

8 *Double Skin.* A lamination type of defect, showing a surface layer separated from the main body of the bloom by a thin film of oxide. Double skin is usually at a maximum in the bottom part of an ingot, and is frequently caused by solidification of original metal splash followed by partial remelting and incomplete welding in rolling.

9 *Guide Scratches.* Scoring caused on the surface of the billet, in the direction of rolling, by improper setting or poor condition of guides.

The imperfections described above are the main surface defects, although occasional instances of rolled-in scale, embedded refractory or other foreign matter, may occur.

Heating Steel for Forging

BY THE SUBCOMMITTEE ON HEATING STEEL FOR FORGING*

THE details to be observed in the practice of heating and forging steel depend to some extent on the type and size of forging, the method of forging, the composition of the steel and the subsequent disposition of the forging. The following suggestions for heating prior to forging are based on normal good practice for the production of carbon and low-alloy steel forgings from bars and billets as large as 9 in. square. The heating of stainless steels, tool steels and the other highly alloyed ferrous materials is not discussed specifically in this article; however, many of the general considerations mentioned here apply also to the more highly alloyed steels.

Eight major factors should be considered in the heating and forging of steel: scaling, decarburization, overheating, burning, equipment used for heating, rate of heating to forging temperature, forging temperature, and cooling after forging.

Scaling. The surface layer of iron oxide resulting from exposure of steel to oxidizing atmospheres at high temperatures is called scale. Scaling causes loss of metal and loss of time in removing the scale, and is responsible for other forging difficulties. Scale may react with the refractory of the furnace lining or hearths to form a slaglike material, with consequent deterioration of the refractory. Scale is often hammered into the surface of the forging, causing a pitted surface and sometimes sticking of the piece in the forging dies. Since it is desirable to have as little scale as possible, a minimum time of heating should be employed. The presence of free oxygen in the furnace atmosphere causes a decided increase in scaling. However, when the presence of free oxygen is avoided, little is gained in reduction of scale if more than a moderate excess of carbon monoxide is present. It has been found that in a gas-heated furnace, using ordinary city gas, nearly the same amount of scale is formed when the atmosphere contains 8.0% CO as when 0.5% CO is present, and it is necessary to exceed 12% CO before a marked reduction in scaling is produced. This applies also to furnaces heated with oil or butane, provided no free oxygen is present. The rate of scaling increases rapidly with increased temperature.

Decarburization. Little is known about the rate of decarburization in different atmospheres at forging temperatures higher than 2000 F. It is probably safe to assume that increasing the heating time or temperature will increase the depth of decarburization. Since decarburization causes great loss of strength at the surface, all precautions should be taken to avoid decarburization or to be certain that the decarburized layer is machined off. Because forging bars and billets are nearly always decarburized as received from the mill, and under ordinary conditions of heating for forging, some additional decarburization will occur, it is essential to machine off the decarburized layer if resistance to high stress is required.

When the hardness of unmachined forgings is measured, it is necessary to remove the decarburized layer in the area to be tested, in order to get accurate readings.

Overheating. Overheating may be produced in the forgings by heating to such a high forging temperature that the austenite grains become excessively large. This grain size results in impaired physical properties of the metal, unless the grain is refined by proper mechanical or thermal treatment. It has been found that the overheating of alloy steels can be so severe that normalizing, quenching and tempering does not refine the grain or refines it incompletely. This may be most easily observed by fracturing perpendicular to the grain flow, after normalizing, quenching and tempering to about 300 Brinell. Sufficient further mechanical working of the steel, as by forging or other means, will eliminate this coarse grain condition, provided it is done at temperatures below those causing the overheating.

Burning. If parts are heated to a temperature above that causing severe overheating, the phenomenon known as burning occurs. Burning is an extremely overheated condition that causes the more fusible constituents of the steel to melt. This melting usually occurs at austenite grain boundaries and results in hot shortness of the material. The term burning, as applied to steel, is somewhat misleading, because the chemical reaction of the steel with oxygen is not necessary to produce the so-called burning. This is evident since steel that is burned entirely on the inside, may appear quite satisfactory on the surface. In general, however, the surface of a burnt forging shows evidence of the burning. The burning of steel entirely on the inside is usually caused either by decarburization on the surface or by an inside temperature much hotter than the surface at the time of forging. However, the presence of turbulent free oxygen in the atmosphere surrounding the steel will usually cause the steel to burn at a much lower furnace temperature than with no free oxygen.

Burning may occur in the heating furnace before the steel has been forged at all. Especially when the flame is of an oxidizing nature, direct impingement of it against the steel is likely to produce spot burning or overheating, and should therefore be avoided. Likewise, impingement of a jet of air against the steel is to be avoided in the heating furnace. Above about 2400 F, air oxidizes steel so rapidly that the temperature of the metal will increase because of this reaction. However, air may be used to blow the scale off the steel during the forging operation, provided the proper forging temperature is not exceeded.

Equipment. Several types of forge furnaces are prominent in the heating of billets for forgings; of these the slot type, gas or oil-heated, is the most common, although it is the most difficult in which to attain good automatic temperature control. For better control, closed furnaces are more desirable, such as the stationary-door type, rotary-hearth or continuous-pusher type, all usually heated by gas or oil. (*See* "Fuels and Fuel-Heated Industrial Furnaces", page 267, and "Electrically Heated Industrial Furnaces", page 273.) Because of the greater ease of temperature control and better control of the heating cycle, continuous furnaces should be employed whenever possible. The use of the continuous furnace has advantages, in that the stock can be uniformly preheated at any rate of heat input desired, and the cycle or time in the furnace can be standardized under mechanical control, thus removing the danger of leaving the stock in the furnace too long or not long enough. Electrical induction heating has been used

*The members of this subcommittee are W. E. Jominy, *Chairman* (Chrysler Corporation), A. F. Christian (Wyman-Gordon Company) and E. O. Dixon (Ladish Drop Forge Company).

for some special applications. (*See* the article on "Induction Heating", page 280.)

All the furnaces mentioned above should have equipment for control of temperature, such as a platinum-rhodium thermocouple or a controlling radiation-pyrometer sighted on the inside of a refractory tube. Extreme care must be taken to protect these couples from contaminating influences, such as iron, silicon and carburizing gases; and frequent checks are necessary in order to be certain of the accuracy of the thermocouples. It is important that the thermocouple should record the temperature of the steel and not that of a cool part of the furnace or flame temperature. By far the most frequent cause of difficulty with temperature-controlled equipment is inequality of temperature in the furnace so that the thermocouple does not indicate the temperature of the steel.

If optical or radiation pyrometers are used, it should be remembered that smoke, the reflection of incandescent flames on furnace walls, the distance from the hot object, the presence of scale and lack of blackbody conditions appreciably affect the accuracy of the reading. It is possible to correct for lack of blackbody conditions and the presence of scale, but much smoke or reflection from flames may make the readings valueless. On the other hand, if conditions can be made ideal, accurate readings are obtainable with the optical pyrometer. (*See* "Pyrometry", page 174.)

In heating with oil, the selection of the proper burner is essential; good atomization and proper combustion are not only economical but lead to safe heating practice. The burner selected should be as simple in design as possible for easy maintenance and for good atomization, and should be constructed to avoid the formation of carbon deposits ("nigger heads") in the burner or furnace. The design of the port and installation of the burner should be given much thought if the burner is to be efficient and economical to operate and repair. When heavy oil is used, provision for preheating the oil must be made in order to obtain proper combustion. Heavy fuel oil is satisfactory for use as a forging fuel when proper precautions are taken to insure satisfactory uniformity of temperature and pressure. The viscosity of oil varies with temperature. Unless special precautions are taken, constancy in rate of flow may be interrupted by alterations in line pressure caused by variations in oil temperature, pump pressure, discharge pressure at the end of the tail pipe, fluctuating use of oil throughout the circulating system, and other conditions subject to change. The temperature-viscosity index of different fuel oils varies. Precautions should be taken also to prevent stratification of various shipments of oil in storage tanks and undue accumulation of sludge. Sludge accumulation may be hastened by overheating. Oil should be free from water, solids and other foreign matter when it reaches control equipment or burners.

Rate of Heating to Forging Temperature. The time of heating should be just sufficient to bring the center of the bar or billet to the forging temperature. Longer heating than this results in greater scale formation, greater decarburization and larger grain size.

Plain carbon steels of 0.50% C and less, in sizes up to and including 3 in. in diam or thickness, may be heated at the maximum rate of 5 min per in. of diam or thickness; alloy steel bars 3 in. in diam or thickness may be heated at the maximum rate of 6 min per in. of diam or thickness. From 3 in. to 9 in., the heating time per inch of diameter or thickness should not be less than 15 min. Although this is common practice, some metallurgists consider a slower rate more desirable. For steel that contains more than 0.50% C somewhat slower rates of heating should be used in order to avoid rupturing from too rapid heating. The rate of heating to be used will depend on the size of the bar and its composition. In general, bars that contain 1% C or more and have a diameter of 1 in. or more, should be preheated between 1300 and 1400 F before being placed in the forging furnace.

Forging Temperatures. The safe forging temperature for steels depends on the composition of the steel, the furnace atmosphere, the temperature-measuring equipment, furnace equipment and type of operation.

In general, for either carbon or alloy steels the forging temperature is lowered as the carbon content of the steel is increased. The effect of the various alloying elements on the forging temperature must be considered in relation to the quantity used and the other elements that are combined with them.

The flow of steel or its plasticity at the forging temperature depends on the composition of the steel and the forging temperature. The higher the forging temperature, the greater the plasticity, with resultant low operating costs; but the finishing temperature is then generally higher, producing coarser grains. With higher forging temperatures the steel is heated nearer to the overheating and burning range; consequently good furnace equipment and accurate devices for measuring temperature are necessary to avoid the danger of burning.

Table I gives the maximum temperatures recommended for forging carbon and alloy steels.

Table I. Maximum Forging Temperatures

Carbon, per cent	Maximum forging temperatures for carbon steels, deg Fahr	Maximum forging temperatures for alloy steels, deg Fahr
0.10	2400	2350
0.20	2375	2300
0.30	2350	2250
0.40	2350	2250
0.50	2300	2200
0.60	2250	2200
0.70	2225	2175
0.90	2150	
1.10	2075	
1.50	1900	

The term "alloy steels" means the usual structural, oil-hardening steels, such as the 4300, 4600, 5100 series and the like. Certain types of stainless steel, steels for use at high temperatures, and tool steels require special time-temperature cycles and, in some instances, special furnace atmospheres.

Finish Forging Temperature. The temperature at which to stop forging depends on several factors, all of which must be considered. It should be well above the transformation range to prevent rupturing of the steel and excessive wear on the forging and trimmer dies. It should be low enough to prevent excessive grain growth. Except for high-carbon steels, a finishing temperature of 2000 F should prove satisfactory.

Cooling after Forging. The rate of cooling after forging is an important factor in the production of sound forgings. Too rapid cooling results in internal ruptures. The material used and the size of the finished forging are controlling factors in determining the rate of cooling.

Alloy steels are much more susceptible to cooling bursts than plain carbon steels. Small forgings with sections less than 3 in. are usually permitted to cool in air. Large forgings weighing more than 100 lb frequently require slow cooling, even though their section is less than 2 in. When slow cooling is required, it is usually accomplished either by furnace cooling or by burying in a medium such as crushed blast-furnace slag. If blast-furnace slag is used, the rate of cooling can be controlled to some degree by the size of the slag particles. It is desirable to bring the temperature down to 350 F before removing the steel from the slow cooling pits.

Precautions to be Observed in Forging.

1 Cold steel should not be loaded into a hot furnace when larger sizes are used. Sizes up to 4 in. in diam are commonly put into a hot furnace, unless made of high-carbon or special alloy steel.

2 The steel should be heated slowly until the transformation temperature range has been passed, then rapidly to the desired forging temperature.

3 The desired forging temperature should be determined and controlled.

4 Stock should not be held at the forging temperature for a long time. (For alloy steels, 30 min at 2200 F should be the limit.)

5 The initial forging operation should be performed in such a way as to prevent rupturing.

6 Material susceptible to cooling bursts should be cooled slowly after forging.

The Hot Working of Large Sections

BY THE SUBCOMMITTEE ON LARGE FORGINGS*

VARIOUS PRECAUTIONS must be observed in hot forming large sections. No definite over-all rules can be set down. Size, chemical composition, working facilities and the like are the governing factors. As the carbon or alloy contents and size increase, careful control becomes increasingly important.

Further, methods of production will vary, depending on a number of conditions, such as whether or not the melt and forge shops are integrated, whether hammers or presses are available, the capacity of the equipment, and other contributing factors. The capacity of the forging tool must be adequate to work the entire section.

In general, trouble may be avoided by observation of the following precautions:

1 Heat the metal slowly and as uniformly as possible.
2 Preheat cold steel when size and composition require this treatment.
3 Control the furnace atmosphere properly.
4 Soak the steel fully at forging temperature, but do not burn or overheat. Avoid direct impingement of the flame on the metal.
5 Charge the entire piece into the furnace whenever practicable.
6 When the composition is susceptible to thermal ruptures, protect heated parts extending from the furnace by covering with heated hoods.
7 Use equipment of sufficient capacity.
8 Completely remove surface defects that open during hot forming, during the same operation, or before the next hot operation.
9 When size or composition requires it, control the cooling to prevent thermal ruptures.

Proper forging technique will avoid internal bursts and lack of consolidation of the central metal, and will ensure best direction of flow lines. Forging operations should be conducted so that the axis of the ingot is maintained in the most favorable relation to finished forging contours.

Where the melt and forge shops are integrated, it is the usual practice, in handling ingots, to transfer them hot from the melt shop to the forge furnace in order to prevent cracks. Where the melt and forge shops are not integral, the size and composition of the steel dictate the method of handling. Under these conditions, it is usually necessary with large ingots, and always with alloy steel ingots, to apply a treatment cycle before they cool to room temperature. Cold ingots, or cold billets of large section or of high alloy content, if not charged into a cold furnace, should be warmed by using a preheater, by heating in water, by placing the metal pieces adjacent to a hot furnace or by some similar method, before charging into the hotter furnace. After this preheating, the ingot or semi-finished steel should be heated very slowly and uniformly, particularly in the lower temperature range, when heating for forging. Ingots that have been stripped hot and charged into heated furnaces, should be equalized at a safe temperature before the reheating cycle is started.

In heating for forging, when the differential between the forging and the furnace is more than 500 °F, the steel should be equalized at furnace temperature, after which the temperature should be raised gradually to approximately 1200 F. At this temperature, the metal should be equalized again for uniformity throughout the mass. From about 1200 F to the forging temperature, the heating may be accelerated, but precautions must be taken not to overheat locally. It must be emphasized that the heated ingot or billet should be as uniform in temperature as possible, before forging.

During the forging operation, the hot work should be stopped when the forging has cooled to about 1500 F, and the partially forged part should be reheated uniformly to forging temperature. On the other hand, as much reduction as is consistent with good practice should be carried out between the heating operations, since extra reheating means loss in weight by scaling. Ample forging reduction should be left for the last forging operation, if control of the finishing temperature is important.

The maximum temperature to which the part should be heated depends primarily on the composition of the steel being used. In general practice, the maximum forging temperature varies between 2100 and 2400 F, depending on the carbon content of the steel. As the carbon content of the steel decreases, the higher forging temperatures in this range may be used.

Control of furnace atmosphere is necessary in good forging practice. Neutral or slightly reducing atmospheres are recommended. Oxidizing atmospheres cause excessive scaling.

When forging large parts, it is a general practice to forge all over the surface first with fairly light reduction. This first reduction can then be followed by heavier reduction consistent with good forging practice. In many instances, the ultimate purpose for which the part is intended may dictate the method of hot forming. As an example, a long shaft forging, subject to torsional stresses, should be drawn out longitudinally; whereas for parts subject to radial stresses, the hot working operation should include some upsetting.

Top and bottom discards vary with the plant practice and the type of product. Sufficient top discard should be cut to remove all central ingot shrinkage that would be injurious in the finished product and as much more as the specification may require. Sufficient bottom discard should be cut to remove any defects that would be injurious in the finished product.

During the hot forming operations, it is quite common for surface defects to open. These tears or cracks should be removed before the operation is continued. The method of doing this varies in different shops, but is ordinarily along the following lines:

1 Hot chipping under the press with special gouges
2 Hot scarfing with special lances
3 Hot grinding
4 Annealing the partially forged part where necessary and removing defects by chipping or grinding; then reheating and further forging

After forging, the best practice is to employ controlled cooling, especially when handling types of steel susceptible to flaking (thermal cooling cracks). A number of different methods and cycles are used before allowing the forging to become cold. Typical cycles include prompt transformation and holding at a temperature that will provide most rapid diffusion of hydrogen and relief of transformation stresses. This temperature varies with different grades of steel but the desired results can usually be accomplished at 1100 to 1200 F. Another cycle includes charging the part into a hot furnace as soon as the forging operation is completed, then equalizing at some temperature approximating the Ac_1 transformation point and cooling slowly until all sections are below the lowest transformation temperature. The controlled cooling may also be co-ordinated with the heat treating cycle. Repeatedly heating and cooling the steel through the transformation range tends to prevent the formation of flakes. Another method employed for large, highly alloyed parts is to forge the ingot partially to a block and then to cycle anneal, reheat, finish the forging operation, and finally to cool under controlled conditions. A widely used method is to cool the forgings very slowly in ashes, pits, silocel, or other insulating material.

Large, hollow cylindrical forgings are made from bored or cored ingots or blocks and are hot worked on a mandrel.

There are no set rules concerning the capacity of press or hammer to be used for individual parts. However it is necessary that the press or hammer should have sufficient capacity to work the steel thoroughly throughout its section.

The amount of hot reduction, though sometimes limited by specifications, varies considerably and is often governed by the ingot sizes that are available.

The steel must be sufficiently worked throughout the mass to refine the ingot structure. The best general practice is to use the smallest ingot that will give the desired amount of hot reduction. Where tangential tests are required, excessive drawing out is objectionable; however, results of longitudinal tests benefit by this practice.

The Piercing of Steel

By Stevenson Findlater*

THE forging operation in the production of seamless steel tubes is classified under four general headings: rotary piercing, hydraulic piercing, cupping, and extrusion. Of these four methods, rotary piercing is ordinarily employed for quantity production.

Rotary Piercing. In the rotary piercing of steel (Fig. 1), the principle of helical rolling is employed. The two steel rolls that bring into play the forces used to produce the cavity in the work piece are located side by side and have their axes inclined at angles (6 to 12 deg) opposite the horizontal center line of the mill. The shafts of these rolls are mounted in bearings, which can be adjusted laterally in the housing to permit the space between the rolls to be properly set for the size of work piece being rolled. The roll surfaces are contoured so that in a horizontal plane through the center line of the pass, the space between the rolls converges toward the delivery side for a length of about 10 in. to a minimum, called the "gorge", and then diverges for approximately 12 in. to form the pass outlet. The elevation of the center line of the pass is determined by two guides, one of which is mounted above and the other below the center of the mill.

Between these guides in the pass outlet, a tapered piercing mandrel is held in position on the end of a water-cooled mandrel support bar located on the delivery side of the mill. The pointed end of the piercing mandrel extends just beyond the gorge toward the entering side of the rolls. The opposite end of this bar is mounted in a thrust bearing, which is carried in a reciprocating carriage that is latched in a stationary position during the piercing.

A solid round bar or billet of the proper length and diameter (2 to 14-in. diam by various lengths to 18 ft) to make the size and weight of tube desired, is heated uniformly to the usual temperature for rolling light sections. With the rolls revolving at a constant speed (800 to 1000 surface fpm) the heated billet is transferred to a horizontal trough that keeps the axis of the billet coincident with the center line of the pass.

The heated billet is pushed forward into the space between the rolls, which have been adjusted so that the gorge is approximately ¾ in. smaller than the diameter of the billet. As soon as the billet has come in contact with the rolls, the force of the pusher is removed. Because of the obliquity of the roll axes, the motion imparted to the billet by the rolls is one of rotation and axial advance. When the leading end of the billet has advanced to the gorge, it encounters the nose of the piercing mandrel. The grip of the rolls is sufficient to continue the advance of the work piece against the retarding effect imposed by the piercing mandrel. Once the end of the piercing mandrel has penetrated the axial center of the billet, the mandrel serves as a third roll so that, with a properly designed pass, the metal of the work piece is helically rolled over the piercing mandrel (rather than extruded) to produce the hollow shell. These shells—as long as 40 ft—are produced in 10 to 30 sec. It should be especially noted that the amount of metal displaced increases considerably as the size is increased. Resulting difficulties have been overcome by further reduction of the wall thickness of the hollow shell through additional rolling in a second piercing mill. This practice has permitted the total displacement to be divided between two operations when large tubes are made. Additional rolling operations are performed on the pierced shells to produce finished tubes.

Hydraulic Piercing. In hydraulic piercing, a heated solid blank, usually of square section, is dropped into a cylindrical container located directly in line with the plunger of a hydraulic ram. The descending plunger causes the piece to assume the shape of the cylindrical container as it is displaced up and around in the space between the plunger and container. When the down stroke has been completed, the plunger is withdrawn by reversing the direction of the ram, after which the pierced blank or cup is ejected by a kicker pin. When this process is augmented by hot drawing, wherein a powerful plunger forces the cup through a push bench in which a series of annular dies or grooved rolls are installed, the length of the piece may be extended to form a tube.

Hydraulic piercing (Fig. 2) is used in the production of large and small cylinders, such as water bottles, gas, and air bottles, and as the primary operation in manufacturing tubes by the "push bench" method.

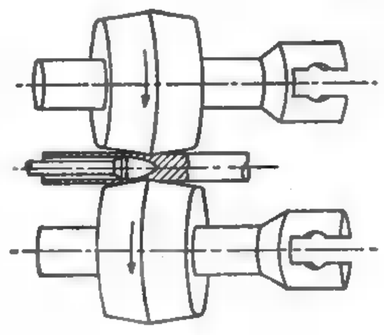

Fig. 1

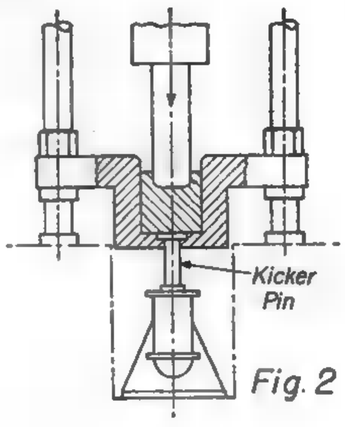

Fig. 2

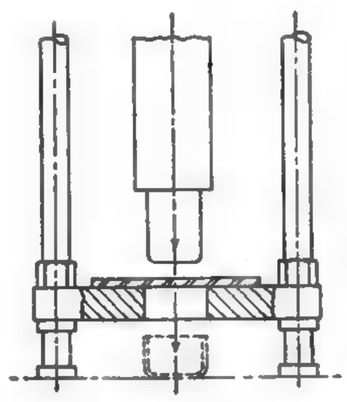

Fig. 3

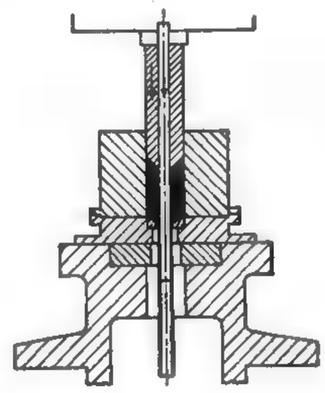

Fig. 4

Fig. 1 Mannesmann pierces, piercing solid billet
Fig. 2 Hydraulic piercing, solid blank
Fig. 3 Cupping operation, plate
Fig. 4 Extruding solid billet

Cupping. In the cupping process (Fig. 3), steel plate of required thickness is sheared, machined or gas cut to circular shape. The heated plate is accurately placed over a die centrally located beneath the plunger of a hydraulic ram. The descending plunger forces the plate through the die to form a cup, which is removed when the plunger has been withdrawn. To avoid buckling when cupping, the annular opening between the plunger and the die is proportioned to exceed the initial thickness of the plate. Requisite alterations in the length, wall thickness, and diameter of the heated cup are subsequently made in a push bench. This process is in common use in manufacturing containers for oxygen and acetylene and for other cylinders which require a closed end.

Extrusion. The extrusion process (Fig. 4) has not been used for the production of steel tubes in the United States, although several European plants employ it. The elevated temperatures which provide the necessary plasticity of a steel work piece require that the operation be rapid to avoid excessive transfer of heat and severe wear of tools during the working stroke of the press. This requisite has resulted in the development of the practice known as "impact extrusion" in which the work stroke, in extruding tubes 30 ft long, is completed in less than 3 sec. In this process, either bored or solid rounds are heated and placed within a cylindrical container, in the bottom of which a die is mounted in alignment with a crank or hydraulically operated plunger. When solid rounds are used, a differentially actuated piercing punch is enclosed within the extrusion plunger. In operation, the weight of the extrusion plunger is allowed to rest on the surface of the work piece while the piercing punch is forced through the work piece and die. When the end of the piercing punch has passed through the die, the piercing and extrusion plungers are locked together, permitting the piercing punch to act as a moving mandrel, while the rapidly

* National Tube Company, Pittsburgh

moving extrusion plunger forces the work metal through the annular opening between the die and piercing punch. Pressures greater than 90,000 psi obtain within the container in producing the 20 to 1 section reduction usually employed. When the plungers have been withdrawn, a flash that remains in the bottom of the container is sheared off, thereby releasing the extruded tube from the die.

When bored rounds are used, the piercing punch is ordinarily attached directly to the working end of the extrusion plunger. The operation is the same as when solid rounds are used, except that piercing is omitted.

Because of the great pressure required, the application of the extrusion process to the manufacture of steel tubes has been limited to tubes less than 5 in. in diam.

Steels for Piercing. The piercing processes described above have enabled seamless tubes to be made from most types of steels and many nonferrous alloys. Usually, killed open hearth and electric furnace steels are preferred, but satisfactory seamless tubes have been made from capped open hearth steels that had been melted under certain prescribed conditions.

Most commercial steels are available as seamless tubes. The SAE steels, high-sulfur free-machining steels, ball- and roller-bearing race steels, and many stainless and heat-resistant alloys are now satisfactorily pierced. In general, steels that have two phases (austenite plus ferrite) at forging temperatures (2000 to 2300 F) are difficult to pierce by the rotary process, but can be formed in the cupping or extrusion processes. Nonferrous alloys that contain more than one phase are also more readily pierced by extrusion methods. Steel is seldom extruded because the high forging temperatures and high pressures are severe on extrusion tools, but the process has been highly successful on nonferrous alloys.

The steels used for seamless tubes must be sound both externally and internally because of the severe forging operations involved in piercing. Steel shown by deep-etching tests on cross sections to be sound and dense, free from porosity and ingot pattern, is most satisfactory for seamless tubes. Tube steels must also be free from surface defects, so it is common practice, before piercing, to peel round or plane square sections in addition to treating them by conventional chipping methods.

The Manufacture of Hot and Cold Rolled Steel Sheet and Strip

BY THE SUBCOMMITTEE ON STEEL SHEET AND STRIP*

HOT and cold rolled sheet and strip, unlike other steel commodities, are used primarily in consumers' goods. This type of market requires materials that are serviceable under a wide variety of conditions, and also adaptable to low-cost techniques of mass production and to considerations of sales appeal in the finished product.

Hot and cold rolled sheets and strip must therefore incorporate, in various degrees and combinations, ease of fabrication, predetermined strength after fabrication, adequate resistance to corrosion, ductility, attractive appearance before and after fabrication, as well as compatibility with various coating processes and materials. In special compositions, such as the alloy and stainless grades, some or all of these qualities are procurable, as well as the properties commonly associated with flat rolled materials. To attain these characteristics under the most economical conditions for production, the bulk of the tonnage of flat rolled steel (which in peace time amounts to about one-fifth of the total steel output) is of low carbon content.

Until the advent of the wide continuous strip mills, all hot rolled sheets were produced from sheet bars on the old-style hand sheet mills. As the wide strip mills continued to develop, more and more hot rolled sheets were produced on these newer mills, until at the present time only a small percentage of the hot rolled sheets are produced on the old hand mills.

Most continuous hot strip mills are capable of producing hot rolled sheets in thicknesses down to and including 18-gage, so that currently those producers who have both continuous and hand-operated mills, produce the 18-gage and heavier sheets on the continuous mills and the lighter sheets on the old hand mills.

Classification of Sheet and Strip. The classification in Table I shows the ranges of thickness and width for sheets and strip. Because of overlapping in the width range of manufacturing facilities there is no sharp dividing line between sheet and strip from a manufacturing standpoint. The selection of facilities will be governed by requirements and by the equipment available.

Hot Rolled Sheet or Strip. Sheets and strip can either be hot rolled directly to the desired thickness, or hot rolled to an intermediate thickness and then cold rolled to the desired thickness. The latter process is used if improved surface finish or special temper and properties are desired. Hot rolling is classified here as including rolling operations in which the material is heated before it is passed between the rolls. Sheets are hot rolled by a number of methods—on broad hot strip mills from slabs, on hand mills from sheet bar, and on hand mills from broad strip sheared breakdowns.

Broad Hot Strip or Continuous Mill Practice. The rolling of broad hot strip, or "sheets in coils", has been a continuous development since 1926, when the first mill was built capable of rolling a strip more than 24 in. wide. The strip process differs from the sheet process since in the strip process, the reduction is performed in long lengths subsequently cut up or coiled, while in the sheet process, the reductions are performed in unit lengths or a small multiple of a unit length.

In strip practice the rolling is generally done parallel to the axis of the ingot, while in sheet or hand mill practice, the rolling may be done either parallel to the ingot axis (breakdown practice), or partially transverse to the ingot axis (sheet bar practice).

In strip rolling, a slab ingot is cast and rolled to a slab 3 to 6 in. thick and of a width and length suitable for charging into the slab-reheating furnace, where it is brought up to a temperature of 2200 to 2300 F for rolling.

The broad strip mills consist of a roughing train and finishing train set in tandem, with the finishing train set on close centers, so that the strip is in all the finishing stands at the same time. The number of roll stands can be varied to suit the variety of products manufactured in any given mill, but usually varies from 4 to 7 roughing stands and from 4 to 8 finishing stands. The roughing train usually consists of a two-high scale-breaker to break up the scale on the surface of the slab, and a spreading mill to spread the slab, when necessary, to the desired width of strip, after which it is turned 90 deg and squeezed to straighten the edges. The slab is then rolled to the desired thickness of the rough bar, in the rest of the roughing mills, which are usually of the four-high type and equipped with vertical edging rolls to hold an accurate width in the bar. In the roughing reductions, the slabs, as they progress through the mills, are usually sprayed with water under high pressure to descale the surface. As a modification in practice, the slab can be rolled to a rough-down bar on a reversing universal mill. After roughing, the bar goes through another scale-breaker and high-pressure spray and into the four-high hot strip stands, where it is reduced to the desired thickness. The speed of these mills is synchronized so that each successive mill takes the strip at a speed exactly the same as the

More than 24 to 32 incl	Sheet	Sheet	Black Plate
More than 32	Sheet	Sheet	Sheet

(a) When a particular temper, as defined in ASTM Specification A 109, or a special edge or special finish is specified.
(b) When no special temper, edge or finish is specified.
(c) When the width is greater than the thickness, with a maximum width of ½ in. and a cross-sectional area not exceeding 0.05 sq. in, and the material has rolled or prepared edges, it is classified as flat wire.

delivery speed of the preceding mill. The delivery speed varies from 1000 to 2100 fpm. The finishing temperature can be varied over a considerable range by varying the slab-heating temperature and the time of holding the slab before it enters the strip mill. In general, the finishing temperature varies from 1300 to 1600 F and must be closely controlled in order to keep the thickness uniform throughout the length, and to provide desired grain size and mechanical properties.

After the strip has been delivered from the last stand, it can be either coiled, or cut to length, flattened by leveling and piled. It must be coiled or piled at a temperature low enough to avoid appreciable grain growth.[1]

The product of the hot strip mill has a wide variety of uses. It may be cut as breakdowns for a hot sheet or hand mill, if a lighter gage is desired than can be produced on the hot strip mill. It may be shipped directly, or after heat treating and pickling, if better properties or surface are necessary for the particular requirements under consideration. After being pickled in coils, the strip may be further processed by continuous cold reduction for the production of lighter gages than can be rolled directly on the hot strip mill. It may be used also for applications where closer control of thickness is required, as well as a better and smoother surface than can be obtained on a hot strip mill.

The process for narrow strip is similar to that for broad strip, except that lighter equipment can be used and less power is needed. The wider the strip desired, the more massive the equipment must be and the greater the power requirements, which are approximately 400 to 500 connected hp per in. of width capacity.

In producing 18-gage and heavier hot rolled sheets on continuous strip mills, rimmed steel is ordinarily used. Typical ladle analyses will show approximately 0.05 to 0.10% C, 0.25 to 0.50% Mn, 0.03% P max, and 0.045% S max. Where only mild forming is involved, a certain latitude is permissible, especially for phosphorus and sulfur. In sheets for deep drawing, the phosphorus in particular, and the sulfur are held as low as possible. Further variations in mechanical properties necessary to fit the requirements are usually secured by subsequent treatments, such as normalizing, open annealing, box annealing, cold rolling, or pickling.

Sheet Bar Practice. The sheet bar practice for the production of hot rolled sheets involves the rolling of an ingot to a rectangular sheet bar. The bar is usually 8 or 12 in. wide and ½ to ¾ in. thick, in order to allow cross rolling on a hot hand mill to the desired thickness and length. The sheet bar is cut so that the length is slightly greater than the width of the sheet to be made from it. The hot mill consists of two stands of rolls, known as the "roughing" and "finishing" stands, and two furnaces. One of these furnaces is known as the "pair furnace" because the bars are withdrawn in pairs for rolling; the other furnace is called the "sheet furnace" because in it the partially rolled sheets are reheated for finishing. The sheet bars are heated in the pair furnace to a temperature of 1300 to 1600 F, depending on the grade of steel and the surface finish required. After the pair of bars has been withdrawn from the furnace, they are rolled to the breakdown gage in single thickness until partially reduced; then the two pieces are matched and rolled in pairs (double thickness) until the breakdown gage is reached. At this point the breakdown sheets are matched, reheated in the sheet furnace, and then rolled to the desired sheet thickness.

After hot rolling to the desired thickness, the sheets in packs are trimmed to the desired dimensions and separated. They are then ready for further processing.

Sheared Breakdown Practice. This process is somewhat like the sheet bar practice, except that the breakdowns are sheared from broad hot rolled strip of a width slightly greater than that of the desired sheet, and of a length sufficient to make a sheet of the desired gage and length. The breakdown operation is eliminated and consequently only one stand of finishing rolls is necessary. This practice lends itself readily to the utilization of continuous pack-heating furnaces and mechanized feeding and catching tables.

In the pack rolling of sheets in the lighter gages (20-gage and lighter), the pressure of the rolls tends to weld the sheets together. This effect can be counteracted by adding phosphorus to the steel, or phosphorus in combination with silicon, a practice sometimes followed, particularly for 26-gage and lighter sheet. However, both phosphorus and silicon harden the steel, and where ease of forming or deep drawing is required, these elements are often a hindrance.

Cold Rolled Sheet or Strip. Sheet and strip are cold reduced to the desired thickness for several reasons: to obtain the desired surface finish, to impart desired mechanical properties, to make gages lighter than the hot strip mill can produce economically, and to produce sheet and strip of more uniform thickness.

The cold reduction can be accomplished either in unit

lengths or in coils, but it is more economical from the standpoint of yield to perform the reduction in coils.

The harder grades of steel, such as alloy, electrical and higher-carbon compositions, are carefully cold reduced to finished gage by introduction of a softening anneal between the first and second stages of cold reduction.

There are numerous types of equipment for performing the cold reduction, but as in hot strip mills, the wider the material to be cold reduced, and the thinner the desired gage, the more rigid the mill, and the more power required. For narrow widths (less than 20 in.) the reductions can be performed conveniently on two-high mills, but for the greater widths, the four-high mill is used almost entirely. As the width is increased or the thickness is decreased, the diameter of the backing-up rolls is increased. The diameter of the working roll is kept as large as is compatible with the maximum screw pressure allowable.

The amount of cold reduction performed is governed largely by the application that is being considered. For example, sheet and strip for drawing are cold reduced from 30 to 70% in thickness. Increasing amounts of cold reduction will tend to make the resulting sheet and strip finer grained and harder after annealing.

For cold reducing steel sheet and strip, equipment is available that makes use of the following applications of power to effect the desired reduction: all power applied to the working rolls; all power applied as forward and back tension; power applied partly to the working rolls and partly as forward tension; and power applied to the working rolls, also as forward and back tension.

All Power Applied to the Working Rolls. The cold tandem sheet mill, or single-stand mill for reduction of strip breakdowns in units, is an example of this method of application of power, which involves the production of more scrap because of the multiplicity of ends sheared from the sheets when heavy reductions are performed. This method is also used extensively in skin rolling sheets after annealing, in order to remove the tendency to form stretcher strains when drawn. Skin rolling involves little reduction in thickness of the section.

All Power Applied as Forward and Back Tension. This method of application of power is employed by the "Steckel Mill", a four-high mill with small working rolls for rolling coiled material. This type of mill is limited in the amount of cold reduction that can be taken in a given pass but, built to reverse, it can reduce steel any number of passes and to any practical thickness desired. The small-diameter working rolls present a small surface area and hence wear rapidly and must be replaced frequently or whenever the surface of the strip being rolled is unsatisfactory. This mill is popular for extremely hard or thin materials and high-priced specialties with extremely close tolerance in variation of thickness.

Power Applied Partly to the Working Rolls and Partly as Forward Tension. This method of reduction is followed in a great majority of tandem cold reduction mills where coil stock is used. In general, the reduction mill is made of three, four or five tandem stands of four-high mills, with a reel that produces forward tension. The capacity of this type of mill is governed largely by the thickness and width being rolled, and by the delivery speed of the mill. Cold mills making tin-plate gages, deliver up to approximately 4000 fpm, whereas the heavier sheet gages are usually delivered up to 1000 fpm. This type of mill has the advantage of high capacity and low cost for labor and for rolls, although the investment is high. Disadvantages are a lack of flexibility for rapid changes in section, and the limited number of passes received by the metal.

Power Applied to Working Rolls, also as Forward and Back Tension. This application of power is exemplified by the single-stand reversing mill. This type of mill, radically different from the Steckel mill, is not limited in the amount of reduction per pass or in the possible number of passes. Besides, such a mill requires a lower investment cost and less floor space than a tandem mill. The energy expended in back tension is regenerated by driving the back reel as a generator against the line load. The back tension also serves to reduce the screw pressure and the net energy required for the deformation. On the other hand, the investment per ton capacity, the cost of labor, and the cost of rolls, is higher than for a tandem mill.

Annealing of Sheet and Strip. It is necessary to perform some annealing operation on hot reduced and cold reduced sheet and strip unless a hard temper is desired. This may not be necessary on some hot rolled strip finished at 1500 to 1600 F or more, and coiled hot so that an annealing is accomplished in the coil. If the sheets are reduced to gage below the recrystallization temperature, as they are on the sheet bar finishing mill, or in cold reduction practice, the grain structure is fragmented, resulting in preferred orientation.

There are a number of softening operations used in the production of sheet and strip. The most important of these are the following: cold strain, low-temperature recrystallization annealing; normalizing; and stress-relief annealing.

The Cold Strain, Low-Temperature Recrystallization Anneal. This process may be used on material cold reduced more than 30% and on hot rolled material finished at a temperature low enough to give strain equivalent to that of material rolled cold. This type of annealing, also known as "processing annealing" and "box annealing", is carried out by placing coils or stacks of sheets on a bottom plate and then covering. The charge may vary from 5 to 200 tons, depending on the size of the sheet or strip and the height of the stack. After heating to the predetermined temperature, variable from 1100 to 1400 F, the charge is allowed to soak until the temperature is uniform throughout, after which it is allowed to cool before being uncovered.

This annealing may be carried out in stationary furnaces into which the charge, including plate and cover, is inserted for the necessary heating and soaking, and then removed for cooling; or in the radiant-tube type of furnace, in which the plate is stationary and the furnace is lifted from charge to charge for the necessary heating and soaking. The source of heat may be gas, coal, oil or electricity.

Material that has been cold reduced or descaled before annealing is usually "bright annealed" in a protective atmosphere, in order to prevent the formation of oxide on the sheet during the heating, soaking and cooling cycle. This protective atmosphere is ordinarily produced by partially burning natural, coke-oven or butane gas to a gas composition that is slightly reducing to iron oxide, but will not break down further and deposit carbon at the annealing temperature. Most of the water vapor produced from the partial burning is removed from the protective gas by refrigeration. Material that is intended to have an oxide finish is either annealed without the protective atmosphere, or "steam blued" by adding steam under the cover, after the charge has been removed from the furnace and when the temperature has decreased to below 1100 F.

Normalizing. The normalizing operation consists of heating the sheet or strip to a temperature above the Ac_3 point (approx 1650 F for a steel that contains 0.10% C max) and cooling to room temperature. This recrystallizes and refines the grain structure through the medium of a phase transformation. The normalizing operation is utilized to the greatest extent on hot reduced material to produce improved drawing properties, since often a low-temperature box anneal would result in critical grain growth resulting from a low residual strain in the hot reduced product.

Furnaces for normalizing sheets are usually of the chain type, roller type or walking-beam type. Fuels may be gas, oil or electricity. With electric furnaces or muffle types, it is possible to "bright normalize" by using an inert or a reducing atmosphere to protect the surface of the strip from oxidation.

The grain size and hardness of normalized material can be controlled within limits by varying the soaking time above the Ac_3 point, and also by varying the cooling rate from the Ar_3 to the Ar_1 point.[2]

Stress-Relief Annealing. This operation is a low-temperature pack or box anneal performed in order to improve the drawing properties by removing the residual stresses that have resulted from the rapid cooling during the normalizing operation, and during leveling or light rolling operations after normalizing. This operation, commonly

known as a "second anneal" or "white anneal", is carried out in the same manner and with the same equipment as the cold strain box anneal, except that the temperature of annealing is in the range between 950 and 1200 F. A protective atmosphere can be used under the cover to prevent oxidation, or the charge may be steam-blued.

Typical values for mechanical properties of mild steel sheet and strip, after the annealing operations referred to, are given in Table II.

Table II. Mechanical Properties of Steel Sheet and Strip

Condition	Yield Point, psi	Tensile Strength, psi	% Elong in 2 in.	Rockwell Hardness Number	Olsen Cup, inch
0.035-in. Sheets					
Hand Mill	50,000	65,000	10	B 70	0.200
Hand Mill Annealed	22,000	38,000	30	B 40	0.390
Hand Mill Normalized	28,000	45,000	35	B 48	0.400
Cold Reduced	85,000	85,000	2	B 90	0.100
Cold Reduced Annealed	28,000	44,000	40	B 45	0.410
0.048-in. Sheets					
Hot Strip	40,000	60,000	30	B 65	0.380
Hot Strip Annealed	33,000	52,000	35	B 55	0.400
Hot Strip Normalized	30,000	48,000	40	B 50	0.420
Hot Strip Normalized and Annealed	25,000	43,000	45	B 45	0.420

Temper Rolling. The processing of cold rolled sheet and strip is varied to control the mechanical properties within the ranges found most suitable. This is done by controlling the hot strip practice, the amount of reduction, the annealing, and the final amount of cold rolling after the anneal. These influencing factors are worked out according to the equipment and conditions in each plant, so that the finished material will have certain desired physical characteristics. The amount of cold work can vary from a pass through the roller leveler, which does not affect the thickness to any appreciable extent, or a pass on the skin mill with reductions up to a maximum of several per cent, to heavy cold rolling that reduces the thickness as much as 50% or more. The increase in hardness compared with the annealed condition depends on the amount of cold work done after annealing. The ductility decreases rapidly as the amount of cold work increases.

Surface Characteristics. The surface texture of sheets and strip can be varied between rather wide limits. For chromium plating and similar finishes, a smooth bright surface is necessary, but for porcelain enameling and many drawing operations, a certain dullness or roughness of surface is more suitable. In porcelain enameling, roughness tends to improve the uniformity of coating and the adherence of the enamel; and in certain drawing operations where heavy pressures are developed, the duller type of surface retains more lubricant, helping the sheet to draw better. This type of surface also seems to aid in the distribution of the draw. Minor surface imperfections and slight strains are not so noticeable on a dull surface as on a bright one. However, the surface should not be so dull that subsequent paint finishes will not cover. The smooth surface may be obtained by grinding and polishing the rolls, and the dull surface may be obtained by either etching or shot-blasting.

Flattening. Sheets are ordinarily sold in two grades of flatness: commercial flatness, in which the sheets are to be severely drawn, so that the original flatness does not have much effect on the shape of the drawn article; and the stretcher-level standard of flatness, in which the sheets are used for panel work, where little forming is done on the sheet and the finished product is desired flat and free from buckles. Simply because sheets are flat before moderate forming does not necessarily mean that they will be flat after fabrication, unless the fabricator takes care that no buckling occurs in the sheets during forming. Commercial flatness can ordinarily be produced on a roller leveler or on temper rolls, but where very flat sheets are required, producers may resort to stretcher leveling or other processes producing a similar standard of flatness.

The permissible variations for commercial standards of flatness in hot and cold rolled sheets and stretcher-leveled standards of flatness are set up by the Technical Committees of the American Iron and Steel Institute, and are stated in their Steel Products Manual, Section 11.

Roller Leveling. A roller-leveling machine consists of two sets of several horizontal rolls of small diameter, held in a housing and arranged so that the top and bottom rows are offset, permitting the rollers to mesh. Consequently the sheet passing through the leveler is flexed alternately up and down (Fig. 1). The amount of flexing is decreased in proceeding from the entrance to the exit end of the leveler. Near the exit end the action is chiefly that of straightening.

Stretcher Leveling. Stretcher leveling is a positive means of producing flatness by stretching the sheet lengthwise between jaws (Fig. 2). The stretching may vary from about 1 to 3% elongation, which exceeds the elastic limit of the steel and hence results in some permanent elongation. It is necessary that the sheet be processed before stretching, so that it will spring back uniformly across its full width and remain flat.

Other types of equipment suitable for producing the stretcher-level standard of flatness are also being used by some manufacturers.

Fig. 2 Diagrammatic sketch of a stretcher leveler

Mechanical Testing. Tests for hardness, ductility and tensile properties are widely used for sheet metal products. For detailed information concerning these tests, the reader may refer to the articles on pages 93, 105 and 128.

For testing the drawing qualities of the material during processing at the mill and at the time of shipment, tension tests are too time-consuming. Consequently the simpler and more rapid tests, such as Rockwell hardness and the Olsen or Erichsen cup-draw or ductility tests, are used as a guide in controlling the quality of the product. In the Olsen and Erichsen cup tests, the surface near the break gives an indication of the grain size, the position of the break gives an indication of the amount of cold work the material has received after annealing, and the shape of the break gives some indication of the character of the anneal. It is usually possible to establish some correlation between Rockwell hardness, ductility tests and actual performance in the drawing dies; it is ordinarily considered that hardness tests and cup tests, properly evaluated, are indicative of drawing quality, but are not a guarantee of satisfactory performance. For determining the drawability of sheets for deep drawing, Boulger and Dahle[3] have described a new test that does not require a compensation for differences in thickness.

Microscopic Examination. The microstructure of the metal is most important in the deep drawing and extra deep drawing grades. Usually samples are taken parallel to the direction of rolling, but it is often desirable to examine the structure in both the longitudinal and transverse directions. Individual samples may be mounted in bakelite or a number of samples may be bolted together, so that the cross section may be polished and examined.

All steels contain nonmetallic inclusions. Whether or not these are harmful depends on the number, size, type and distribution of them in the steel. The same is true of the carbides that are found even in the very low-carbon steels or irons.

Various types of drawing require different grain structures, varying from rather large to very fine grains. The grain structure may be controlled within reasonably close limits through control of the composition of the steel and

close control of processing. Usually the grain size will vary somewhat from the surface to the central plane of the material as a result of segregation. On a straight rolled material there will be some difference in grain size from edge to center, and some difference from end to midlength of sheets cross rolled from sheet bars.

Any irregularity in normalizing, and the usual differences in temperature within the annealing box, are reflected as slight differences in grain size. These are normal and expected differences that cannot be entirely eliminated. These differences affect the drawing quality only when they are abnormally large.

At present there are many variables in testing practice, and it would be almost impossible to devise "standard" tests that would meet all contingencies to the satisfaction of both producer and consumer.

Inspection. Certain defects are more likely to occur on strip and sheet made by the continuous process, while certain other defects found in sheet-mill sheets are absent from the strip product. The following is a partial list of the imperfections that may be found during inspection—some warrant immediate rejection, others cause the material to be degraded into a lower class, or rejected, depending on the severity of the defect.

Fabrication. Breakage in drawing operations often is not the fault of the material. The die practice may be poor, as a result of poor design, improper clearance, too much deformation between anneals, improper hold-down or drawing adjustments, or poor lubrication. In some instances the sheet is too thin for the amount of deformation it is expected to withstand.

When multiple draws are involved, there is always a possibility of allowing too much time to elapse between successive drawing operations, with the result that the sheet may age and undergo consequent changes in properties, and breakage. In many instances this hazard can be overcome by expediting the various operations, or by using nonaging steel.

Winlock and Kelley[4] have stated: "The manner in which the draw is accomplished is, within limits, of equal if not greater importance to the success of the operation, than the physical properties of the steel itself." Montgomery[5] points out that, next to design of the dies, lubrication is the greatest factor in producing good stampings. "Efficient lubrication in production operations will effect a greater net saving to the average stamping plant than any other single factor except die design and construction."

The actual strength of the sheet or strip for most forming and drawing jobs is comparatively low. Except in the harder tempers, where the carbon content may be as high as 0.25%, the steel used for drawing contains a maximum of 0.10% C, determined by ladle analysis. Winlock and Kelley state[6] in regard to the strength of the material: "Strength and rigidity are usually imparted to a stamping by designing it so that it will most effectively resist the forces imposed upon it in use by virtue of a high section modulus."

Aging.* Aging of rimmed and capped steels is another factor influencing the drawing quality of sheet and strip. A material at the time of shipment may be perfectly suited for the job, but if it is not used within a reasonable time and aging takes place, probably increased breakage will result and surface disturbances will be present in the finished part. The amount of aging depends on the composition, method of manufacture of the steel, amount of skin rolling, time and temperature of storage and the original hardness range of the material.[7, 12]

After a material has aged to a certain extent, it loses in ductility, and if it is then worked or formed, stretcher strains occur. Winlock and Lavergne,[8] along with many others, have studied "stretcher strains", "worms", or "Lüder's lines", and have found that this disturbance may occur in parts deformed 1.5 to 10% during forming. In tension, the lines are low spots; in compression, they are elevations. These investigators attribute the stretcher strains to fluctuations at the yield point. Cold working, by roller leveling or skin rolling, generally eliminates the sharp yield point and the tendency to stretcher strain.

Composition Suitable for the Various Grades. The whole field of low-carbon steel (less than 0.15% C), as it relates to the manufacture of sheet and strip, has received much less attention in educational and research institutions than its economic importance deserves. Since the difference between success and failure in any given job may amount to only a small number of defective parts in each hundred fabricated, it is imperative that both the application and the processing of the steel be carefully controlled.

Except for special compositions, or special requirements, rimming steel is used for the majority of sheet and strip applications. The softness and ductility of rimming steel are particularly well suited to certain work, such as deep drawing and forming. In some applications the type of steel makes no particular difference, but in some fabricating requirements killed steel is preferred.

In a rimmed steel the dissolved gases are allowed to separate as the liquid metal freezes. The rimming action progresses until the ingot is capped or freezes over the top. When properly carried out, rimming produces a thick-skinned ingot with a heavy "rim", which may be hot rolled with a minimum of surface defects. The rimming action also reduces the carbon content and, to a lesser extent, the manganese content, in the outer or rim portion of the ingot, and increases the content of these elements at the "core" or segregate. This segregation of metalloids accounts for variations in composition found in different parts of a sheet or order.[9, 10]

Killed steels are made by adding a sufficient quantity of a strong deoxidizer to the furnace, ladle, or ingot molds. The deoxidizing materials have a greater affinity for oxygen than carbon, iron or manganese have, and form largely stable insoluble compounds that may be eliminated during subsequent solidification, processing and cropping. Since little gas is formed, either by reactions or by gases coming out of solution, the top of the ingot freezes rapidly and the ingot solidifies as a comparatively homogeneous mass with little segregation taking place. The compositions of the various parts of the ingot are more uniform than in a rimmed steel.

These characteristic differences in the two types of steel have definite effects on the sheet and strip produced from them. The rimmed steel has a thicker skin, which results in a sheet comparatively free from surface defects. A killed steel generally has a more sensitive skin, which may or may not be ruptured in the mills during hot reduction from the ingot to the bar or slab. If a rupture occurs, it may result in either surface laminations or seams. For this reason, when surface is important, rimmed steels are generally used.

A modification of rimmed steel that is finding increasing application is the so-called "capped" grade. This differs from rimmed steel in that the top of the liquid metal in the ingot mold is artificially chilled either by the introduction of a steel cap or by the addition of shot aluminum to provide a solid top, while the bulk of the ingot metal is still fluid. This greatly reduces the effervescing action in the metal and serves to trap most of the dissolved gases, thus providing less over-all segregation while maintaining the surface benefits of the low-metalloid skin. Largely because of the entrapped gases, such a steel is inherently finer grained, harder and less ductile than rimmed steel, but is proving satisfactory for applications requiring a uniformly fine grain throughout the section.

There are certain advantages in favor of the killed steels, such as uniform composition and properties.

In recent years extremely deep draws have led to the development of a fully aluminum-killed steel of high uniformity and excellent ductility. This grade, subject to the natural surface disadvantages of killed steels, and requiring extremely careful control of all processing steps,

* *See also* the article entitled "Aging of Iron and Steel", page 438.

has provided fabricators with a material eminently suited to economical production techniques.

In the heavier gages, such as those rolled on the hot strip mill, many specifications require special mechanical properties or check analyses. Here killed steels are often specified or required, because the composition of the sheet will usually correspond closely to the ladle analysis.

The characteristics of rimmed steel leave much to be desired, especially in the deep drawing of cold reduced sheets. Although, with present methods of control, greater uniformity from heat to heat is now possible, there still remains the variation within the ingot (top to bottom as well as rim to core) and the variation from ingot to ingot within a heat. Differences between top and bottom may be somewhat lessened, if desired, by diverting the top portion and, on occasion, even the bottom portion of the ingot to other work. However, such diversion is not economical. In straightaway rolling, the rimmed area is usually in the hold-down of the die where it is not detrimental.

Perhaps the most objectionable characteristic of rimmed steel in cold reduced sheets is the aging that occurs after the final temper rolling. This is manifested by the return of the tendency to stretcher strain, by an appreciable increase in hardness and yield strength, and by a decided decrease in ductility, as measured by cup tests, by elongation in tension testing and by performance in the press shop. Aging begins immediately after the final cold working, but it is usually not serious until after three or four weeks. The extent to which it affects performance depends largely on the properties of the steel at the time of temper rolling. For example, a 20-gage sheet with a hardness of 45 Rockwell B and Olsen value of 0.420 in., may age harden to Rockwell B 50 and 0.400-in. Olsen value and still draw satisfactorily. However, if the initial Rockwell B hardness had been 50 and the Olsen value 0.400 in., and the same amount of aging had occurred, it is possible that breakage would result in certain difficult fabrication.

The theory of aging of cold reduced sheet and strip has been fairly well established, and material is now being marketed in which the aging characteristics have been virtually eliminated.

Sheets for Specialized Application. *Sheets for Porcelain Enameling.* Sheets for porcelain enameling are subjected to high temperatures during the fusion of the enamel, and may warp and sag considerably unless the composition and processing are closely controlled. A typical composition for a sheet of suitable quality for vitreous enameling, is 0.03% C, 0.05% Mn, 0.010% P and 0.025% S. Some improvement in drawing quality may be obtained by increasing the manganese content to approximately 0.15%.

Low-Alloy High-Strength Sheets. The low-alloy high-strength steels are used when higher strength and improved resistance to atmospheric corrosion are required. These steels are used primarily for transportation equipment where greater strength of the steel allows appreciable saving in weight.[11] These steels have a minimum yield strength of 50,000 to 60,000 psi and a minimum tensile strength of 65,000 to 75,000 psi. The minimum elongation is generally around 20%. Various elements and combinations of elements are used as strengtheners in this type of steel, in order to obtain the best combination of strength, ductility and resistance to corrosion. The ranges are approximately as follows: 0.12% C max, 0.20 to 2.00% Mn, residual up to 0.200% P, 0.045% S max, residual up to 1.00% Si, 0 to 1.5% Cr, 0.30 to 1.75% Cu, 0 to 2.25% Ni, 0 to 0.12% Mo, 0 to 0.20% Al.

Electrical Sheets. Sheets with guaranteed magnetic properties are furnished to several subdivisions of the composition range 0.03 to 0.08% C, 0.15 to 0.45% Mn, and 0.20 to 4.50% Si, with other elements as low as possible. These grades may be manufactured by either the hot rolling or the cold reducing processes, or by both.

Metallic Coatings. In recent years there has been considerable development in coatings for sheet and strip.

Tin coatings may now be applied by either the hot dip method or by electrodeposition. The same is true of galvanized or zinc coatings. Coatings of terne (an alloy containing approximately 85 to 90% Pb and 10 to 15% Sn) are applied by the hot dip method. More recently sheets with a much higher lead content in the coating have appeared on the market. A number of producers of sheet are now able to supply sheets with a coating of zinc phosphate to promote adherence of paint.

For information concerning metallic coatings, the reader may refer to pages 703 to 724 in this Handbook.

Cold Drawing Steel Wire

By A. E. Hibschman*

WIRE is a term that may be applied to any thread or filament, or to any slender rod or bar of metal that has a uniform cross section. A great many products shaped by pulling metal through a die are called wire. The most common shapes are round, square, hexagonal, octagonal, oval, half oval, half round, and flat or rectangular. Numerous other regular and irregular shapes are produced. As many as 785 different shapes of wire have been made by one manufacturer.

Wire is of ancient origin. Evidence has been found that the Assyrians and Babylonians used wire as long ago as 1700 B.C. Almost nothing is known about the methods of manufacture used by these ancients, although the specimens of ancient wire that have been found are flat and were probably made by hammering. It is not known when, how, or of what material round wire was first made. Many believe that drawn wire was used for making the chain armor worn by the knights in the Middle Ages.

Available records indicate that wire was drawn on a commercial scale in France as early as 1270. The first wire mill in this country was built in 1775 by Nathaniel Miles at Norwich, Connecticut.

General Description of Process. The limits for drawn wire range from 0.001 in. to approximately 1 in. in diam. The process of drawing steel wire begins with the rod hot rolled in coils that weigh from 100 to 600 lb, depending on the type of rod mill and quality of rod desired. The fabrication of the wire and requirements of service determine whether Bessemer, acid or basic open hearth, or electric-furnace steel should be used. Alloy steels are used mostly for the coarser sizes of wire, which are subjected to heat treatment to develop special mechanical properties. Com-

* Division Metallurgist, American Steel & Wire Co., Cleveland

binations of composition, heat treating of rods and process wire, and cold working, may produce a wide range of properties for a varied range of applications.

The range of composition of plain carbon steel is 0.05 to 1.30% C, 0.15 to 1.65% Mn, with the other elements standard for the type of steel.

Most common wires are drawn from a No. 5 size (0.218 in.) rod, which is the smallest usually hot rolled. The largest percentage of the wire is drawn dry; however, fine sizes and some special finishes are drawn by the so-called wet process.

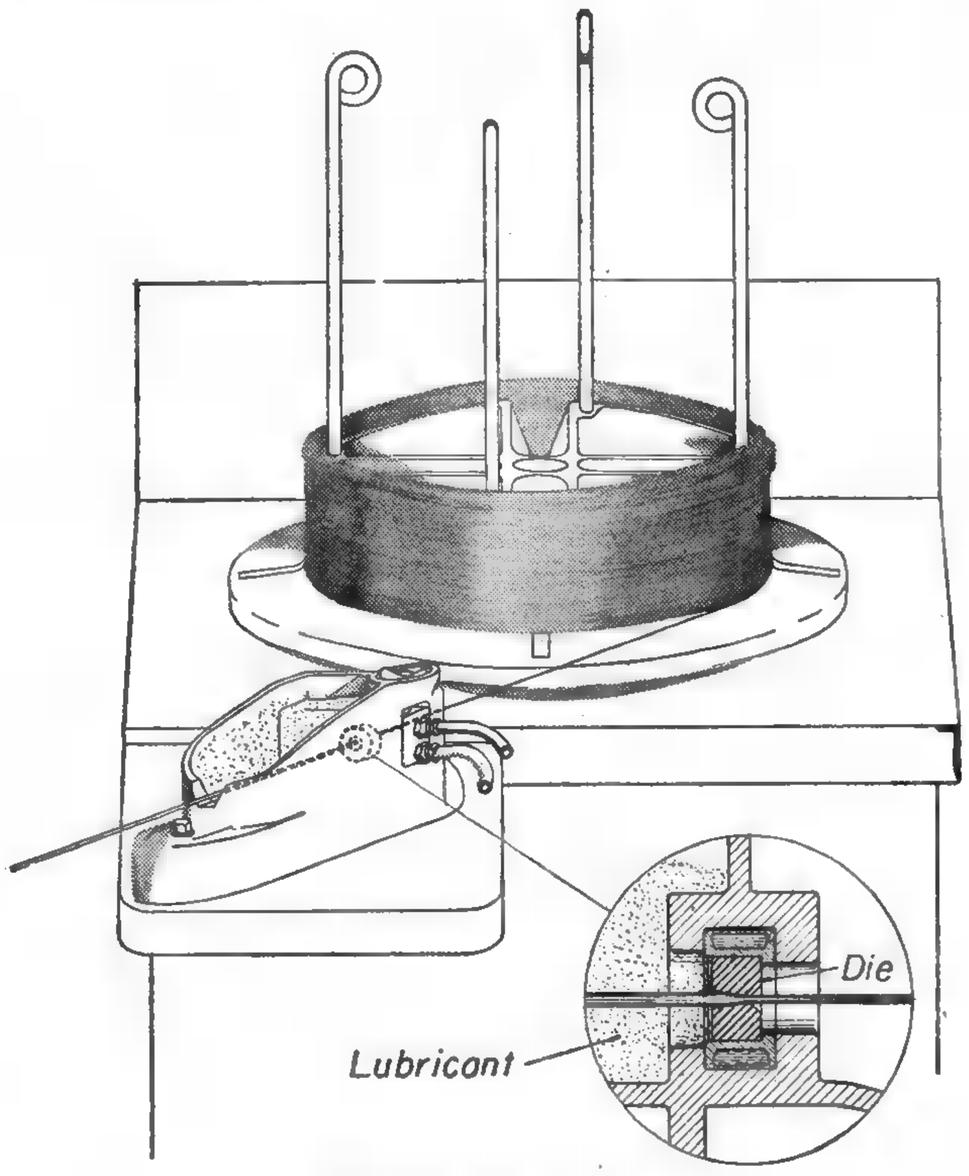

Fig. 1 Wire-drawing block

Usually the rod is cleaned in hot acid, coated with lime or some other alkaline solution, baked, and drawn through a die with a dry soap lubricant in the die box. The rod is swaged to a point, then pulled through the die and the end is anchored to the wire-drawing block, which then revolves, drawing the wire continuously and coiling it on the block. (*See* Fig. 1.)

In wet drawing, the wire, after having been cleaned, is usually metallic coated by dipping in a solution of copper and tin sulfates, and is then drawn with a solution of soap or soluble oil as lubricant.

Cleaning and Baking. The production of good wire depends on the proper cleaning of the rods before wire drawing. Insufficient cleaning leaves residual scale on the rods, produces scratched wire and reduces die life, while overcleaning causes a pitted, rough and mottled surface with possible acid brittleness of the wire. The rods are usually cleaned by immersion for 15 to 30 min in a vat of hot sulfuric acid, the concentration of which is governed by the composition and type of material being cleaned (pickled). Inhibitors in the acid bath prevent excessive use of acid, which would cause a loss of steel, pitting of the steel surface, and excessive fuming of acid.

After they have been cleaned in acid, the wire rods are rinsed in cold water and are washed with a high-pressure hose to remove impurities that may cling to the surface. Usually the rods are dipped in a lime or emulsion-like whitewash. A sull or rust coat, or copper-dip coat may be applied previously, depending on the wire finish desired. According to the number of drafts to be used, the lime coating may be controlled by the following concentrations of lime in the vat: light lime, 3 to 5%; medium, 6 to 9%; heavy, 10 to 12%; and extra heavy, 12 to 15%. The larger the number of drafts, the heavier the lime coating.

The limed rods are baked at the proper temperature and for the length of time necessary to dry the lime and release occluded hydrogen, which would cause brittleness if not eliminated. The rods are usually baked at about 300 F for 5 to 10 hr. Modern fast bakers perform this process in 5 to 30 min at approximately 550 F.

Drawing. *Dies.* In general, the wire-drawing die can be defined as a small plate or nib of suitable material, containing one or more tapering holes called "die holes". The die is an important element in wire-drawing equipment. For the production of a satisfactory product the die must be made of strong material highly resistant to wear, and the hole must be smooth and properly shaped. Chilled iron, several of the alloy steels, tungsten carbide, and diamond possess the required qualities and are used for particular applications, although the tungsten carbide single-hole die is becoming more widely used. Diamond dies are still preferred for finishing drafts on very fine sizes of wire; and because of the limited production of "shape" wire, hardened, punched chromium steel dies are employed. However, tungsten carbide dies are being used increasingly for drawing shapes.

Lubricants. In dry drawing, some form of lubricant is required, in addition to the coatings previously described, in order to prevent excessive heating and wearing of the die, and to produce a uniform smooth surface on the wire. A suitable lubricant is usually placed in the box of the die holder so that the rod or wire passing through will draw a sufficient amount into the die hole. Various substances are used for this purpose, including specially prepared greases or drawing compounds, tallow, pulverized soap, or a mixture of oil and flour or meal. The choice of lubricant depends on the number of drafts a wire is to be drawn, as well as the coating or freedom from coating desired on the finished wire. In wet drawing, a thin solution of liquid soap or soluble oil may be used.

Drawing Equipment. Cold drawn wire may be produced on what is known as a wire-drawing frame. Each frame is composed of a bench with several wire-drawing blocks or cylinders, revolving and drawing the wire through the die. Such a block mechanism and die box is shown in Fig. 1. In such an arrangement of several blocks to a bench or frame, the wire is drawn on the first block, then transferred to a reel and drawn a second draft onto a second block, and so on. In this respect, the method differs from multiple drafting.

"Bull blocks" are used for drawing large sizes of wire. A bull block is a large cylindrical block or capstan, 30 to 36 in. in diam, which revolves at a slow speed about a central spindle or shaft, usually horizontal, drawing the wire through a die and winding it around the bull block. When several hundred pounds of wire has been coiled and stored on the block, it is stopped and the wire coil removed. Bull blocks are used mainly for drawing wire that is from ½ to about ⅞ in. in diam.

Double-deck and triple-deck wire-drawing blocks are designed in tiers, one above another, with the same central spindle or shaft having a special arrangement of die holders in relation to the various levels of the blocks and permitting the wire to be drawn continuously for two or three drafts.

Continuous wire drawing has been made possible by modern improvements in wire-drawing equipment. The wire is drawn through a succession of dies simultaneously in a machine of the type illustrated in Fig. 2. The amount of reduction per draft and the number of drafts are limited by work hardening. After a certain amount of work hardening, the steel becomes so brittle that it must be softened by heat treatment before further drawing can be accomplished.

Since the pull required for drawing the wire through a die, may be more than half the strength of the wire, it is necessary to supply the power individually by placing a block after each die, and winding the wire at least two or three times around each block or drum in succession.

Since the wire is reduced in diameter at each draft and lengthens accordingly, the speed of wire travel increases at a corresponding rate. This increase may be compen-

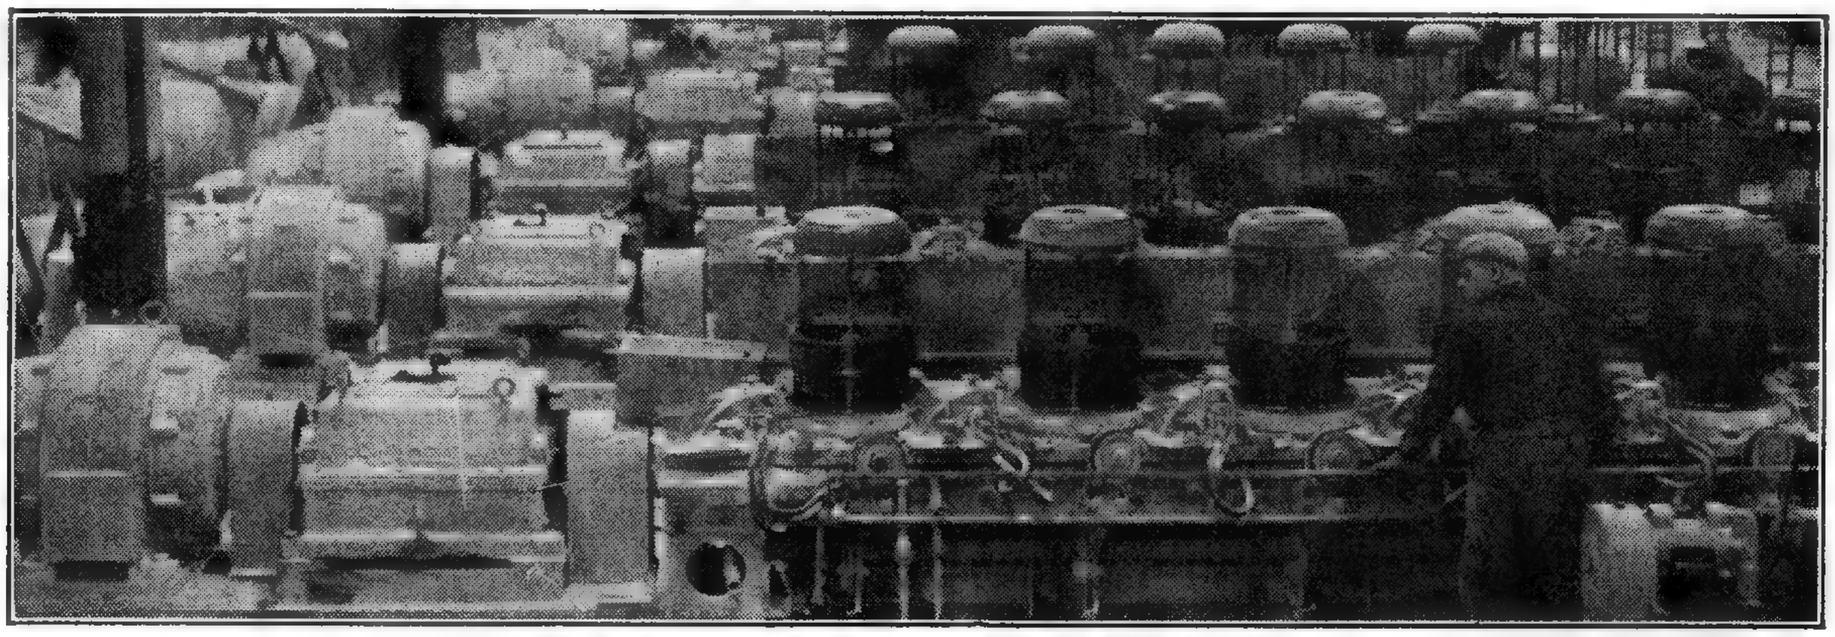

Fig. 2 A machine for the continuous drawing of wire

sated for by increasing the successive block diameters or block speeds in direct proportion to the increase in wire length. The blocks are usually 26, 22, or 16 in. in diam for wire sizes down to 20 gage.

Because plastic deformation of the wire, during travel through the die, produces both frictional and internal heat in the wire at each draft, the accumulated heat resulting from dry drawing may become great enough to affect adversely the quality of both lubricant and wire. This injurious effect is more pronounced in drawing the harder high-carbon steels than in drawing low-carbon wire, and provision is usually made, therefore, to restrict this heat in the wire by the use of water-cooled die holders and either air-cooled or water-cooled drawing blocks.

Continuous machines for wet drawing fine wire may be used for four or more successive drafts. These machines generally consist of the cone type of wire-drawing sheaves. In order to minimize slippage and wear, these sheaves of variable diameter on the same shaft are designed in steps for various surface speeds in relation to the increase in length of wire at each draft. In some types of equipment the sheaves are arranged in a tub of soap solution, which serves as a lubricant for the wires that pass through it. In other types the dies are lubricated by streams of solution forced through jets.

Dry drawing may reduce the area about 40% or less per draft for low-carbon steel and 35% or less for high-carbon steel. In wet drawing, the reduction of area may amount to only 20% or less.

Process Heat Treatments. To improve drawing quality and to meet special requirements of mechanical properties, many sizes and grades of wire are heat treated in rod, process, or finished sizes. Low-carbon wires are usually annealed for softening or recrystallization in preparation for further drafting (Fig. 3*a*, 3*b*, 3*c*); some high-carbon wires may also be process annealed or spheroidized (Fig. 3*d*) for fabrication purposes. The high-carbon steels are usually patented (Fig. 3*e* and 3*f*) in process to improve drawing quality as well as to fulfill predetermined requirements for mechanical properties. The high-carbon wires of very high tensile strength are made from "lead patented" process wires.

Annealing. Annealing may be of several different types, depending on the structures or mechanical properties desired, although much of the annealing of hard drawn low-carbon process wire may be largely to remove the hardness induced by wire drawing and to soften the wire for further drawing. The annealing processes are: (1) normalizing—either batch or continuous, (2) continuous lead annealing, (3) salt pot or "batch" annealing, and (4) pot or bell-type annealing or spheroidizing. Except for normalizing and full annealing, which are performed at temperatures above the transformation range, common annealing is usually accomplished by heating the wire to temperatures in the vicinity of, or below the critical point. The common or subcritical annealing practices may differ widely in the time of annealing; the continuous lead annealing is finished in several minutes, while the others require increasing time, in the order listed above. Spheroidizing, done mostly on higher-carbon steels, may require 24 to 48 hours for completion.

The effect of time and temperature of annealing cold drawn wire of various carbon contents is indicated in the lower curves of Fig. 6. Subcritical short-time-cycle annealing results in incomplete recrystallization, and wire so treated has tensile properties higher than the same material full annealed above the transformation range and slowly cooled for complete recrystallization. Subcritical annealing with a longer heating and cooling cycle similar

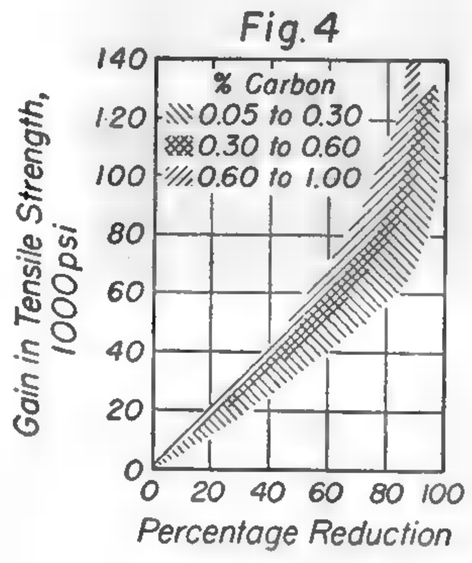
to that of full annealing or pot annealing, will result in tensile properties about the same as with full annealing.

Patenting. Patenting is a form of heat treatment used primarily on medium-carbon and high-carbon steels, and consists in heating continuously strands of rod or process wire to a temperature well above the upper transformation point, and then quenching to obtain definite structures and mechanical properties and also to restore the ductility of hard drawn process wire for further reduction. In one type of patenting called "OP" (Old Process) patenting or "air patenting", the rod strand is heated above the transformation range in a long furnace for about two minutes and quickly cooled in the open air to room temperature. "Metallic hardening" or "MH patenting" consists in heating the strands of rod or wire in a similar furnace and quenching in molten lead at about 1000 F. In "double lead patenting", practiced mostly on process wire, the steel is both heated and quenched in molten lead. The type of patenting used depends on the grade of wire being produced, its particular application and required tensile strength, stiffness, or ductility. Patenting gives a high initial strength with the best characteristics to conform with drawing to high tensile strengths in the finished wire.

The structures obtained by OP patenting and lead patenting are shown in Fig. 3*e* and 3*f*; the approximate tensile strengths obtained by these types of patenting are shown in Fig. 6, for steels of various carbon contents.



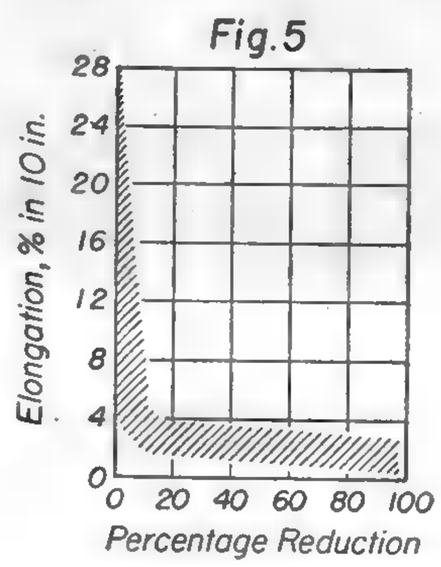


Fig. 4 Increase in tensile strength with increase in reduction
Fig. 5 Effect of reduction on elongation. The carbon content varies from 0.05 to 1.00%.

Mechanical Properties. The initial tensile strengths of rods or wire may be controlled by the chemical composition of the steel. When made of low-carbon steel, hot rolled rods, such as a No. 5 gage (0.218 in. in diam), may have a tensile strength of about 55,000 psi, while similar rods of higher-carbon spring-wire steel may have a tensile strength of about 140,000 psi. Regardless of the initial tensile strength of rod or process wire—whether hot rolled, annealed or patented—the increase in hardness, resulting from cold work in drafting such wire, follows a reasonably definite trend as shown in Fig. 4; the elongation follows a decreasing trend, as shown in Fig. 5.

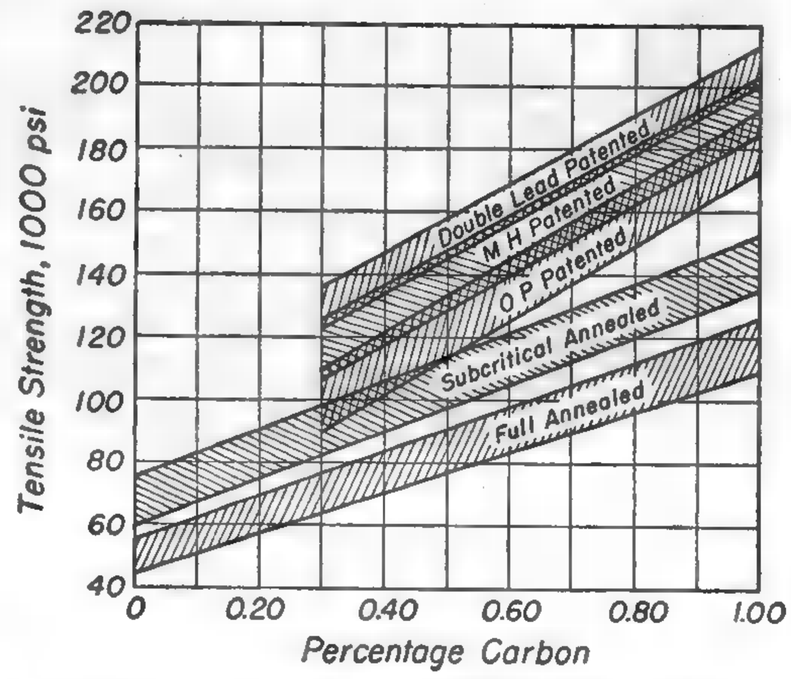

Fig. 6 Approximate effect of heat treatment and carbon content on the tensile strength of steel wire. The bands indicate the effect of wire size.

Applications. Wire may have one of several different surface finishes—either black annealed, bright, coppered, tinned, or galvanized. Wire is fabricated into a wide variety of household articles, including pins, strainers, fly swatters, egg beaters, toasters, window screens and many others. Farmers require bale ties, barbed wire and woven fencing. Industry demands such items as nails, telephone wire, bolt wire, rope wire, piano wire, and various grades of spring wire including oil tempered wire. A large proportion of the special types of wire are designed to meet severe service requirements and the production processes are rigidly controlled.

Machinability of Steel

By O. W. Boston*

IN the machining of metals, the metal being cut, the cutting tool, the size and shape of cut, the cutting fluid, the process, the type of machine tool, and the cutting conditions all influence the results. If any one of these factors is changed, different results will be obtained. It appears impossible to have a set of cutting conditions that will utilize all factors equally and ideally. Therefore, it is necessary to combine factors for the most effective compromise.

"Machinability" is a term used for indicating the relative ease or success with which a material is machined by sharp cutting tools in operations such as turning, drilling, milling, broaching, threading, reaming, sawing or grinding. Machinability is evaluated in several different ways, depending on the objective. In commercial machining, objectives vary widely and machinability may be evaluated in terms of tool performance as represented by the tool life per grind under given conditions; the speed at which the material can be cut, under different conditions, while maintaining a given tool life; the force, energy or power required for the cutting; the surface finish produced; or the dimensional accuracy maintained among like pieces under given conditions.

Values of machinability are usually comparative and represent the behavior of the material under given conditions. The material, shape and size of the tool, the size and shape of the cut, the cutting fluid used, and the cutting speed must be held constant in order that the values may be directly comparative. If any one of these variables is changed for the tests, other directly comparative results will be obtained that may not agree with those of the first test. Also, the machinability rating of a material as determined by one process, may be different from that obtained by another process.

Materials Being Cut. Many materials have optimum cutting conditions in regard to speed, feed, depth, tool shape, tool material, or cutting fluid, some or all of which are different from those for other materials. Ratings of machinability for such materials should be determined under these optimum conditions. The values of machinability for different materials will then be comparative, although the details of the tests are individual.

* Chairman, Department of Metal Processing, University of Michigan, Ann Arbor, Mich.

Tests for Machinability. The factors of importance in machinability are cutting speed, tool life, power consumption or cutting force, the size and shape of the chips, the finish left on the cut surface, and the accuracy of dimensions of the finished product.

Many types of tests have been developed for indicating the machinability of a given metal. If machinability is to apply to the tool, then the material being cut should be constant; if machinability is to apply to the material, then the tool should be constant. Cutting fluids may be introduced as the variable while the material and tool are held constant. Machinability may be expressed as:

1 The *life* of the cutting tool in turning, milling, drilling, broaching, tapping or sawing, when cutting under fixed conditions of speed, feed, depth of cut, and with a given cutting fluid.

2 The force, energy, or *power* required for cutting by various processes, such as milling, turning, drilling; or the energy required for removing a single chip of a given size or shape in milling.

3 The *torque and thrust* in drilling or counterboring.

4 The *cuttability* as measured by

(*a*) The rate of penetration of a drill in a given time under a constant feeding pressure;

(*b*) The traverse of a turning tool when fed against the work by a constant pressure, as in cutting off;

(*c*) The time in minutes or number of strokes required for cutting off a given cross-sectional area with a hack saw subjected to a given feeding load rather than a positive rate of feed.

5 The condition or surface quality of the *machined surface* produced on the material by the cutting tool.

6 The *temperature* developed at the point of the tool.

7 The *cost* of removal of 1 cu in. of the metal under specific conditions. This would involve both power and cost of the tool.

Factors Affecting Machinability. The factors affecting machinability in accordance with the above classification are, as follows:

1 Material being cut—its composition, structure, shape and size.

2 The cutting speed, size and shape of cut.

3 The cutting tool—its material, quality, treatment, shape, size, surface quality and condition.

4 The condition of the machine tools on which the cutting is done, together with the processes involved.

5 The cutting process. A given material may have different ratings of machinability for the different processes; that is, for turning, drilling, milling, grinding and the like.

6 Rigidity of the tool and work-holding device.

7 The characteristics of the cutting fluid used.

The best cutting condition involves the material being cut, the tool, the mechanical device and the cutting fluid. For any material being machined, obviously one specific combination of conditions is best. In order to secure the greatest production at the least cost, the cutting tool should be of a given material of a certain definite quality. It should have a certain contour of cutting edge, and combination of angles influencing its geometrical shape. A certain cutting fluid should be used, having properties especially suited to the given conditions, and the mechanical equipment for the particular process involved should be suitable. If the physical or mechanical properties of the material are changed, or if another material is substituted, some of the factors involving the tool, cutting fluid, or mechanical equipment should be changed also to maintain optimum conditions. The present state of the art of metal cutting leaves the selection of the various factors for a given problem to be determined largely by cut-and-try methods.

The steel being cut, the cutting tool and the cutting fluid used in any cutting operation present variables that affect machinability. Each is discussed separately below.

Fundamental Principles

Several factors involved in the machinability of steel are closely associated with both the tool and the work material, as discussed separately below.

Chip Formation. Chips of ductile metals are removed invariably by plastic flow. They are of two general forms, the ribbon or elementary type, and the sectional type. The elementary type, Fig. 1, is continuous and of virtually uniform cross-sectional area but is made of very thin transverse slip bands or slip elements. In the sectional type, Fig. 10, the small slip elements are grouped into clusters or sections of approximately equal size. Frequently these sections cling together to form a long, continuous chip, the outer surface of which is saw-toothed; but often the various sections become detached, giving broken-up chips that are more easily disposed of.

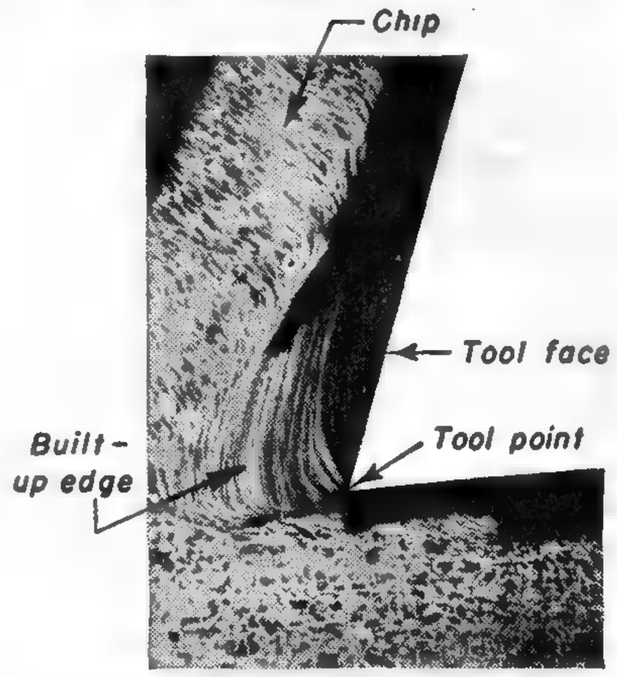

Fig. 1 Chip formation and typical built-up edge formed during the cutting of annealed low-carbon steel with a single-point tool having a 15-deg rake. The depth of cut was 0.020 in. and the speed of cutting, 120 fpm. A mineral oil containing sulfur and chlorine was used.

The bar was stopped suddenly after prolonged cutting and the section at right angles to the cutting edge was prepared for microscopic examination, which revealed the structure that is shown.

Almost immediately after a cut is started, a small particle of the material being cut is trapped on the face of the tool and forms a "built-up edge", somewhat triangular in shape, thickest directly ahead of the cutting edge, and becoming thinner as it extends backward over the face of the tool, as shown in Fig. 1. In all types of metal cutting, such as turning, shaping, drilling, sawing or milling, this built-up edge protects the cutting edge of the tool by causing the undeformed material immediately ahead of the tool point to flow plastically into a chip that slides over the built-up edge and across the face of the tool.

The built-up edge depends on the composition and structure of the material being cut, the rake of the tool, the cutting speed, the cutting fluid, and the size of the cut. The thinner the chip, the smaller the built-up edge becomes and the more nearly the cutting edge of the tool cuts the material to leave a smooth finished surface. This surface is smooth, but appears as a torn surface similar to the face of a very fine file. For thick chips, the cutting edge of the tool transmits directly only a small portion of the total force involved in cutting, since it is protected by the built-up edge. The built-up edge appears to be a rather permanent structure as long as the cut is continuous. Portions of this accumulation may slough off and be carried away on the underside of the chip, and frequently portions of it adhere to the surface of the work material as it passes the flank of the tool (*see* Fig. 1).

In given conditions, the built-up edge is largest at low speeds. As the speed is increased, the edge is reduced in size, particularly in height. At extremely high speeds, the built-up edge is smallest. When metal is cut at a very high speed (with cemented carbide tools, for example), the built-up edge disappears and the cutting edge of the tool actually cuts and forms the machined surface that has the highest surface quality.

Chatter. Often high-frequency vibrations occur in the formation of the chips, because of the sliding of the elements of the chip into sections or because of the periodic sloughing off of the built-up edge. These vibrations may set up a natural period of vibration of the tool, of the work, or even of the whole machine, which may become very

objectionable because of noise, poor surface finish and possible damage to the machine. Rigidity of tooling, or change in speed, feed, depth of cut or tool shape may cause the vibration to cease. Whenever long, thin chips are taken, as with a tool that has a large radius at the nose or ■ long, straight cutting edge, the danger of vibration is increased.

Surface Finish. The finish on the cut surface is improved as the built-up edge is reduced in size. This reduction may be accomplished by increasing the rake of the tool, using high speeds, reducing the size of the chip, changing the structure of the metal being cut, or introducing a cutting fluid. Any one or a combination of these measures is commonly used to secure better finish.

Machining operations of the finishing type are designed to provide flaw-free surfaces that resist fatigue. Surface finish is important not only in connection with surface machining with single-point tools, but with surfaces made by abrasives and other means. The American Standards Association Committee on Surface Quality has been working on this subject for several years. The first report was made to industry in December 1938.

Surface qualities, by definition, are the physical characteristics of a boundary that separates solid substances. These qualities include such factors as the geometry of the surface in three dimensions, crystal structure, appearance, color, resistance to corrosion, hardness, size and shape of surface flaws. The committee report deals particularly with the geometry of the surface deviations from the nominal surface (cylinder, flat, sphere). These deviations are of three kinds—surface flaws, waviness, and roughness, all three of which can be specified in inches. Surface flaws are occasional irregularities; waviness consists of widely spaced irregularities, more than 1/32 in. apart, such as feed marks; and roughness consists of finely spaced irregularities, less than 1/32 in. apart, which determine what is usually called the "finish" of the piece. Flaws and waviness are now measurable, but roughness, being inside the waves, calls for a new measuring technique. The committee has been concerned with the means of specifying roughness and has adopted the average height of the finely spaced irregularities as a measure of roughness. This height is expressed directly in micro-inches (millionths of an inch) across the surface in a direction to give the largest reading. It is recognized that this average height of irregularity is by no means a complete specification of any surface and that other information concerning the character of the irregularities, as well as waviness, flaws, and other surface qualities, will often be required for solving practical problems. Consideration is being given to means of specifying some of these other surface qualities. A preferred set of roughness classes has been suggested by the committee, to be designated by appropriate symbols that range from ¼ micro-inch to 63,000 micro-inches, root-mean-square average.

During the past 20 years a number of investigators have worked on equipment for measuring surfaces. The equipment most widely used is of three types:

1 Profile recorders that draw an enlarged graph of the actual surface profile. Two types of these laboratory instruments have been described: (*a*) the Profilograph, which uses mirrors, lenses, and a light beam;[3,16] (*b*) an electric profile recorder using vacuum and cathode-ray oscillograph.[1]

2 Several arrangements of microscopic observations (profile microscope) have been used with special illumination for observing surface profiles directly.[2,17]

3 A Profilometer is a portable meter that does not draw a record of the profile, but takes an automatic running average of the height of the surface irregularities and indicates that average directly on a meter. This instrument is portable, self-contained, and has found direct application in the shop.[1]

Tool Wear. When steel is being cut with tools of carbon tool steel, or when cast iron is being machined with any type of tool material, tool failure is caused by wear on the flank of the tool directly beneath the active cutting edge. Tools that fail in this manner should be reground when the width of this abraded surface reaches 0.030 in. or causes an appreciable increase in power. When steel is cut with tools of high speed steel, normal tool failure is caused by a gradual cupping on the face of the tool. After the chip has been formed, it slides over a built-up edge that protects the cutting edge, and rubs against the face of the tool some distance back from the cutting edge, as shown at *A* in Fig. 2. The area of sliding contact between the chip and tool becomes heated, decreases in hardness, and is abraded by the flowing chip. A groove, gradually worn into the face of the tool, becomes larger and larger until its edge meets or nearly meets the cutting edge, as shown at *B*, Fig. 2. The flank below the cutting edge may wear also, causing the newly formed cutting edge to move toward the enlarging groove, as shown at *C*, Fig. 2. The built-up edge is gradually reduced in size from the start of the cut until the edge of the groove meets the cutting edge. A new irregular cutting edge is formed, resembling a ridge of mountains. At this point the built-up edge disappears. The tool cuts most efficiently under this condition, but unfortunately the irregular mountainlike peaks break off and then the tool fails quickly.

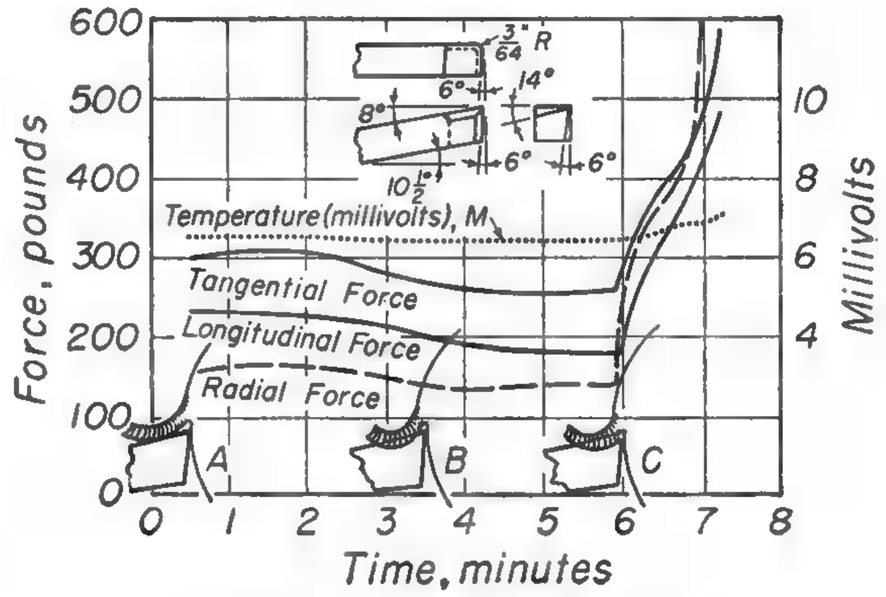

Fig. 2 Failure of a tool by gradual cupping

The progress of tool wear can be estimated readily from the color, shape, and size of the chips produced. In the turning of steel, the chips produced are first long and straight or only slightly coiled and are blue or purple in color at proper cutting speed. The color indicates the development of excessive heat even though the tool has been newly ground and has cut for only a small part of its total life. While the groove is forming in the face of the tool, the chips become coiled either in short spiral or in long helical forms of small diameter. In this condition, the chips are at a lower temperature (are not colored); the tool cuts such chips for the greater part of its life. When the newly formed cutting edge starts to fail, the chips become irregular in shape, rough on the bottom, and again blue in color.

The manner of wear and failure seems to be the same in taking both heavy and light cuts. The time for complete tool failure is easily observed when heavy cuts are being taken, because of the sudden change in shape of the chips, the high blue color, and the burnished surface of the cut shoulder. When light cuts are taken, the failure is similar, but it is more difficult to determine the instant of tool failure. French and Digges[4] used a trailer tool that was set to cut when the leading tool was worn so that the test log became 0.002 in. larger in diameter. However, it has been found that while taking a light cut, there is virtually no change in diameter of the work because of wear on the tool, until tool failure occurs; so the trailer tool, or any device that will indicate the sudden appreciable increase in diameter of the work piece, does give a true value of the time for tool failure under light cuts.

The cutting edge of a tool usually fails first at one point and then at another, long before total failure. This is known as preliminary failure. It may occur on the end of the single-point tool and therefore cause ■ poor finish and a greater diameter of the work piece than is desired. On forming tools, this preliminary failure determines the life of the tool, since the tool must be removed and reground. Single-point tools can be ground with a greater

angle on the side cutting edge or a larger radius at the nose, so that the preliminary failure occurs on the side of the tool and the quality of only the cut shoulder of the work is affected. However, such a tool will cut for a considerable time before complete failure.

Relation Between Cutting Speed and Tool Life. For a given steel, tool, and cutting condition, the life of a turning tool varies inversely with the cutting speed, as indicated by the equation $VT^n = C$, in which V is the surface cutting speed in feet per minute; T is the tool life during cutting, up to the time of tool breakdown measured in minutes; n is the exponent of T and equals the tangent of the angle of slope of the curve of cutting speed versus tool life, when plotted on log-log paper; and C is a constant depending on various conditions, such as type of material; size, shape, and material of tool; size and shape of cut; and cutting fluid. This relation gives a hyperbolic curve on cartesian or rectangular co-ordinates, but a straight line on double logarithmic paper, as shown in Fig. 3.

It is shown below that the constant C and exponent n will vary for virtually every set of conditions as the steel, tool, or cutting fluid is changed, so that no single value of n in the equation $VT^n = C$ can be used safely to represent conditions in general.

Relation Among Forces, Energy and Power. Formulas for cutting forces in turning, and torque and thrust in drilling are given below. These curves indicate that the values of the constant and exponents may vary as the material or tool shape is changed.

Influence of Tool Wear on Cutting Force. The three components of the cutting force and the temperature indicated in millivolts as determined by a thermocouple at all times during the tool life are shown when cutting an annealed SAE 2335 steel dry at 145 fpm. The depth of cut was 0.100 in. and the feed was 0.0125 in. A high speed steel lathe tool was used that had an 8-deg back rake angle, 14-deg side rake, 6-deg end relief, 6-deg side relief, 6-deg end cutting edge angle, 0-deg side cutting edge angle, and 3/64-in. nose radius. The condition of the tool and the built-up edge at ½, 3½, and 6 min after beginning the cut are shown in Fig. 2 at *A*, *B* and *C*, respectively. Tools of cast cobalt-base alloy and of sintered carbide have less rake and therefore require more power.

The Steel Being Cut

The steel being cut presents many factors that affect its machinability, as outlined below.

(1) Composition, such as carbon, alloy, or special steels developed for free-machining that contain sulfur, lead, selenium, or manganese. (2) Melting and casting practice and characteristics of grain size. (3) Fabrication—whether cast, forged, drawn, or rolled (hot or cold finished). (4) Heat treatment. (5) Mechanical properties—tensile strength, hardness, and work hardening capacity. (6) Metallographic structure. (7) Size of the material.

Composition, Heat Treatment and Grain Size.* The machinability of steel varies with its composition, treatment and structure. In cold finished bar stock for screw-machine work, the lamellar pearlitic structure is best for the low-carbon and medium-carbon steels. In the high-carbon steel, such as 1095, a spheroidized condition increases tool life. It is reported that the best machinability of normal cold drawn steels is obtained with an elongation of 13 to 16% in 2 in. and a minimum reduction of area of 40%. There is danger of reduced tool life if the elongation is less than 10% and the reduction of area is less than 35%. Tools will last longer when the steel that is being cut has low hardness and low tensile strength. In screw-stock steels, well broken-up chips, a good finish, and a long tool life at high speed are desirable, but not always obtainable together. High-carbon alloy steels that work harden appreciably are machined in the hot rolled and annealed condition if it is desired to have the tools last as long as possible.

For favorable machinability, a normalizing treatment (or annealing) is recommended by McQuaid[5] for the more highly alloyed steels. It is seldom necessary to normalize carbon carburizing steels, because satisfactory machinability is usually obtained in the hot worked condition. In the fine-grained, shallow-hardening type of low-alloy steels, higher normalizing temperatures are necessary to obtain the lamellar pearlitic structure that is best for machining.

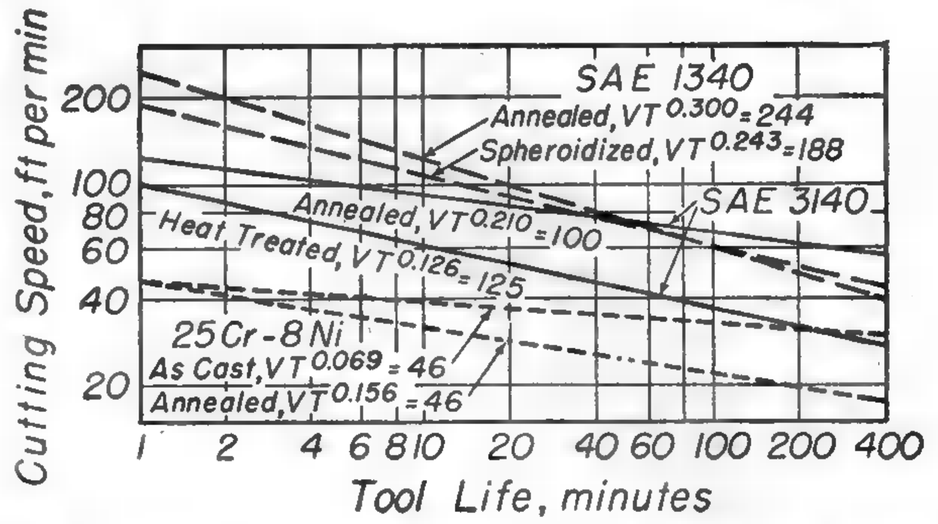

Fig. 3 Curves of cutting speed versus tool life for various types and conditions of steel. Note log-log scale. The curves indicate that each material with a different structure has a curve with a different slope. Thus one equation is not suitable for describing the relation between cutting speed and tool life for all materials. *See* text.

For rough lathe work where surface finish is inconsequential, low hardness is more important than low ductility. For finishing cuts on such steels as 6140, 4140 and 3140, tool life is impaired if the Brinell hardness is more than 207, even though the structure is lamellar pearlite.

Steels of fine grain size (ASTM 5 to 8), when used as oil-hardening or carburized steels, are very ductile, particularly if they are abnormal. These steels show less warpage in heat treatment and appear to be best for producing a fine finish. W. G. Hildorf states: "In general, coarse grain size (ASTM 1 to 5) is better for heavy cuts. Steel of each grain size should be cut with tools appropriately ground. The resulting cost of metal cutting for each steel with favorably ground tools is approximately the same over a long period of time. Difficulty would be encountered, however, should an attempt be made to machine the coarse-grain steels on a machine properly set up for machining fine-grain steels."

For further discussion of grain size of steel, the reader may refer to the articles by Wilson[6,15] and to the article on page 399 of this Handbook.

Cutting Speeds and Feeds in Turning. The cutting speeds listed in Table I* will give satisfactory duration of service from tools when the various steels are being machined in turret lathes with high speed steel tools that have been properly ground for roughing cuts from 1/16 to 3/16 in. deep and feeds from 0.020 to 0.060 in.

Table I. Cutting Speeds Recommended for Turning[a]

Steel	Cutting Speed, surface ft per min
Alloy	
annealed	50 to 60
treated	25 to 40
Castings, miscellaneous	50 to 60
Machine	
hard	35 to 60
medium hard	60 to 85
soft	100 to 120
Threading	25 to 40
Tool	
annealed	60 to 80
unannealed	25 to 35

(a) Recommendations of Warner and Swasey Co. for machining in turret lathes with high speed steel tools, roughing cuts from 1/16 to 3/16 in. deep and feeds from 0.020 to 0.060 in.

Frequently the tools must be ground to produce a certain shape of work that calls for reduced cutting speeds. At best the speeds recommended above are for setting up work and may be modified as experience and conditions indicate. The use of cutting fluids may permit cutting speeds higher than those indicated. If cast cobalt-base

* See also the article on "Metallurgical Factors Affecting the Machinability of Steel", page 369.

* Data as recommended by Warner and Swasey Co.

alloy tools are used, these speeds may be increased from 25 to 75%, depending on the material being cut and the finish desired. If cemented carbide tools of a suitable type are used, speeds as great as 250 to 300 fpm are recommended. If carbon tool steels are used, the values given should be reduced 50%.

Many types of steels are prepared in the form of bars for use in hand and automatic screw machines. For this work, the cuts are usually much lighter than those used in turret lathes, and for that reason the speeds are generally higher, ranging from 100 to 180 surface ft per min.

The machinability of many of these steels is improved by providing some nonabrasive constituent to break up the continuity of the ferrite. Sulfur is used commonly for this purpose. Steels containing sulfur are known as free-cutting steels. For accuracy of dimensions, freedom from rolling mill scale, and improvement in machinability, cold drawing is practiced widely for many low-carbon steels. Usually the hot rolled bars are not equal in machinability to the cold drawn product. Those alloy steels that work harden excessively in cold drawing are often machined in the hot rolled, annealed condition. Good free-machining steel has low ductility and must also have a low order of work hardness. The tools should be ground so that the chips break up into small particles, instead of forming long coils. The article on page 369 lists the machinability ratings of the principal types of carbon and low-alloy steels, based on the rating of AISI-B 1112 steel as 100%. These speeds are suggested only for setup purposes. They may be modified extensively to meet the requirement of the particular operation and cutting fluid used. The article on "Cutting Fluids", page 66, includes an extensive table that gives ratings for the various metals, arranged in groups according to the speed of cutting.

Relation Between Cutting Speed and Tool Life in Turning. Many examples indicate that the analysis or condition of the steel being cut influences the exponent n and and the constant C in the equation of cutting speed versus tool life, $VT^n = C$, described previously. Under Cutting Tools below, it is shown that the tool material and tool shape change this equation; cutting fluids also change it.

In turning cast steel containing 25% Cr and 10% Ni, tool bits ⅜ in. sq were used, ground to 8-deg back rake, 14-deg side rake, 6-deg end relief, 6-deg side relief, 6-deg end cutting edge angle, 15-deg side cutting edge angle, and 3/64-in. nose radius. In taking a cut 0.050 in. deep with 0.0255-in. feed per revolution, it was found that, when the bar was machined as cast, the resulting equation was $VT^{0.069} = 46$, but when a corresponding bar was machined after it had been quenched from 2000 F, the equation was $VT^{0.156} = 46$. These two curves, plotted in Fig. 3, show a considerable change in the value of the exponent merely through the change in structure. For a tool life of 1 min, the cutting speed for each curve is 46 fpm, but for a 60-min tool life, the cutting speed for the heat treated bar is 25 fpm, and that for the as-cast bar is 35 fpm.

Similarly, different bars of 3140 steel 2¼ in. in diam were machined under identical conditions, with a cut 0.0625 in. deep and 0.0377 in. feed, and a high speed steel tool ⅝ in. sq ground to 6-deg back rake, 12-deg side rake, 6-deg end relief, 6-deg side relief, 13-deg end cutting edge angle, 0-deg side cutting edge angle, and ⅛ in. nose radius. The bar was heat treated by quenching in oil from 1525 F and then tempering at 900 F for 1 hr to give a Brinell hardness range of 311 to 340, an elastic limit of about 150,000 psi, a tensile strength of about 165,000 psi, an elongation in 2 in. of about 16%, and a reduction of area of 55%, the resulting equation was $VT^{0.210} = 100$, as shown in Fig. 3. When a similar bar was annealed by cooling from 1575 F, giving a Brinell hardness of 202 to 207, the resulting equation was $VT^{0.126} = 125$, shown in Fig. 3. The cutting speeds for the annealed bar are higher for all values of tool life than corresponding speeds for the heat treated bar.

Similarly, when 1340 steel was machined in the annealed condition with the identical tool and cut outlined in the above paragraph, the equation obtained was $VT^{0.300} = 244$. When the steel was machined in a spheroidized condition, the equation was $VT^{0.243} = 188$. These lines cross at a tool life of 90 min. The annealed bar permits higher cutting speeds for any tool life shorter than 90 min, but the spheroidized bar is better for greater values of tool life. Many other similar examples have proved this point.[7]

For a 20-min tool life, V_{20}, in cutting a 1045 steel under a given cutting condition, high speed steel tools have a cutting speed of 150 fpm for the annealed bar, about 139 fpm for the cold finished bar, about 102 fpm for a bar quenched and tempered at 1000 F, about 93 fpm for a bar quenched and tempered at 600 F, and about 84 fpm for a bar quenched in oil from 1520 F. This wide variation in cutting speed results from the structure and cold finishing.

When cutting dry a 2340 steel annealed with a high speed steel tool of the 8-22-6-6-6-15-3/64 shape, the cutting speeds for 100-min tool life varied as the size of chip was varied, as follows:

A cut 0.0125 in. deep and 0.0125-in. feed gave a cutting speed of 176 fpm and removed 33 cu in. of metal per tool grind for a tool life of 100 min.

For the same tool life, when the cut was 0.035 in. deep and the feed 0.0125 in., the cutting speed was 120 fpm, and 63 cu in. of metal was removed per grind.

When the depth was 0.100 in. and the feed was 0.0125 in., the speed was 72.5 fpm, and 108.8 cu in. of metal was removed per grind.

When the depth was 0.200 in. and the feed was 0.0125 in., the speed was 71 fpm, and 213 cu in. of metal was removed per grind.

For the same cross-sectional area of cut as with the 0.100-in. depth by 0.0125-in. feed, but with the depth reduced one-half and the feed doubled, the cutting speed for a 100-min tool life was changed from 72.5 to 60 fpm, and the metal removed per tool grind was reduced from 108.8 to 90 cu in.

Cutting-Force Relations in Turning. For a given steel and a turning, planing, or shaping tool, the cutting force in pounds (represented by its tangential T, radial R, and longitudinal L components) varies as the feed F and the depth of cut D, as indicated by the following equations:

$$T \text{ (tangential force)} = C_1 F^x D^y$$
$$R \text{ (radial force)} = C_2 F^a D^b$$
$$L \text{ (longitudinal force)} = C_3 F^c D^d$$

C_1, C_2, and C_3 are constants and x and y are exponents. Values of C, x, and y in this equation will vary with the steel or the shape of the tool.

The equations for the three components, when cutting dry a fully annealed low-carbon steel at 80 fpm with a tool ground to 8-deg back rake, 22-deg side rake, 6-deg end relief, 6-deg side relief, 6-deg end cutting edge angle, 0-deg side cutting edge angle, and 3/64-in. nose radius, are as follows: $T = 102{,}500F^{0.80}D$; $R = 704F^{0.46}D^{0.13}$; and $L = 12{,}600F^{0.42}D^{1.35}$.

These equations, determined by Kraus, are shown to vary both in the value of the constants and in that of the exponents, as the shape of the tool is varied, by changing the side and back rake angles, or the nose radius to such an extent that it is difficult to give a general formula.[8]

F. W. Taylor[9] determined a formula for tangential force on a tool having a large nose radius, when turning steel from 30 to 60 fpm, as follows: $T = C\ D\ F^{0.934}$.

The values of C ranged from 230,000 for soft, medium-carbon steel, annealed to a tensile strength of 70,000 psi, to 296,000 psi for hard steel. Taylor used a round-nose tool ⅞ in. wide. The back rake was 8 deg, side rake 14 deg.

The author has found that the equation $T = CD^{0.95}F^{0.79}$ is reliable in the turning or planing of an annealed 3150 steel. The value of the constant ranged from a minimum of 108,200 when a sulfurized mineral oil was used to facilitate cutting, to a maximum of 128,200 during dry cutting. The high speed steel tool had 8-deg back rake, 14-deg side rake, 6-deg relief, 6-deg end cutting edge angle, 0-deg side cutting edge angle, and 1/32-in. nose radius. The setting angle was 90 deg.

It is evident that the change in material affects greatly the value of the cutting force. Figure 4 shows the power resulting from the tangential cutting force when a variety of metals are being machined, as compared with the resistance to cutting by milling and drilling.

Power, Torque and Thrust in Drilling. Values of torque, thrust, and power were determined from drilling a normal-

ized and annealed chromium-vanadium 6150 steel under various commercial conditions, with standard commercial taper-shank drills of high speed steel, the points of which were ground carefully on a machine. For further details regarding drills and for detailed information when drilling other metals, see "Metal Processing".[10] The feed of each drill corresponds, as nearly as could be obtained on the machine, to those generally recommended values shown in Table II. The actual number of rev per minute is based on a peripheral speed of about 60 fpm for all drill sizes, although torque and thrust are not affected by speed. One part of soluble oil to 16 parts of water was used as a cutting fluid in all tests.

These equations are used to determine the torque and thrust for 6150 steel under any cutting condition. The torque and thrust for any drill diameter and feed may be determined graphically from Fig. 5 and 6, respectively. The torque for a drill 1 in. in diam, operating at 0.013-in. feed is shown to be 63 ft-lb. Similarly, the corresponding thrust is shown to be 1820 lb.

Table III also shows factors F_1 and F_2 for torque and thrust by which the torque and thrust, as determined from Fig. 5 and 6, can be multiplied in order to get the torque or thrust for any one of the other forged steels listed. To illustrate, it is desired to know the torque when drilling 2320 steel with a ¾-in. diam drill operating at

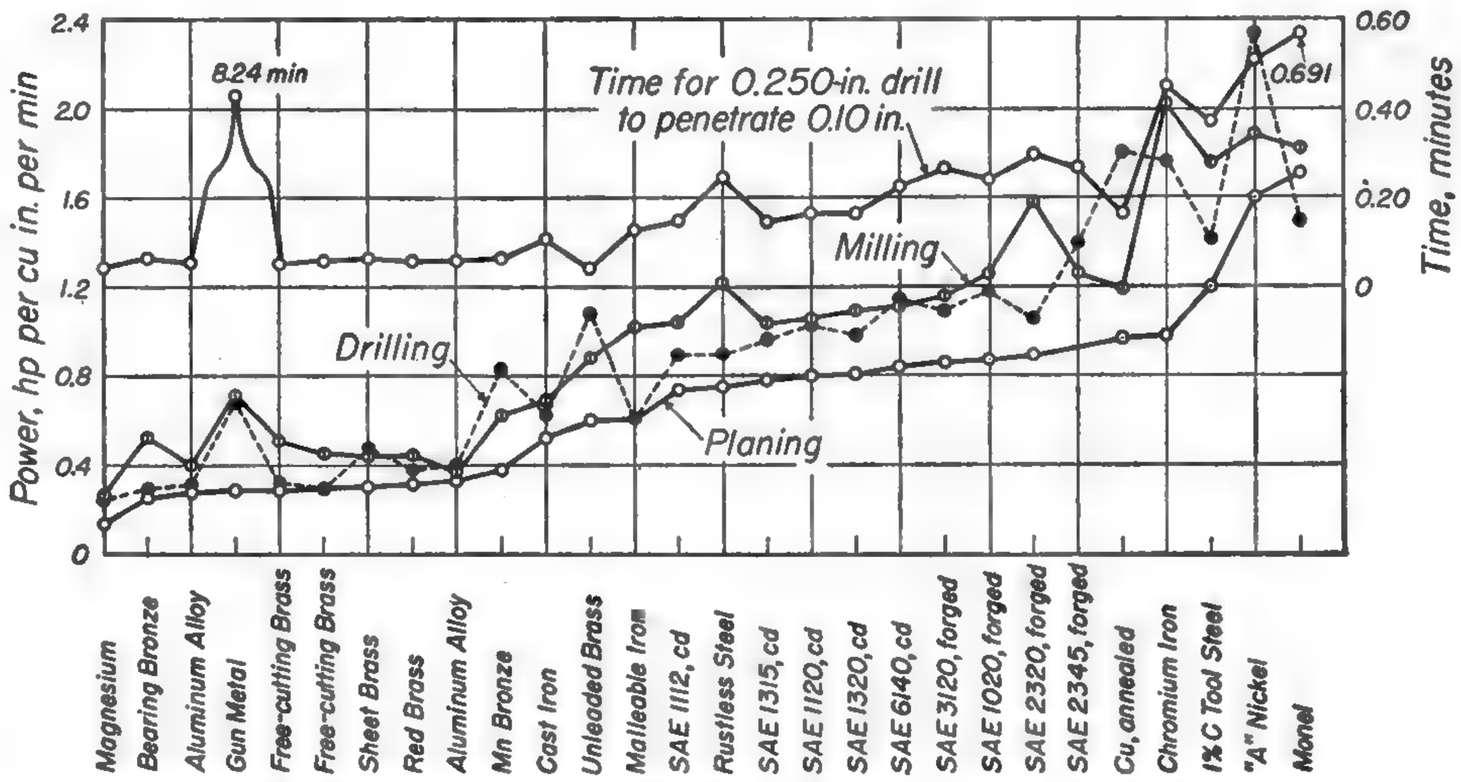

Fig. 4 At the tool point, net values of horsepower per cubic inch of metal cut per minute for various metals. Values were determined for drilling, milling and planing under standardized conditions

In order to make it possible to determine the torque T in pound-feet, the thrust B in pounds, or power, for any other combination of drill diam d in inches and feed f in inches per revolution, the following equations were

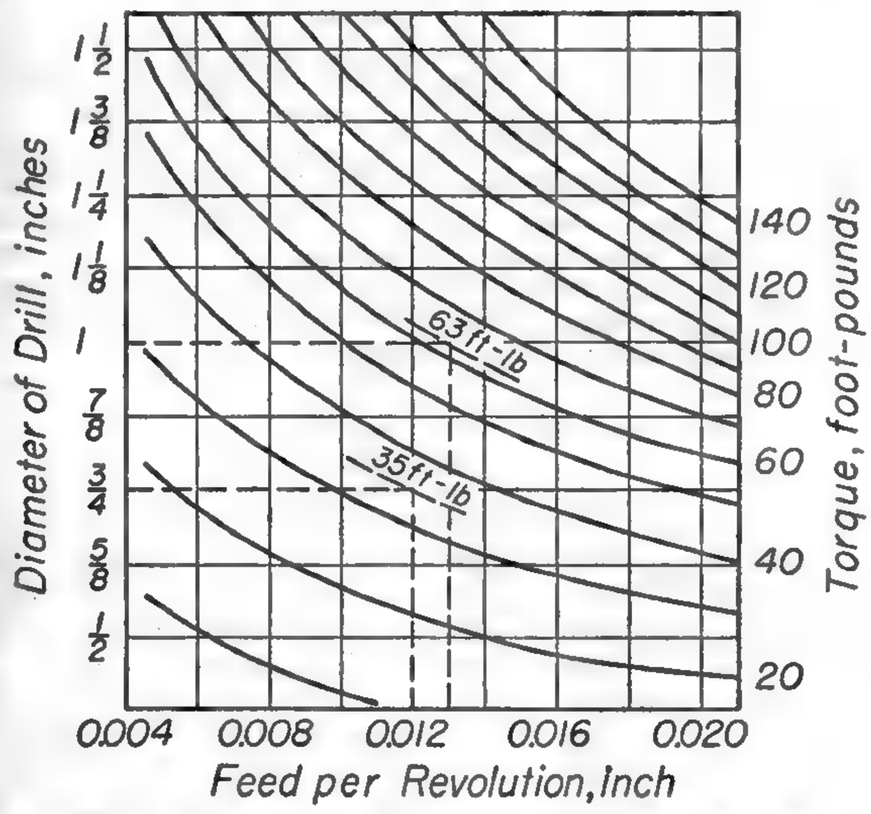

Fig. 5 Torque at the drill point in drilling 6150 steel

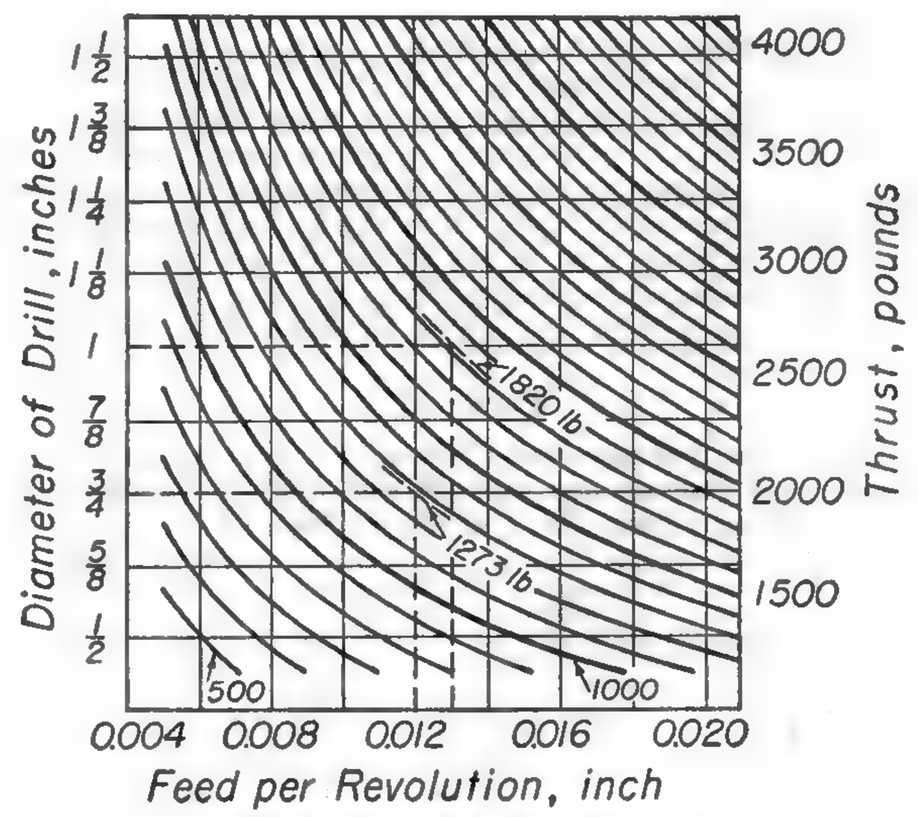

Fig. 6 Thrust in drilling 6150 steel

determined: $T = Cf^{0.78}d^{1.8}$; $B = Kf^{0.78}d$. C is the constant for the material, drill, and cutting fluid in the torque formula, and K is a similar constant in the thrust formula. For drilling 6150 steel that has a Brinell hardness of 186, the formula becomes: $T_{6150} = 1840\ f^{0.78}\ d^{1.8}$. The thrust formula becomes: $B_{6150} = 53{,}400\ f^{0.78}\ d$. The constants for torque and thrust are shown for a number of other steels in Table III.

0.012-in. feed. From Fig. 5 the torque is shown to be 35 ft-lb for the 6150 steel. The torque factor for the 2320 steel is found to be 0.820 in Table III. The resulting torque for the 2320 steel is equal to 35 times 0.820 or 28.7 lb-ft.

The total horsepower developed at the drill point equals the horsepower resulting from the torque plus the horsepower resulting from the thrust as follows:

$$HP = \frac{2\pi TN}{33{,}000} + \frac{B\ f\ N}{12 \times 33{,}000}$$

To illustrate, the drill 1¼ in. in diam with a feed of 0.015 in., rotating at 171.1 rpm (60 fpm) when cutting 6150

Table II

Speeds and Feeds Recommended for High Speed Drills in Various Metals When Cut Using a Suitable Coolant

Size of Drill, inch	Feed per Revolution, inch	Bronze, Brass	Alloy Steel Drop Forging	Cast Iron	Tool and Carbon Steel Drop Forgings	Mild Steel	Malleable Iron	Cast Steel	Hard Cast Iron

1½	0.016	762	127	357	153	306	229	102	204
1⅝	0.016	705	118	329	141	282	212	94	188
1¾	0.016	654	109	306	131	262	196	87	175
1⅞	0.016	610	102	285	122	244	183	81	163
2	0.016	571	95	267	115	229	172	76	153

steel, has a torque of 110.8 lb-ft and a thrust of 2430 lb. Substituting these values in the above equation would give the total horsepower as follows:

$$HP = \frac{2\pi 110.8 \times 175.1}{33{,}000} + \frac{2{,}430 \times 0.015 \times 175.1}{12 \times 33{,}000}$$

$$= 3.692 + 0.016 = 3.708$$

The horsepower resulting from the thrust is only 0.016 or only 0.44% of the total power developed; so for ordinary purposes the output of horsepower from the thrust may be neglected. The thrust is important in design, however. Table II shows that the efficiency of the machine, as determined by dividing the input by the output, is highest when small drills are used, operating at high speed with resulting low values of torque and thrust. Similarly, the efficiency is lowest when the torque and thrust are high, even though the speed of the machine is lower.

Table III

Constants for Torque and Thrust Formulas for Various Steels, and Factors for Torque and Thrust Conversion When Using the Curves of Fig. 5 and 6

S.A.E. Number	Bar Number	Brinell Hardness Number	Torque Formula		Thrust Formula	
			C	Factor, F_1	K	Factor, F_2
1020	1	137	1590	0.865	40,000	0.749
1045	2	159	1590	0.865	42,000	0.786

4135	15	156	1560	0.848	43,000	0.805
4130	16	156	1700	0.946	48,000	0.899
1095	19	154	2180	1.184	69,000	1.291

It has been found that torque and thrust are affected little by a change in cutting speed, but the power is a direct function of the speed, as illustrated above.

The horsepower per cubic inch of metal cut per minute is lower for larger values of feed and drill diameter. In drilling 6150 steel with a drill ½ in. in diam at 0.009-in. feed, a value of 1.443 is obtained. For drilling the same steel with a drill 1¼ in. in diam at 0.015-in. feed, the horsepower per cubic inch per minute is 1.075.

In another set of experiments[11] it has been shown that, in the drilling of several steels with 11 different types of cutting fluids, the equation for torque as given above holds true for all steels. When the steels or the cutting fluids are varied, only the constant is changed, as shown in Table IV. The formula given for thrust above in connection with the 6150 steel holds approximately, but for more accurate work, considering the variation in web thickness w of the drills of different sizes, a more accurate formula for thrust has been developed as follows:

$$B = Kf^{0.87}\left(\frac{d}{5} + \frac{w}{d}\right)^{2.12}$$

The performance of one cutting fluid on one steel does not indicate its relative performance on another steel. Actual values of torque and thrust for drilling an annealed 1035 steel with each of 11 cutting fluids, are shown in Fig. 7 and 8. (*Also see* "Cutting Fluids", page 66.)

Table IV shows the values of torque and thrust for standard drills ½ in. and 1¼ in. in diam, operating in each of four steels with three cutting fluids. The equations for torque and thrust and values of the constants are indicated also.

Similar values for torque and thrust are shown in Table V, for drills ranging from ⅛ to ½ in. in diam, when operating in the same steels with an emulsion consisting of 1 part soluble oil to 16 parts water. The equation for torque shown for small drills in Table V is the same as that for larger drills shown in Table IV. The equation for thrust for the small drills shown in Table V is of a simpler form, since it does not account for variations in web thickness.

Table IV

Torque and Thrust Values When Drilling Various Steels with Twist Drills More Than ½ in. in Diam. and Using Three Types of Cutting Fluid

$$T = C\, f^{0.78}\, d^{1.8} \qquad B = K\, f^{0.87} \left(\frac{d}{5} + \frac{w}{d}\right)^{2.12}$$

Cutting Tools

The efficiency of a cutting tool is based on the length of time per grind that it will cut at a certain speed under given conditions (termed "tool endurance"); on the power consumed by the tool in removing the metal, and on the finish it produces. The smaller the cutting angle and the greater the rake, the more efficient is the cutting action, from the standpoint of power. When cutting hard metals, the sharp lip will not stand up so well as the blunt lip. The greater the lip angle, the greater the reinforcement to withstand the cutting force and to carry away the heat generated. The tool that has a large rake induces the chip to flow over its face with less distortion, while the tool that has a small rake pushes the metal off with excessive shear and compression. In general, a tool may fail (1) by abrasion on the flank below the active cutting edge; (2) by abrasion on the face behind the cutting edge, causing development of a groove that wears forward to the cutting edge and results in the fairly sudden breaking off of the cutting edge; (3) by a combination of 1 and 2; (4) by spalling or crumbling of the cutting edge; and (5) by a decrease in hardness because of excessive heat generated at the cutting edge.

Table V

Torque and Thrust Values for Drilling Various Steels Using a 1 to 16 Emulsion[13]

Torque in lb-ft $= C\, f^{0.78}\, d^{1.8}$
Thrust in lb $= K\, f^{0.87}\, d$

SAE 3150, annealed	2.38	318	1500	108,500
SAE 1112, cold finished	1.58	217	1000	74,100

Types 1, 2 and 3 are normal types of tool failure. Tools made of carbon tool steel usually fail in the first way when cutting steel and cast iron. High speed steel tools fail in the first way when cutting cast iron, but normally in the second or third way when cutting steel, as illustrated in Fig. 2. Carbide tools fail by flank wear, by cupping, or by the two together.

Factors entering into the performance of tools include (1) composition, (2) melting and casting practice, (3) fabrication—whether forged, ground from rolled bars, cast, or sintered, (4) heat treatment, (5) mechanical properties—hardness, ductility and hot hardness, (6) tool form, such as profile of cutting edge, and various tool angles, (7) tool sharpness, (8) metallographic structure, (9) tool setting.

Cutting-Tool Materials. Cutting tools must be formed to meet the requirements of the material of which they are made. Cutting speeds and the size of the cut also must be in accordance with the tool material in order to help obtain satisfactory commercial tool life. Cutting tools are commonly made of carbon tool steel, finishing steel, high speed steel, cobalt-base alloys, sintered carbide, and diamonds. Carbon tool steels are used to some extent where light cuts at comparatively low speeds are permissible, in screw machines on free-cutting materials where the tool is well cooled, or where formed tools are stocked for infrequent use. The great majority of tools being used are made of high speed steel. The 18-4-1 high speed steel is the type most commonly used for all-around work. It is uniform in performance. The 18-4-2 type of

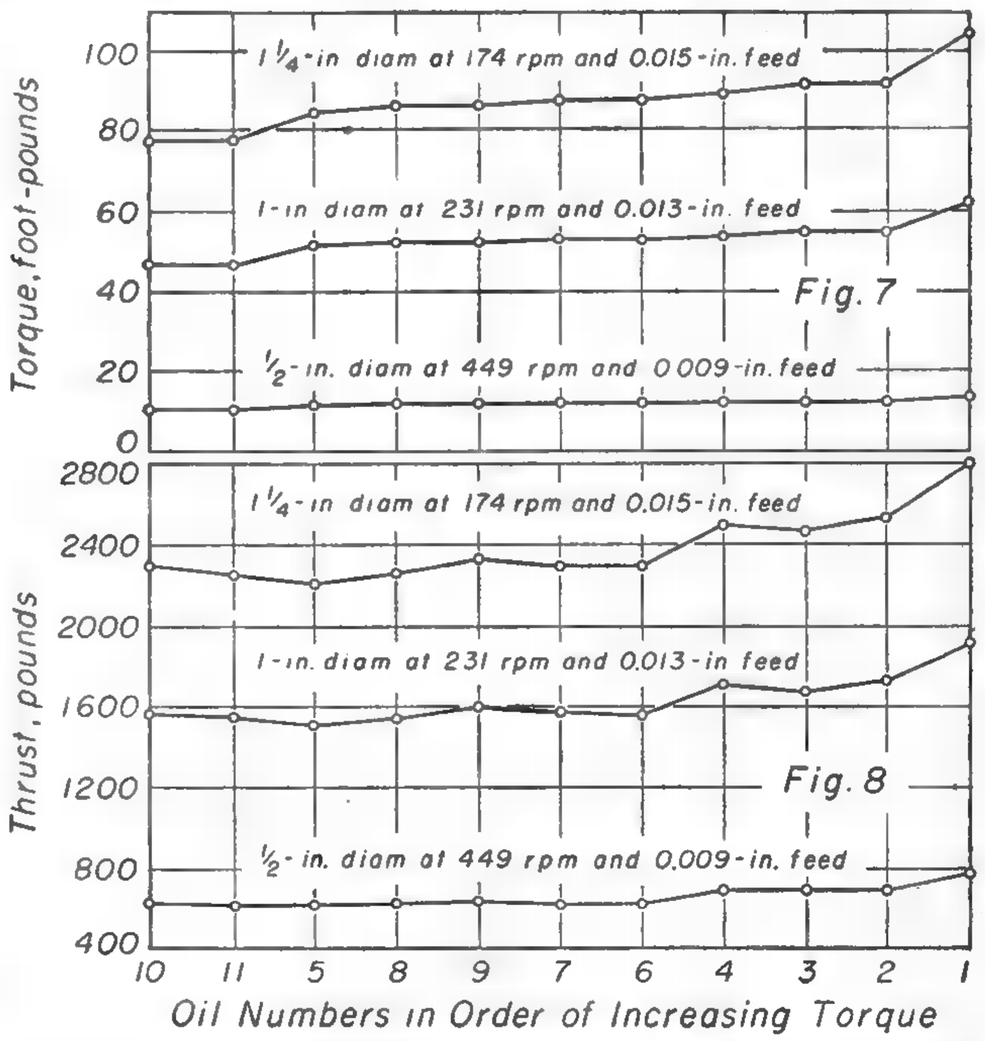

Fig. 7 Torque required to drill an annealed 1035 steel forging with various sizes of drills operating at a speed of 60 fpm and with cutting fluids as indicated by the numbers along the horizontal axis of the graph. These numbers refer to different cutting fluids, as follow: (1) dry cutting; (2) 1½% borax in water; (3) 1 part soluble oil to 50 parts water; (4) 1 part soluble oil to 10 parts water; (5) No. 1 lard oil; (6) light mineral oil; (7) heavy mineral oil; (8) 10% lard oil; (9) mineral 5% oleic acid; (10) sulfurized mineral oil; and (11) sulfurized-base oil, blended 1 to 5 with light mineral oil.

Fig. 8 Thrust values required to drill the 1035 steel of Fig. 7

steel generally gives slightly better performance than the 18-4-1 type. The 18-4-3½ type of high speed steel is coming into favor for heavy-duty work. Molybdenum steels, such as 8-4-1, 8-4-2, and 9-1½-4-1 also are coming into general use where high speed steels are involved. The cobalt high speed steels give as much as 25% greater production for certain heavy-duty jobs.

Cast cobalt-base alloy and sintered carbide tools are nonferrous in character. These alloys are cast or sintered to shape and are finally ground. Neither can be forged or heat treated, and both are used ordinarily in the form of tips welded to the end of heavy steel shanks. Both cobalt-base alloys and cemented carbide are less ductile than high speed steel and serve best when cutting abrasive materials. They must be ground with less clearance and rake in order to provide a greater lip angle to support the cutting edge. Both should be supported rigidly to avoid bending or chattering. Terminology applied to a ground tool is presented in Fig. 9 and 10, which apply to a typical high speed steel, shank-type tool.

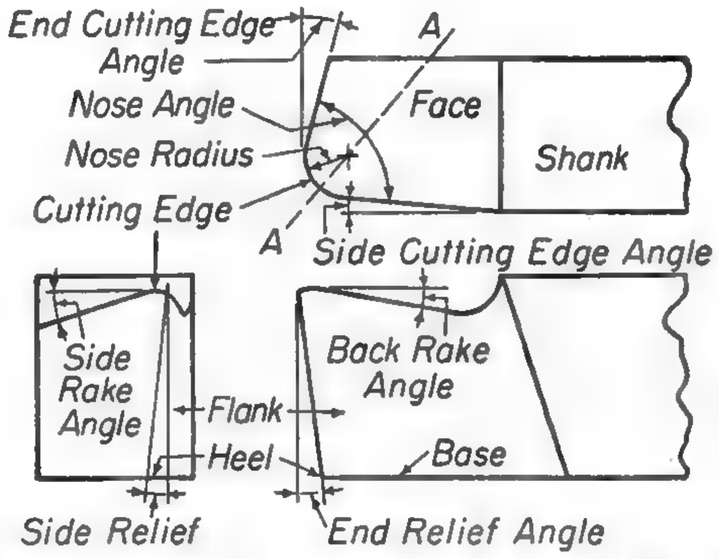

Fig. 9 Nomenclature of a ground right-cut, single-point tool that has a straight cutting edge and straight shank. (American Standards Association)

Performance of Tools. In the cutting of a given steel, the composition or treatment of the high speed steel tool, as well as its geometric shape, has a bearing on its performance. A series of tests for speed of cutting in relation to tool life, was performed on each of four high speed steel tool bits, two of which were of the regular 18-4-1 type of high speed steel; the third was a cobalt high speed steel; the fourth was a molybdenum high speed steel. When these four tool bits were ground to a specific shape for turning dry, annealed 2345 steel, individual equations were obtained, indicating that the constant, as well as the exponent, of the tool life equation is subject to change because of the tool material.[7]

Influence of the Tool Shape on Tool Life. For a 60-min tool life, the cutting speed is increased 125% as the radius of the nose of the tool is increased from zero to ¼ in.[14] Increasing the side cutting angle similarly shows a great increase in cutting speed for the same tool life. Frequently, if side cutting angles are greater than 30 deg on deep cuts where deep thin chips are taken, chatter is likely to occur. This chatter may be eliminated by changing the cutting fluid, the cutting speed, the size or shape of cut, and preferably by reducing the side cutting edge angle. The speed for a 60-min tool life is increased 55% as the side cutting edge angle is increased from zero to 60 deg. The side rake angle similarly indicates an increase in cutting speed for any given tool life, but for cutting an annealed 2335 steel, the maximum speed was reached when using a side rake angle of 22 deg. However a 70% increase in cutting speed was obtained by increasing the side rake angle from zero to 22 deg. In the cutting of soft steel, the greatest tool life for any given speed, is obtained when the tool is ground as follows: 8-deg back rake, 22-deg side rake, 6-deg relief, 6-deg end cutting edge angle, 45-deg side cutting edge angle, and ⅛-in. nose radius. For harder steel, the side cutting edge and side rake angles should be reduced.

Influence of Tool Shape on Cutting Force. For a cut 0.100 in. deep with a feed of 0.0125 in. in a 0.61% steel of 207 Brinell and 99,000 psi, with a basic tool ground to 8-deg back rake, 14-deg side rake, 6-deg end cutting edge angle, 15-deg side cutting edge angle, and $\frac{3}{64}$-in. nose radius, the cutting force varies as follows: As the nose radius is increased from zero to ¼ in., the tangential force remains virtually unchanged at 395 lb; the longitudinal force is reduced from 185 to 95 lb; and the radial force is increased from 25 to 150 lb. As the side cutting edge angle is increased from zero to 60 deg, the tangential force remains almost constant at 395 lb. It decreases slightly for the 30 and 45-deg angles. The longitudinal force is gradually reduced from 173 to 90 lb, and the radial force is increased from 48 to 180 lb. As the side rake angle is increased from zero to 40 deg, the tangential force is reduced from 440 to 335 lb, the longitudinal force is reduced from 245 to 98 lb, but the radial force remains virtually constant. A change in back rake angle from zero to 16 deg produces only a slight reduction in tangential and longitudinal forces, but reduces the radial force from 75 lb to zero.

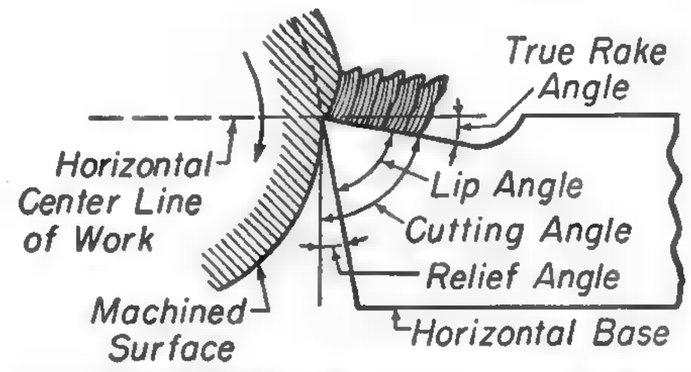

Fig. 10 A section through the active cutting edge *A* — *A* of Fig. 9, including nomenclature

As the cutting speed is varied for an otherwise fixed cutting condition, all components of the cutting force remain virtually constant at the higher speeds. At very low speeds, all values of components vary. The temperature between the tool and work, as determined with a thermocouple, rises rapidly until a speed is reached between 10 and 20 fpm, depending on certain variables, after which it increases in direct proportion to an increase in speed.

Metallurgical Factors Affecting the Machinability of Steel

BY THE SUBCOMMITTEE ON METALLURGICAL FACTORS AFFECTING MACHINABILITY*

MACHINABILITY may be defined as that property of a metal which governs the performance of the metal in machining reactions. Machinability is a complex, elusive quality, seldom subject to positive control by any single factor. Further, no entirely satisfactory and generally accepted laboratory test has ever been devised to evaluate the machining properties of steel although investigators have made and are continuing attempts to develop such a test. In conjunction with actual machining experience correlated with metallurgical data and manufacturing practices these investigations have brought forth some information on fundamental factors that affect the machining of steel. Factors that arise in the cutting operations are outside the scope of this article; only factors metallurgical in character and inherent in the steel are considered here. They are grouped according to manufacture, composition, processing and physical characteristics.

Steelmaking. Aside from the adjustment of chemical composition, many features in the operation of any steelmaking process will affect the machining characteristics of the final product. It has been learned, for instance, that ease of machining Bessemer steels is generally increased by carrying the steelmaking process to a further point of oxidation of carbon than in making other Bessemer products. Furthermore, any steelmaking procedure that favors the absorption of an appreciable nitrogen content seems to improve machinability. Machining appears to be affected adversely if the final total sulfur content of either Bessemer or open hearth steels consists largely of residual sulfur rather than of sulfur addition.

The Bessemer Process. Acid Bessemer sulfurized carbon steels, commonly known as "Bessemer screw steels", had their origin in the early days of the Bessemer process. Late in the nineteenth century it came to be recognized that high-sulfur blows, erratically produced in the cupola-converter combination, made a product superior to lower sulfur steel in machining qualities. The introduction of the hot metal mixer, the improvement of Bessemer converters and the success of deliberate additions of sulfur to Bessemer steel are now history.

The Open Hearth Process. The addition of sulfur to Bessemer steel led to a similar practice for low-carbon open hearth steel. Thus open hearth screw steels came into existence, having machining quality distinctly better than that of nonsulfurized open hearth steels, though generally poorer in machinability than Bessemer screw steels.

Composition. The chemical composition of a steel has a major influence on machinability, since the composition affects the structure and mechanical properties. Because the effect of composition is obscured by other factors, it is difficult to state the exact influence of each element.

Carbide-forming elements decrease machinability by increasing hardness, but their detrimental effects can be modified by annealing processes. Elements that dissolve in ferrite ordinarily cause poorer machinability on account of the hardness or toughness which they impart. Elements forming inclusions have harmful effects when the inclusion is hard or abrasive, such as alumina or silica. Elements such as sulfur, which form soft inclusions, appear to have a beneficial effect. Best machinability is associated with an optimum hardness and brittleness produced by the combined effect of elements present. Thus an increase of manganese should be accompanied by a decrease of carbon to avoid passing beyond the optimum hardness. General statements concerning the effects of the more important elements and compounds are given below.

Carbon. Very low carbon steels are usually of poor machining quality because they have less than the optimum hardness. The best carbon content for machinability is approximately 0.10% for Bessemer steel and 0.20% for open hearth steel. Cutting quality decreases rapidly with increase of carbon to more than 0.15% in Bessemer and more than 0.30% in open hearth steel.

Manganese. The effect of manganese depends largely on the total content of carbon, manganese and phosphorus. In free-machining steels, the most favorable manganese content is 0.75 to 1.00% in Bessemer steel and about 1.00 to 1.30% in open hearth steel.

Phosphorus. In Bessemer steel phosphorus should be in the range of 0.06% to 0.10%. Added phosphorus, as high as 0.10% in open hearth steel, is mildly effective in improving machinability.

Sulfur. Sulfur is the element most commonly used for obtaining better machinability. As the percentage of sulfur is increased to some limit not yet accurately determined, machinability is improved. From a practical manufacturing standpoint, this limit is approximately 0.30%.

Silicon. Cutting quality ordinarily decreases as the silicon content increases, chiefly because of the silicate inclusions usually present.

Other Elements. The general effect of the other alloying elements is to decrease machinability by imparting hardness and toughness to the steel. For this reason most alloy steels will require a special heat treatment, usually annealing, to secure the best machining properties. Some alloying elements, such as molybdenum, vanadium or chromium decrease machinability less than others, such as nickel. Lead is added to structural steel to improve machinability. Selenium is added to stainless steel to improve machinability; its effect is similar to that of sulfur. Tellurium has also been added to stainless steel to improve machinability.

Inclusions. In accordance with the best accepted practice of screw steel manufacture, every precaution is taken to avoid abrasive inclusions in the finished product. Sulfides, usually occurring in the form of MnS and oxysulfide, variously diluted with FeS, MnO or FeO are generally accepted as benefiting cutting quality; however, it is desirable that such inclusions be small and uniformly distributed. Iron oxides and manganese oxides, either singly or in combination, are believed not to be detrimental. Their presence in high-sulfur steels is usually associated with sulfur (oxysulfides) in which form they are considered distinctly beneficial. The combination of high percentages of these two oxides with SiO_2 is also said to reduce the abrasive and detrimental qualities of silicates. Because of its high hardness and abrasive properties, Al_2O_3 is considered definitely detrimental. Silicates low in FeO or MnO content have a high degree of hardness and are believed to affect machining quality detrimentally.

Processing. Principal processing methods that affect the machining characteristics of steel are hot working, cold working and thermal treatments.

Hot Working. Experience indicates that large structural grain size is ordinarily preferable for most types of machining operations. The desired structural grain size can usually be obtained within reasonable limits by controlling the finishing temperature in hot working. For carbon steels, finishing temperatures are held near 1700 F, or higher when machining characteristics are important and the steel is to be machined before further heat treatment.

For alloy steels that have high hardness when finished at temperatures well above the upper transformation range, temperatures just above A_3 provide somewhat lower hardness (because this decreases the rate of cooling through the transformation range), which may aid machining more than larger grain size with attendant higher hardness.

The effect of hot working on machinability may be considered minor when compared with the effects of such factors as chemical composition and annealing treatment.

Cold Working. Machining characteristics of most steels can be greatly improved by cold working. Machinability is favored by relatively low strength and low ductility. Cold working increases the strength but decreases the ductility. Therefore machinability of steel can be improved by cold working to the point where the cold working increases the

(a) Also classified as carburizing steels.

hardness beyond the good machining range of about 187 to 217 Brinell. Cold work brings the greatest improvement in steels that have a low order of work hardening and a high order of work embrittlement.

Thermal Treatments. The machining properties of steel can be affected markedly by heat treatment. Steels that contain less than 0.10% C can be improved in machinability by quenching in water from above A_3, which lowers the ductility and reduces the tendency to drag in machining. Except for these very low-carbon steels, however, quenching and tempering is detrimental to machining properties. The tempered structure is one of the least favorable for machining.

Annealing and normalizing treatments can be very useful in improving the machining properties. In medium-carbon steels they should be designed to coarsen the grain and break up the continuity of the ferrite as much as possible. The carbide should be present as lamellar pearlite. At about 0.50% C with this type of structure, the strength becomes too high for best machinability and it is necessary to modify the annealing cycle so that just enough carbide will be spheroidized to keep the strength within the best machining range, in the vicinity of 100,000 psi tensile strength or about 200 Brinell. Otherwise the structural characteristics should remain the same. As the carbon increases to more than 0.50%, the percentage of spheroidization should increase until, at about 1.00% C, virtually complete spheroidization is necessary to keep the strength factor within the best machining range.

In the alloy steels, the same general principles again apply, but other factors also must be taken into consideration. Alloying elements such as vanadium may form carbides or, like nickel, may form solid solutions. Sometimes the same alloying element may act in both ways; that is, it may go into solution in the ferrite and form a carbide. Examples are chromium and manganese. In this discussion the alloying elements will be considered under two general classifications—those forming carbides and those forming solid solutions.

The elements forming carbides have the same effect as carbon on machining properties; but because of the effect of these elements on hardenability, the carbon content at which the strength factor becomes too high for good machinability is lower than in the plain carbon steels. When heat treatments are used to lower the strength, the annealing cycle should be designed to produce a coarse-grained lamellar pearlite, well broken up. Part of the carbide is spheroidized in the higher carbon alloy steels as in the plain carbon steels. It follows that carbide-forming elements give no particular difficulty in producing good machining properties in alloy steel.

The elements forming solid solutions present a different problem. They toughen and strengthen the ferrite and therefore their tendency is to retard machinability. Attempts can be made to produce a lamellar pearlite structure by thermal treatments (or lamellar with a certain percentage of spheroidized carbide) the same as outlined for carbon steels, but the characteristics of the ferrite matrix cannot be changed much. It is more difficult to produce a lamellar pearlite structure if much of the alloying element is in solid solution in the ferrite, since such elements make the transformation of austenite more sluggish, and if cooling is a little too rapid, the pearlite reaction will be suppressed. If the cooling is a little too slow,

						A-8742	51	....			

however, the structure may be predominantly spheroidized. When little can be accomplished with heat treatment, machinability of these alloy steels can be improved by cold working to reduce ductility. This is particularly true in the low-carbon alloy steels like 4615, where free ferrite is the predominant structural constituent. Experience has indicated that it is an advantage to cold work the more highly alloyed steels like 2512 to higher hardness than is usually considered best for free machining, in order to reduce the ductility further. This applies to drilling or broaching where steel that has been cold worked to a Brinell number up to 250, or above, may give better results than softer material with high ductility and toughness.

Physical Characteristics. Like other factors affecting machinability, physical characteristics depend on manufacturing and processing practices. Therefore a discussion of some physical details has been included in the preceding sections. In general, the qualities desired, though not clearly defined, seem to be a low capacity for work hardening with a high degree of work embrittlement, under the conditions of cold work that exist during cutting.

Grain Size. There is a divergence of opinion about the relation of structural grain size to machining quality, but it is generally agreed that some improvement in machining performance usually occurs with large structural grain size. However, the improvement is not proportional to the degree of coarsening. Steel that has a small austenitic grain size is usually structurally fine grained as rolled. Certain precautions, such as finishing at a high temperature, tend to coarsen the structural as-rolled grain size and thus aid machining. However, fine-grained steels, made usually by additions of aluminum are generally of poorer machinability because Al_2O_3 present in the steel has an abrasive action on the tool.

Hardness. Many investigators have tried to correlate closely Brinell hardness numbers and machinability; but much of the work has been unsuccessful because composition, structure and mechanical factors are not taken into account in a simple hardness test. Nevertheless, some consider that Brinell hardness is an indication of machining quality and that the range of hardness for ease of machining is about 187 to 229 Brinell.

Tensile Properties. Tensile properties are an index of machinability only in giving comparative values of strength and ductility of different steel compositions. Good machining steels are soft and brittle and have the property of low work hardness. Tensile properties can therefore be used to show the relation of tensile strength to ductility. It is also probable that shearing properties are related to machining properties.

Metallographic Structure. Lamellar pearlite is the most favorable structure in which carbon occurs in steel for free machining, unless there is too much of it, as in very high-carbon steels. The presence of too much pearlite results in strength too high for machining, and it is necessary to spheroidize the cementite as mentioned before.

Many authorities hold the opinion that nonabrasive inclusions that break up the ferrite particles are strong factors for improved free cutting. Sulfides are an outstanding example of this type of inclusion. Perhaps the smaller the inclusions, the more effective they are. The effect of submicroscopic particles is not known, although some have speculated that such particles exert greater influence on machinability than visible inclusions do.

Classification. A study of the factors influencing the machinability of steel indicates that the various steels may be classified in groups that have more or less similar machinability. The various AISI steels with corresponding SAE numbers have been arranged in the Classification Tables I and II.

Those grades having machinability significantly affected by annealing have been rated both "annealed" and "as-rolled" (not annealed). The values given are intended to serve only as a guide. Adjustments should be made to suit specific operations and conditions, since the variation in any one grade may readily overlap similar grades immediately preceding or following in its series. These values are appropriate for turning, forming, drilling and cutting-off operations where high speed tools and a conventional cutting fluid are used.

The Welding of Ferrous Metals

BY THE SUBCOMMITTEE ON WELDING AND CUTTING*

THE METALLURGICAL aspects of fusion welding and certain allied processes are discussed in a general way in the article entitled "Welding Processes", on page 71 of this Handbook. The present article will summarize the application of these methods to ferrous metals.

Table I lists the welding methods that are commonly used and those occasionally used for joining 26 grades of ferrous materials. The welding of these materials will be discussed in the order given in Table I.

Iron

1 Wrought Iron. The low carbon and high slag content have a marked effect on the weldability of wrought iron.

Forge Welding. Wrought iron is an ideal material for forge welding.

Resistance Welding. Spot, seam, projection, flash and resistance butt welding may be applied satisfactorily to wrought iron. To produce solid, clean welds and to prolong electrode life, all scale, oxide and other foreign matter must be removed from the work.

Thermit Pressure and Fusion Welding. Wrought iron can be successfully welded by either of these processes. On old wrought iron that contains heavy layers of slag it may be necessary to make two thermit welds in order to produce a satisfactory joint. The first of these may melt into the laminated iron-and-slag piece, and porosity, caused by the slag layers, may be found in the thermit steel. If so, the collars are trimmed off and the original gap is cut through the section, leaving the porous thermit steel to be remelted in a new weld made on these same ends. The new weld will fuse only as far as the original weld did, from which the slag has been eliminated. Most modern wrought iron sections contain so little slag that this reweld is unnecessary.

Gas Welding. In oxyacetylene welding of wrought iron, the slag content sweats to the surface at a comparatively low temperature. This may deceive the inexperienced operator who may regard it as an indication of fusion. Heating must be continued until the base metal itself actually breaks down into a puddle.

This puddle of molten metal must be maintained and the welding rod must be kept immersed in it to assure fusion and penetration without oxidation. Excessive stirring of the puddle should be avoided since this causes needless exposure and resulting oxidation.

An oxyacetylene welding rod for wrought iron should either be made of low-carbon iron or should contain sufficient manganese and silicon so that a weld metal relatively high in these elements will be obtained. The welding flame should be strictly neutral.

Arc Welding. Arc welding of wrought iron, both in flat and vertical positions, with coated electrodes, is hindered by accumulations of slag that become entrapped in the weld, and care must be taken to melt out this slag. In general practice, as little as possible of the wrought iron is melted, and reverse polarity reduces the formation of slag accumulations substantially but not entirely.

* The members of this subcommittee are C. W. Obert, *Chairman* (The Linde Air Products Company), C. L. Altenburger (Great Lakes Steel Corporation), Roger W. Clark (General Electric Company), C. H. Jennings (Westinghouse Electric Corporation), H. L. Maxwell (E. I. du Pont de Nemours & Company), H. R. Morrison (The Linde Air Products Company), and E. H. Roper (Air Reduction Sales Company).

The welding of wrought iron with bare electrodes is comparable with welding of low-carbon steel. The arcing characteristics of the electrode and the ability to obtain proper fusion between the parent metal and the deposited weld metal are the same as in the welding of mild steel.

Welds made with bare mild steel electrodes have strength approximately equal to that of the parent metal, while welds made with heavily coated mild steel electrodes are stronger than the parent metal.

Bronze Welding. The bronze welding process can be applied readily to wrought iron.

Oxyacetylene Pressure Welding. Wrought iron will respond satisfactorily to standard pressure welding.

Submerged-Melt Welding. A two-pass procedure is necessary to assure consistently sound joints. The first pass, which is approximately the full depth of the V, fuses and fluxes the accumulated slag from the base metal, but is porous because the gas evolved has not been completely eliminated. The second pass re-fuses the first and adds reinforcing. The resulting weld, which is made with materials ordinarily used for low-carbon steel welding, is sound and its strength exceeds that of the base metal.

2 Low-Carbon Iron. Iron with a carbon content of 0.06% max is one of the most readily welded of the ferrous metals.

For welding low-carbon steels, preheating is not necessary and subsequent annealing is not required unless it is desired to eliminate the residual stresses set up during the welding operation.

Forge Welding. Low-carbon iron is readily welded by the forge welding process.

Resistance Welding. Low-carbon irons are readily resistance welded by any of the processes that are suitable for welding wrought iron.

Gas Welding. This process is similar to the gas welding of low-carbon steels, except that the filler rod utilized is necessarily of low-carbon iron in order to retain the corrosion resistance of the parent metal and to obtain a weld of similar characteristics.

Arc Welding. Arc welding of low-carbon iron is accomplished with the use of mild steel electrodes, heavily coated. The welding current and procedures are the same as for welding mild steel. Bare electrodes can be used with a resulting decrease in the corrosion resistance of the weld and adjacent parent metal. Iron with carbon content less than 0.15% absorbs gas readily from the atmosphere during welding. Welds of highest quality require complete shielding.

Bronze Welding. Low-carbon iron may be bronze welded quite readily by either the arc or gas process. One decided advantage is that neither process requires heating the steel to the high temperature necessary for fusion welding.

Thermit Welding. Iron with a carbon content of 0.06% and less can be successfully welded by both thermit fusion and thermit pressure processes.

Submerged-Melt Welding. The use of rod and granulated material of suitable composition makes possible a sound weld having a metalloid content not exceeding 0.40%, and equal in strength to the base metal.

Carbon Steels

1 Low-Carbon Steel (0.30% C and less). These steels are easily welded by all the welding processes and the resultant welds and joints are of extremely high quality.

Gas Welding. The joint edges should be clean and properly prepared to facilitate good fusion and a sound weld. In welding long seams, allowance must be made for the effect of heat along the line of weld, which causes contraction during cooling and tends to pull the unwelded ends of the plates together. The spacing allowed normally in welding is a ¼-in. opening per foot of seam. Fast welding speeds will reduce the amount of contraction substantially. For making fillet welds, the overlapping plates should be held close together.

A neutral flame is frequently used for welding steel of this class. Increased welding speeds are possible, however, by using a slightly reducing flame. This type of flame carburizes the kerf surfaces, thereby lowering the melting temperature and making possible the fusion of the deposited metal to the plates at a temperature lower than would normally be required. Welded joints made in this way are of high quality and the fusion zone is not hard or brittle.

The preference for filler metal is for the so-called "high-test" welding rods with about 0.15 to 0.20% C and certain metallic elements that will insure freedom from included oxides and give the molten metal proper fluidity.

Arc Welding. Low-carbon steels are readily welded by all forms of this process. Many types of electrodes may be used —bare, dust-coated, washed or dipped, shielded-arc, or flux-coated. Carbon-arc welding is also practical for these steels and the results depend on the technique employed.

In the welding of long seams, the progressive shrinkage of the deposited metal tends to pull the plates together. However, this condition is less severe than with gas welding

and ⅛ in. per ft is enough to allow for shrinkage. Proper clamping and tacking and special welding procedures, such as the "step-back" and "skip" procedures, are commonly used to prevent distortion and residual stresses. The design of the structure, preparation of the joint, the size of electrode, welding current and voltage all are important.

Carbon-arc welding varies from metal-arc welding in that the arc is drawn between the base metal and a carbon or graphite electrode. The arc heat in this process is used only to melt or fuse the base metal, and the filler metal, when required, must be obtained from a specially prepared flange or upset edge at the joint or from some extraneous source. Filler metal can be added by placing more metal on the seam to be welded or by feeding suitable metal into the weld much as in the oxyacetylene process.

Carbon-arc welding performed without a flux or shielding atmosphere, may result in brittle welds. Shielding the arc, by painting the weld with a special flux or by introducing a suitable fluxing material into the arc, produces welds of high quality.

Bronze Welding. Low-carbon steels may be bronze welded quite readily. The joint surfaces are "tinned" by means of a suitable flux and copper alloy welding rod. The rod is then melted into the space between the tinned surfaces to be joined. This work is ordinarily a continuously progressive operation; the tinning is carried out for a distance and then additional filler metal is deposited before the section becomes cold. With recently developed copper alloy rods, strengths of the order of 55,000 psi can be obtained in the welds. This process does not require the steel to be heated to as high a temperature as in fusion welding, a difference that is often a decided advantage.

Thermit Welding. Fusion thermit welding is successfully carried out on low-carbon steels by using forging thermit. The welds have tensile strengths of 70,000 to 75,000 psi, elongations of 15 to 20% in 2 in., and good impact values. Before welding, the joint surfaces are preheated between 1600 and 1700 F. The purity of the weld deposit eliminates the need for subsequent forging or heat treatment to develop satisfactory physical properties.

Oxyacetylene Pressure Welding. Steel tubing of this carbon content can be welded by the closed butt process with either a plane, flat butt or an 8 to 12-deg included angle preparation, outwardly open. Solid sections are welded with the flat butt preparation. Considerable tolerance is permissible on the quality of face preparation, but clean surfaces are necessary. A holding pressure of 1000 psi of cross section is generally applied during preheating, followed by an upsetting pressure of 4000 psi of cross section. With the open butt process, the surfaces to be welded are held apart during the heating cycle, then brought together under pressure to complete the weld. For this method of pressure welding, the preparation of the faces is less critical than with the closed butt process, but the resulting upset is more uneven. The strength of the joints will equal that of the parent metal.

Submerged-Melt Welding. Butt welds from 16 gage to 2½ in. thick can be made in one pass, using suitable means for backing the joint, or multiple-pass procedures can be used for welding even greater thicknesses. The usual joint design requires that the abutting edges be in contact for the full length of the joint. Tack welds must be used to prevent the joint from opening ahead of the welding zone. This phenomenon, which is the exact opposite of that obtained with gas or ordinary arc welding, is caused by the high rate of heat input and speed of welding, which are the features of the process.

Since the major portion of the fused metal consists of base material, the physical properties of the weld metal more nearly approach those of the base material. Thus a single rod composition and granulated material may be used for welding a variety of base-metal compositions.

The loss of dimension as a result of shrinkage, either parallel to or transverse to the weld, is only one-third to one-half that usually encountered in an ordinary arc weld. Distortion is greatly reduced and is quite uniform in the usual automatic applications of the process. Certain simple procedures can virtually eliminate distortion. Stress patterns of the welds are about the same, in shape and magnitude, as those obtained with ordinary arc-welded joints.

2 Medium-Carbon Steel (0.30 to 0.50% C). Steels in this class can be welded by the various fusion processes. The technique and materials used are dictated by the metallurgical characteristics of the base metal. In some instances, preheating and subsequent heat treatment may be required to produce the desired weld quality, especially in steels containing more than 0.40% C.

Gas Welding. In welding medium-carbon steel, better welds can be obtained if an excess of acetylene is used in the welding flame. The recommended welding procedure is similar to that for low-carbon steels. As a rule, little trouble is caused by the formation of hard and brittle constituents as a result of rapid cooling. The quality of the finished joint will be improved if it is heat treated after welding.

Arc Welding. The weldability of steels of this grade depends on the carbon content of the base metal, because the rapid cooling may produce martensitic or troostitic structures; and the formation of such structures in the fusion zones tends to make these areas hard, brittle, and of an undesirable character. Steels that have higher hardenability and greater carbon content are likely to be susceptible to toe-and-root cracking from electrodes that contain hydrogen.

Preheating temperatures from 300 to 500 F have been found effective for eliminating and reducing the hard and brittle areas. By heating between 1100 and 1200 F after welding, it is possible to restore the desired properties in the areas affected by the welding heat. Modifications of welding technique, especially in heavy sections, can improve weldment properties considerably in this class of steel.

Shielded-arc electrodes of the type used on low-carbon steels are satisfactory for the welding of medium-carbon steels. The use of "hydrogen-free" shielded electrodes will greatly decrease susceptibility to toe-and-root cracking.

Thermit Welding. This process is carried out as successfully on medium-carbon steels as on the lower-carbon grades. Forging thermit is generally used, but the increase in carbon from the parent metal produces a somewhat higher tensile strength and lower ductility than when the lower-carbon steels are being welded.

Oxyacetylene Pressure Welding. Procedures applied to the pressure welding of low-carbon steel are also satisfactory for medium-carbon steel.

Submerged-Melt Welding. Steels of this class are welded somewhat more readily by this process than by ordinary arc welding, because the higher rate of heat input results in a slower quench and a wider and softer heat-affected zone. Heavy sections should be preheated to reduce further the hardness of this zone.

Rods and granulated material normally used for low-carbon steels are generally used for welding the medium-carbon steels. The carburization from the base metal is sufficient to provide the strength desired in the weld metal. Slightly larger V's and slower welding speeds are an advantage in reducing the hardness of the heat-affected zone, although this procedure is not always necessary.

3 High-Carbon Steel (0.50 to 0.90% C). Because of the higher carbon content, these steels are more difficult to weld.

Gas Welding. Since these steels are often heat treated, the welding heat will affect such treatment and produce a joint with properties different from those of the original metal. Care should be taken to prevent overheating the parts and the weld should be completed as quickly as possible. High-carbon steels melt at a lower temperature than the lower-carbon steels and tend to spark when overheated, a condition that helps to avoid overheating the parts.

A carburizing or excess acetylene flame is advantageous in securing strong sound welds. High-carbon filler rods are often used, although satisfactory results can be obtained with medium-carbon filler metal, which produces a weld of only moderate strength; however, the increase in ductility is often beneficial. By heat treating after welding, it is possible to eliminate the effect of the welding heat and to improve the strength of the weld.

Arc Welding. Steels in this group do not have good mechanical properties after arc welding. Hardness and brittleness may be produced in the fusion zone. For the best results, it is recommended that the parts be preheated to at least 500 F before welding, and subsequently heated between 1200 and 1450 F.

High-carbon steels are often welded to rebuild a worn surface or to develop a hard, wear-resistant surface. Unless the carbon content of the parent metal approaches the higher limit, preheating or subsequent heat treatment is not necessary in such instances.

Mild steel electrodes of the shielded-arc type can be used to make joints on these steels. The deposited metal tends to absorb carbon from the base metal and so loses considerable ductility. Austenitic electrodes are often recommended and the resultant welds have good physical properties, but the fusion zone may still be hard and brittle.

The remarks that apply to medium-carbon steel in regard to arc-welding technique and toe-and-root cracking apply as well to high-carbon steels. In special instances where steels are heat treated before welding, the electrodes selected should be of a sort that will permit attaining desirable ratios of weld metal strength to parent metal strength.

Thermit Welding. High-carbon steels are readily welded by the fusion thermit process. Because of the lower melting temperatures of the parent metal, slightly lower preheating temperatures are used than with the lower-carbon steels.

If forging thermit is used, carburization will be sufficient to produce a weld strength of 90,000 to 100,000 psi. Often, however, when hardness or wearing qualities are of prime importance, special thermits are required.

The preheating and inherent characteristics of the thermit process prohibit the rapid cooling that is obtained in arc and gas welding; therefore, subsequent heat treatment of joints even on these high-carbon steels is not required for satisfactory mechanical properties.

Oxyacetylene Pressure Welding. To produce a joint of high quality it is necessary to use the flat butt preparation and to obtain a smooth finish on the abutting surfaces. Care must be taken to avoid overheating high-carbon steels, since hot cracks and checks usually result. Higher pressures are used for upsetting at lower temperatures.

Submerged-Melt Welding. This process is seldom used to make joints in high-carbon steels. Layer deposits have often been made to rebuild worn surfaces on high-carbon base material, and hard, wear-resistant surfaces are possible by choosing suitable rod composition. Preheating is not usually required, nor is subsequent heat treatment.

4 Tool Steels (0.80 to 1.50% C). These steels are relatively difficult to weld.

Gas Welding. Drill rods, available in the various diameters required for welding, and of carbon content sufficiently high to cover the carbon range, are generally used in welding these steels. The use of a carburizing or excess acetylene flame is advantageous in securing sound strong welds. Flux suitable for welding cast iron should be used sparingly. Preheating and annealing are usually necessary.

Arc Welding. Because of the heat effects of arc welding, this process is seldom used for tool steels. If welding is required, one of the following procedures is recommended:

(1) After annealing, preheat the parts and weld with a suitable shielded-arc electrode; then heat treat to restore the desired properties. (2) Preheat the parts and use an austenitic electrode. Preheating will aid in preventing the formation of a hard fusion zone and the weld will not be hard because of its austenitic condition. (3) Preheat the parts and deposit one or more layers on the kerf surfaces of the parts with a shielded-arc electrode. These layers dilute the carbon so that the parts can then be more readily welded together. It should be noted that this process does not produce a high-carbon weld.

The remarks that apply to medium-carbon steel in regard to arc-welding technique and toe-and-root cracking apply as well to tool steels. In special instances where steels are heat treated before welding, the electrodes selected should be of a sort that will permit attaining desirable ratios of weld metal strength to parent metal strength.

Thermit Welding. Fusion thermit welding is not commonly used on these steels, but successful joints have been made on materials containing 1.10% C. Forging thermit can be used but the tensile strength will not be equivalent to that of the parent metal. Higher-carbon thermit can be used if the strength is of prime importance. Heat treating the weld and fusion zone, after welding, is recommended in order to produce the best properties.

Oxyacetylene Pressure Welding. Tool steels are frequently joined to less expensive steels in the production of drills and other machining tools. Pressure welds are made in these steels at relatively low temperature in order to produce on the tool steel no harmful metallurgical effect that cannot be removed by subsequent heat treatment. Heat treatment is usually necessary to produce the desired physical properties in the welded article. Pressure cycles used on tool steels vary with the material and may be considerably higher than for low-carbon steels.

Submerged-Melt Welding. The process has not been used for joining, but has been used for building up punches that have been scored in hot punching operations. A single layer of welding will pick up sufficient alloying elements from the base material to provide as satisfactory service as the original punch.

Copper-Bearing Steels. These steels, ordinarily of the low-carbon variety, contain from 0.20 to 0.30% Cu. The same welding processes are applicable as for ordinary steels of the same carbon range. Welded joints made by the gas or shielded-arc processes are, in general, as resistant to corrosion as the copper-bearing steels.

Oxyacetylene Pressure Welding. Copper-bearing steels are pressure welded by procedures comparable with those used on carbon steels of similar carbon content.

Submerged-Melt Welding. These steels are welded as readily as ordinary steels in the same carbon range. Since welded joints contain a large proportion of the base metal, they are as resistant as the base material to corrosion.

Steel Castings

Welding of low-carbon steel castings presents no particular difficulties if the casting is properly prepared, is reasonably clean, and the ordinary precautions are taken to avoid setting up excessive expansion and contraction stresses in the metal. With castings that contain more than 0.25% C and with special alloy compositions, certain precautions are necessary in welding.

1 Plain Carbon Steel Castings. Before the welding of steel castings, an effort should be made to learn the chemical composition in order to weld successfully the high-carbon and the alloy castings. Castings under this heading should not contain more than 0.25% C and a negligible amount of alloying materials. Castings of such compositions present no difficulties in welding by approximately the same procedures as with low-carbon wrought steel.

Gas Welding. It is customary to use a general-purpose filler rod for welding these castings, although for the best results the chemical composition of the filler metal should be similar to that of the base metal.

Arc Welding. The procedure for the electric-arc welding of steel castings (low-carbon and medium-carbon) is essentially the same as for wrought steel of similar composition. For the best results, a high-grade electrode heavily coated is considered desirable. The surfaces to be welded should be carefully cleaned of sand inclusions, cracks, porosity and dirt. Multilayer welding and high currents should be employed if the carbon content is low, but small-diameter electrodes and low currents are necessary when the carbon content is high; while in some instances preheating and slower cooling are desirable.

Bronze Welding. Bronze welding is satisfactorily applied to steel castings, especially where the difference in surface appearance of the casting is not objectionable. Both gas and electric-arc processes are used. Before being welded, the surfaces should be prepared and cleaned as described above under Low-Carbon Steels.

Thermit Welding. Repairs are readily made and heavy cast steel parts are commonly reclaimed by the thermit process. Where the work consists of applications such as replacing teeth in large gears or pinions, the fact that the tooth is a comparatively small projection on an extremely heavy casting must be taken into account. If the casting were preheated at the weld only, the heat would be carried away into the casting so rapidly that fusion between the weld metal and the parent metal could not be obtained. Therefore it is necessary to preheat the entire casting. Forging thermit may be used for this work, although where

parts are subject to abrasion and wear, "wabbler" thermit may be employed, to provide a hard, wear-resistant machinable steel.

Oxyacetylene Pressure Welding. Applications of joining cast steels are not normally of such a nature as to meet pressure-welding requirements. The material is weldable using procedures similar to those applied to wrought steels of like composition.

Submerged-Melt Welding. The procedure is essentially the same as for wrought steel of similar composition. Sand inclusions, cracks, porosity and dirt should be removed from the surfaces to be welded. The selection of suitable rods and granulated material permits multipass welding in extremely heavy thicknesses. Intermediate stress relief has been found desirable after the joint has been built up to a thickness of about 5 in.

Defects in castings may be repaired either by usual multipass welding or by a deposit made as a continuous puddle, provided the area of the defect is not so large that the melt will solidify during welding.

2 High-Manganese Steel Castings.* Welding these castings is mostly for the purpose of restoring parts that have been worn away, or for the repair of cracked and broken pieces. The manganese content is frequently as high as 12% or more, and the carbon content ranges from 1 to 1.40%.

Resistance Welding. Electric resistance welding has not been used to any great extent on parts made of manganese steel, because of the difficulties that have been encountered in obtaining strong welds by this method. It is possible, however, that resistance welding can be used successfully by proper adjustment of current and time of application.

Gas Welding. In the welding of high-manganese steel castings, a shallow zone must be heated to a temperature close to 2200 F; the filler metal should then be applied. The rod that is selected should have the same manganese content as the casting; and if the rod contains from 3 to 5% Ni in addition, reliable welds can be produced. The high nickel content tends to inhibit embrittlement under slow cooling so that no quench is necessary.

Arc Welding. For arc welding high-manganese steel (12 to 14% Mn and not more than 1.25% C), a shielded electrode should be used, of a type that will produce properties in the deposited metal approximately the same as those of the base metal. The weld should be in an austenitic condition even after slow cooling, and the welded part should not be quenched because of the danger of cracking. In such instances the weld deposit is rather soft but cold working will produce a hardness of 45 to 50 Rockwell C.

Thermit Welding. Thermit welding of manganese steel is not generally practiced, because of the effect caused on the adjacent steel by the heat of the weld. A fairly successful weld can be made if the whole mass can be preheated and then heat treated after welding.

Submerged-Melt Welding. The limited amount of work that has been done in this class of material indicates that chromium-nickel steel rods should be used for welding, in order to maintain the weld in an austenitic condition.

3 Alloy Steel Castings. In general, alloy steel castings are welded by the same process as that used for wrought alloy steel of the same composition. The number and character of the alloying elements have a decided effect on the welding properties of the castings.

Resistance Welding. Electric resistance welding has not been applied commonly to alloy steel castings because of the varying forms and contours encountered. It is possible, however, to use resistance welding methods if the work pieces are held in suitable jigs and there is proper adjustment of current and time of application.

Gas Welding. It is customary to use a filler rod of composition different from that of the type used in welding carbon steel castings, so that the weld deposit will be similar to that of the alloy steel casting. The same requirements for fluidity of deposit are necessary as with carbon steel castings, in order that impurities may be brought to the surface in the melting operation.

Arc Welding. The procedure for electric-arc welding of alloy steel castings is quite similar to that used with carbon steel castings. The only modification is in the coating of the electrode, which should be so proportioned as to influence the deposit of weld metal. It is customary to use heavily coated electrodes for this purpose. The surfaces to be welded should be thoroughly cleaned before welding. In some instances, preheating is considered desirable, and in virtually all instances, a heat treatment is desirable after the welding has been completed.

Thermit Welding. With the thermit weld metal, it is possible to match the composition of the casting by the addition of alloying elements to the thermit mixture.

Oxyacetylene Pressure Welding. Alloy steel castings are generally of such shapes as to make pressure welding impractical. The material may be welded by the procedures applied to low-alloy steels of similar composition.

Submerged-Melt Welding. The procedure with this type of casting is quite similar to that employed for plain carbon steel castings. Preheating is generally desirable in heavier thicknesses of material. The rod composition may be selected so as to develop the full strength of the base metal, and virtually the same response to heat treatment.

Cast Iron

1 Gray Iron. In the welding of gray cast iron, preheating is usually necessary to avoid stresses. Gray iron castings may be welded hot and then allowed to cool slowly so as to maintain their characteristic gray iron structure. Only in certain instances where the structure of the weld metal is of little importance can preheating be avoided.

Forge Welding. Gray cast iron cannot be forge welded.

Gas Welding. Gray iron castings should be preheated to a low red heat and welded while hot, with a cast-iron welding rod containing a high percentage of silicon. A suitable flux should be used to remove oxides. When the weld is completed, the whole casting should be allowed to cool slowly to room temperature. With this procedure the weld will be strong, yet soft and machinable.

Arc Welding. Preheating the casting to a dull red heat accelerates the welding, relieves stress, reduces the tendency toward unmachinable spots and cracks, and helps to retain the characteristic gray iron structure. Excessive strain or breakage, which may occur in the welding of gray cast iron, may be intensified by a hard area, containing iron carbide, outside the weld. For this reason castings thinner than ¼ in. are seldom welded. It is desirable that the casting be annealed after welding.

The electrodes used are special ones, either coated or uncoated, that make a good bond with the casting. A rather low current should be used, and the welding should be done intermittently. Each bead should be slightly peened and allowed to cool somewhat before depositing the next bead. All these considerations reduce the hardening effect along the line of fusion. Where machinability is of primary importance and strength is of secondary importance, nonferrous electrodes such as high-nickel alloy (67% Ni) are available. These electrodes produce a soft, machinable deposit that does not harden at the fusion line. The deposit is also advantageous where appearance is important, since the color matches that of the cast iron.

Bronze Welding. When gray iron castings are bronze welded, comparatively little preheating is necessary. When the temperature of the base metal is increased to between 1500 and 1600 F, the copper alloy will "tin" the cast-iron and make a bond at least as strong as the cast iron.

For bronze welding with the arc, preheating is generally unnecessary. It should be kept in mind that too much current is detrimental to satisfactory welding; the currents used should be as low as possible consistent with the size of the electrode and of the part being welded.

Thermit Welding. Although entirely suitable for welding gray iron, the thermit process cannot be used on all castings because of the difficulty of allowing properly for shrinkage of the weld metal when it cools. Contraction of thermit steel is approximately twice that of cast iron so that, generally, if the length of the crack to be welded is more than eight times the thickness of the section, the difference in shrinkage along the line of fracture will result in small hairline cracks in the weld.

Submerged-Melt Welding. This process has not yet been applied successfully to the welding of any of the cast irons.

* See also the article entitled "Austenitic Manganese Steel", page 526.

2 Malleable Iron. Fusion welding of malleable castings is generally regarded as unsatisfactory (even when the castings are remalleablized afterward). For this reason, repairs to malleable castings are generally made by bronze welding. Malleable iron foundries frequently reclaim defective castings by fusion welding the white iron castings before malleablizing.

Gas Welding. For the oxyacetylene welding of defective white iron castings before malleablizing, white iron welding rods of the same approximate composition are used. The salvaged castings are then malleablized.

Arc Welding. Malleable iron castings can be welded with the arc process, using low heat. In general, these castings should be treated the same as gray cast iron, using the same precautions and procedure. After welding, the castings should be put through the same annealing process by which they were made originally. Annealing is helpful if full heat treatment cannot be given.

Bronze Welding. The temperature of 1500 F required in the base metal for bronze welding is not so high as to affect seriously the properties of malleable iron; consequently, effective repairs can be made by this process. Either the gas or the arc method may be used.

3 Alloy Cast Irons. The welding procedures for most alloy cast irons are essentially the same as for gray iron. Filler material should be of the same alloy content as the base metal, or if such material is not available, the welds should be made with high-quality gray iron rod. Arc welding is discussed under Gray Iron.

Low-Alloy Steels

The low-alloy steels are readily welded by the various welding processes. The amount of alloying element in these steels is only slightly greater than in ordinary mild steels and is considerably less than in many alloy steels. These steels have higher mechanical properties than carbon steels and usually possess higher resistance to atmospheric corrosion. When low-alloy steels are being welded by a process wherein metal is added, it is not necessary for the metal to have the same composition (provided it has the same physical properties), unless resistance to corrosion is a factor; in such situations the weld metal should be of a composition similar to the base metal. Heat treatment is desirable for the various alloys, to develop the required mechanical properties.

Included among the low-alloy steel classifications are the proprietary compositions known as high-strength low-alloy steels, and described in the article on page 534 of this Handbook. These steels, which are not quenched and tempered, include the manganese-titanium and manganese-vanadium steels used by the navy. These steels have been the subject of considerable research in recent years. They have been designed generally to have yield strengths of 50,000 psi min, and to be weldable by ordinary methods without special precautions. Low-alloy steels approximate the mild carbon steels in weldability.

Gas Welding. Where strength is important, a welding rod of the high-test steel type will give satisfactory results in oxyacetylene welding. Where corrosion resistance is a factor, the welding rod should be of the same composition as the base metal.

Arc Welding. For arc welding these materials, a shielded-arc type of special electrode is generally used.

Thermit Welding. Through the addition of metallic elements to the thermit mixture, either by means of metallic pieces, which are melted during the reaction, or in the form of combinations of oxides of the required elements with aluminum, a wide variation in the composition of thermit steel is made available so that it is entirely possible to match the compositions of a number of low-alloy steels. The following are chemical formulas of the aluminum reduction of several oxides used for this purpose:

$$3Mn_3O_4 + 8Al = 4Al_2O_3 + 9Mn$$
$$Cr_2O_3 + 2Al = Al_2O_3 + 2Cr$$
$$3V_2O_5 + 10Al = 5Al_2O_3 + 6V$$
$$3NiO + 2Al = Al_2O_3 + 3Ni$$

Since these steels are used mainly for developing strength, ductility and resistance to shock, it is usually desirable to heat treat the welds made in these steels. The heat treatments for these alloys are given below.

Oxyacetylene Pressure Welding. Low-alloy steels are readily joined by the pressure-welding process. Sometimes the basic welding cycle must be varied to weld steels high in chromium content. The principal variation consists in the application of a high initial pressure for a small percentage of the total upset, followed by a lower upsetting pressure for the remainder of the cycle. Joint faces are preferably prepared immediately before welding, in order to reduce the possibility of forming an oxide film.

Submerged-Melt Welding. Low-alloy, high-strength steels of proprietary compositions are generally welded with the same rod, granulated material and welding conditions as are used for welding ordinary low-carbon steels. Because of their enrichment in alloying elements from the base metal, the welds develop the desired mechanical properties and resistance to corrosion.

For welding the other alloys listed below, satisfactory physical results can be obtained by selecting rod and granulated material from the various standard materials available. These standard materials will produce a weld of chemical composition identical with the base metal for steel in the manganese-molybdenum and carbon-molybdenum class. If identical weld-metal composition is desired for any of the other alloys, then rods of similar composition should be used.

1 Plain Nickel Alloy Steels. While the 3 to 3½% Ni alloy steels do not necessarily need heat treatment if the carbon content does not exceed 0.25%, such alloy steels with carbon contents greater than 0.25% require a preheat in the range from 300 to 600 F. Steels in this class have a tendency toward air hardening and require slow cooling in order to retain the desired mechanical properties.

2 Nickel-Copper Alloy Steels. The alloy steels in this class contain from 1 to 2% Ni and 1 to 1.6% Cu, while the carbon content is usually limited to 0.25% max. No preheating is required for the ordinary welding of these alloys except when the carbon content exceeds 0.20%; then in some instances preheating is considered desirable. Preheating such alloys within the range between 250 and 300 F makes the desired mechanical properties obtainable.

3 Manganese-Molybdenum Alloy Steels. The steels in this class are alloyed with 0.60 to 1.60% Mn and 0.30 to 0.70% Mo, and the carbon content is usually kept at less than 0.25% max. These steels do not ordinarily require preheating except in certain instances where the carbon content approaches the higher end of the range. In such alloys and for heavy or difficult sections, preheating at 250 to 300 F is an advantage.

4 Carbon-Molybdenum Alloy Steels. This class of steel is similar in many respects to the manganese-molybdenum alloys, except that the manganese content is held to a normal range from 0.30 to 0.60%; the molybdenum content is a little high, ranging from 0.30 to 1% and the carbon content is limited to the same maximum of 0.25%. Here, also, preheating is not required under ordinary conditions, although when the molybdenum content approaches the higher end of the range (more than 0.50%), preheating at 350 F is considered desirable for best results in welding. Similar preheating is also considered desirable if the carbon content approaches or exceeds the limit of 0.25%.

5 Nickel-Chromium Alloy Steels. This classification includes several compositions in which the nickel content ranges from 1% min to 3½% max, while the chromium content ranges from 0.40% min to 1.75% max; the carbon content varies from a maximum of 0.20% for the lower tensile ranges to 0.55% for the higher tensile ranges. These steels cannot be welded safely without preheating. For the lower tensile ranges in steels that contain 0.20% C max, preheating between 200 and 300 F is all that is necessary, but with the higher carbon contents that accompany the increased percentages of nickel and chromium, preheating between 600 and 800 F is considered desirable, followed by slow cooling. For steels that have the highest carbon, nickel, and chromium contents, it is even desirable to raise the preheating temperature to the range between 900 and 1100 F.

6 Chromium-Molybdenum Alloy Steels. These steels are similar in many respects to the nickel-chromium steels. A

much used series of alloys in this classification contains 0.25 to 0.55% C; 0.15 to 0.25% Mo; and 0.50 to 1.10% Cr. Because of such chromium contents, these steels, designed especially for service at high temperature, require a considerable degree of preheat, ranging from 300 to 800 F, and slow cooling is desirable after the welding operation.

7 Nickel-Chromium-Molybdenum Alloy Steel. This steel contains 1½ to 2% Ni, 0.20 to 0.40% Mo, and 0.30 to 0.90% Cr. Although the alloy is used extensively, it has not been welded in enough instances to warrant a statement.

8 Nickel-Molybdenum Alloy Steels. In these steels the carbon content is kept low, the nickel content ranges from 1.65 to 3.75%, and the molybdenum content ranges from 0.20 to 0.30%. Welding has not been applied often enough to furnish the desired data.

9 Chromium Alloy Steel. This steel is used in two ranges of carbon contents—one 0.25% or less, and the other from 0.35 to 0.55%. With the lower range of carbon contents the chromium range is 0.60 to 0.90%, whereas with higher carbon contents, the chromium range is from 0.80 to 1.10%. Preheating is essential before welding. The temperature range recommended is 200 to 800 F.

10 Chromium-Vanadium Alloy Steel. This steel has two ranges of carbon contents—one 0.25% C or less, and the other 0.25 to 0.55% C. Regardless of carbon content, the chromium content is from 0.80 to 1.10% and the vanadium content is from 0.15 to 0.20%. These steels all require preheating in order to obtain satisfactory results from welding. The preheating range is from 200 to 800 F. With this alloy, sample welds may be required in order to ascertain the properties that can be obtained from the welding operation, and particularly the effect of the heat treating operation.

11 Manganese Alloy Steels. These steels contain 1.6 to 1.9% Mn and 0.25 to 0.55% C. For satisfactory welding of these alloys preheating is essential; the desirable range is from 400 to 800 F.

Stainless Steels

The stainless alloys may be grouped into two classifications for welding considerations: (1) stainless irons that contain from 3 to 28% Cr, with or without traces of nickel, and that are essentially magnetic and ferritic in character, and (2) stainless steels that contain chromium and nickel, with or without smaller amounts of molybdenum, manganese, columbium, silicon, or titanium, all of which are in proportions that give an essentially austenitic structure.

1 Iron-Chromium Alloys. The materials in this classification contain from 12 to 28% Cr as the essential alloying constituent, and are termed "stainless irons". They show a tendency toward grain growth in and near the weld. This coarsening of the grain increases markedly with the chromium content and frequently results in undesirable brittleness in the welded equipment made from the higher ranges of chromium content. Small additions of nitrogen decrease this tendency toward grain growth.

Probably the most widely used compositions for fabricated equipment contain between 15 and 18% Cr with 0.10% C max. This material is readily welded and when the fabricated equipment is properly heat treated (to 1450 F, and then slowly cooled) it possesses a satisfactory combination of physical properties in both weld and plate and sufficient corrosion resistance to meet the needs of the majority of applications.

Gas Welding. Chromium irons may be welded by the oxyacetylene method provided adequate precautions are taken; best results are obtained with a flame that is virtually neutral. A slightly reducing flame will result in brittleness of the weld area on account of carbide formation, caused by the affinity of chromium for carbon. A slightly oxidizing flame will result in the formation of refractory chromium oxides, which sometimes cause insufficient penetration of the heat, with consequent reduced weld strength and slag inclusions.

Arc Welding. Electric-arc welding, mainly the metal-arc method, is successfully used in welding stainless irons. A coated wire electrode is recommended, with the metal wire of composition similar to the plate metals, but preferably with slightly higher chromium content, in order to provide for the loss of metal during welding.

Oxyacetylene Pressure Welding. These alloys are welded by the procedures applied to low-alloy steels.

Inert-Gas-Shielded-Arc Welding. Limited experience indicates that the stainless irons are readily welded by the inert-gas-shielded-arc process. The welds appear to be very similar to those made on the iron-chromium-nickel alloys by the same process. More extensive data are currently available showing the suitability of this method of welding. Present practice uses direct current, straight polarity, with argon or helium as the shielding gas. On thin sections, alternating current has been employed—usually with superimposed high-frequency current to start and maintain the arc. When high-frequency current is used, the equipment must be especially designed and insulated.

Submerged-Melt Welding. Stainless irons of the 5% Cr class, with 0.5% Mo and with or without columbium, are welded readily. A preheat of 300 F is recommended, followed by heat treatment for stress relief, grain refinement and maximum ductility. The rod used is of the same general composition as the base metal, while the granulated material, edge preparation and welding conditions are approximately the same as those used for similar thicknesses of low-carbon steel.

Stainless irons containing between 15 and 18% Cr with 0.10% C max are readily welded, using rod and granulated material of compositions that maintain the chromium, manganese and silicon in the weld within the desired limits. When properly heat treated (to 1450 F and then slowly cooled), the weld develops mechanical properties and corrosion resistance equal to those of the base metal.

2 Iron-Chromium-Nickel Alloys. Alloys in this classification contain sufficient nickel and manganese in addition to the chromium, with or without small amounts of other metals, to maintain an essentially austenitic condition. The composition that probably represents the major tonnage of plates and sheets fabricated into equipment by welding, is 18% Cr, 8% Ni, and 0.10% C max. These chromium-nickel steels are also furnished commercially in ratios of 25 to 12 and 25 to 20, all of which have been successfully welded by methods described below.

All stainless steels, except those stabilized by columbium or titanium, will show an accumulation of carbides at the grain boundaries when exposed to temperatures between 700 and 1500 F. This "carbide precipitation" is found also in lines approximately parallel to the weld bead and perhaps a quarter inch distant, even in stainless plates that have been properly heat treated before welding. This accumulation, resulting from the heat of the welding operation, is evidence that the plate metal in that narrow zone has been heated to a temperature range wherein carbide precipitation can take place.

This accumulation of carbides at the grain boundaries in the narrow zones adjacent to the weld bead will, in most instances, show less resistance to many corrosive mediums than will the metal at some distance from the weld and where it has not been held in this susceptible temperature range. It is coming to be standard practice, therefore, in fabricating stainless steel vessels by welding, to heat treat the equipment after completing the welding, with all compositions except those in which columbium or titanium is present as a stabilizing element. The treatment commonly used involves heating to approximately 1950 F and quenching in water. The heat treatment increases the over-all resistance of these alloys to corrosion and also puts the metal in its softest, most ductile and impact-resistant form.

Gas Welding. This method is generally applied to the lighter gages. On the thinner sections, a flange type of weld is used and the edges are joined without the addition of welding rod. On gages where metal must be added, a bare (uncoated) rod is used with a flux applied as a thin paste to the work.

The wider distribution of heat from the acetylene flame, as contrasted with the intense and local effect of the arc methods, makes it desirable to use chill blocks when welding with gas. Likewise, as a result of the more general heating and expansion of the metal sheet (since stainless steel has a 50% higher coefficient of expansion than carbon steel) jigs and clamps will be found convenient for holding the work piece.

In the gas welding of stainless steel it is of paramount importance to adjust the flame so that it is virtually neutral, thus avoiding excessive carburization of the metal, which would reduce materially the corrosion resistance of the resultant weld.

Arc Welding. The usual methods of arc welding are successfully applied in joining the stainless steels. Satisfactory electric welding is done by means of direct current in preference to alternating current. Reversed polarity is normally used; that is, work negative and electrode positive. Coated metallic electrodes are preferred. The composition of the welding wire should be similar to the composition of the plate, preferably with the chromium content of the wire slightly higher.

As pointed out previously, austenitic steels are susceptible to grain growth at high temperature; therefore overheating is to be avoided. When the current has been adjusted to give a smooth arc, the bead may be laid down as rapidly as is consistent with good welding practice.

Oxyacetylene Pressure Welding. The 18-8, 25-20, 25-12 and other stainless compositions are pressure-welded with good results. Welding characteristics permit corrosion resistance equal to that of the base metal when stabilized materials are used and joint and parent metal are chemically homogeneous. Smooth, clean joint faces are necessary for the welding of these high-alloy materials. No oxide should be allowed to form on the joint faces before welding. Welding cycles used are the same as those applied to low-alloy steels.

Inert-Gas-Shielded-Arc Welding. The inert-gas-shielded-arc process has been found to be especially well suited for the welding of stainless steels. Depending on the application, these steels can be welded manually; or with suitable equipment the process can be mechanized, the holder being adjusted either manually, or by electronic means.

Welds made on stainless steel by the inert-gas-shielded-arc process show a minimum of discoloration, or oxidation, requiring very little finishing. There is no spatter to be removed, and the amount of reinforcement can be controlled to some extent, again reducing finishing costs. Virtually no chromium, nickel, or stabilizing elements are lost when stainless steels are welded by this method.

Welds can be made with or without filler metal, as dictated by the application. Direct current, straight polarity is used, with argon or helium as the shielding gas. Alternating current has been used to some extent on thin material; superimposed high-frequency current is employed, when necessary, to start and maintain the arc. Equipment used with superimposed high-frequency current must be suitably insulated.

Submerged-Melt Welding. These alloys can be welded almost as readily as low-carbon steels of the same thickness. Joint preparation and welding speeds are similar to those used for low-carbon steels, but some reduction in welding current and voltage is necessary. The compositions of both rod and granulated material are selected to provide weld metal of desired chemical composition, mechanical properties and resistance to corrosion. In the columbium-stabilized types, the process is not recommended for welding butt joints less than $\frac{3}{16}$ in. thick, nor for fillet, plug or multipass welds, since with existing procedures such welds crack as a result of the hot shortness of these alloys.

The Cutting of Ferrous Metals by Gas and Electric Arc

BY THE SUBCOMMITTEE ON WELDING AND CUTTING*

THIS ARTICLE describes the cutting of ferrous metals by means of a gas flame. Cutting by means of an electric arc is much less common; such cutting is discussed briefly at the end of the article. "Cutting", as the term is used here, includes not only severing, but also "flame machining", which refers to the planing, milling, turning, drilling and boring of metal by a gas flame.

Gas Cutting of Ferrous Metals

Gas cutting of ferrous metals is a process of preheating material to its kindling or ignition temperature and then oxidizing it rapidly by means of a closely regulated jet or stream of oxygen issuing from a special tool called a "cutting blowpipe" or "torch". Hence, the process is primarily a chemical one, based on the chemical affinity of oxygen for ferrous metals that have been heated to the kindling temperature or higher.

The chemical reaction that results when commercially pure oxygen is brought into contact with most steels or iron at the kindling point, is an active one. Carbon steel is preheated in daylight to a bright red color, a condition reached between approximately 1400 and 1600 F. For accurate control, the gases supplied and the rate of progression of the cutting should be closely regulated.

Only the metal within the direct path of the oxygen jet is acted upon. In linear cutting, or severing, a "kerf" is formed; that is, a narrow race, having uniformly smooth and parallel walls. Under skilled workmanship, using mechanically guided cutting torches or blowpipes, cutting tolerances, with respect to squareness and longitudinal alignment of the cut surface, may be held closely.

The faces or walls of the kerf, in the commonly used carbon steels, are not injured by the cutting operation. On the contrary, the strength and toughness of the faces are slightly increased. The effect of heat on the metal, as a result of normal cutting operations, rarely penetrates farther than approximately 0.1 in. below the cut surface, except in the so-called "stainless steels", where precipitation of carbide may extend as far as 0.375 in.

In addition to linear gas cutting or severing, other types of controlled oxidation are in use, employing the free-burning reaction of oxygen with ferrous metals that have been heated to kindling temperature, in order to sever, shape and work such materials. One application, known generally as "oxygen-lance cutting", utilizes a relatively long section of small-diameter iron pipe. A pipe with a stream of oxygen flowing through it is ignited and kept aflame, thus forming a lancelike cutting tool that furnishes preheat as well as free oxygen for cutting and is used primarily for emergency and heavy-duty cutting, such as opening furnace tap holes.

Another application of gas cutting is known as "flame machining". This method is used primarily to surface ferrous metals in much the same way as a planer or milling machine. The cut does not penetrate the work as in severing or linear gas cutting.

Chemistry of Cutting. The oxide of iron formed in gas cutting is a black, brittle substance, identical in composition with hammer scale or magnetite ore; the chemical formula is Fe_3O_4. This substance contains a proportion of oxygen smaller than in rust or red iron oxide, Fe_2O_3. For cutting as in Fig. 1, the completed equation for the oxidation reaction in gas cutting is:

$$3\,Fe + 2\,O_2 = Fe_3O_4 + 26{,}691\ cal$$

The following data may be computed:

1 lb oxygen will oxidize 2.618 lb or 9.186 cu in. of pure iron.
1 cu ft oxygen will oxidize 0.217 lb or 0.761 cu in. of pure iron.
1 lb of pure iron requires for oxidation 0.382 lb or 4.610 cu ft O_2
1 cu in. of pure iron requires for oxidation 0.109 lb or 1.314 cu ft O_2

In actual gas cutting, the iron or steel removed from the kerf is, as already noted, not entirely oxidized or consumed by the oxygen, but because of the eroding effect of the cutting oxygen jet, about 30 to 40% of the metal is

*The members of this subcommittee are C. W. Obert, *Chairman* (Linde Air Products Company), C. L. Altenburger (Great Lakes Steel Corporation), R. W. Clark (General Electric Company), C. H. Jennings (Westinghouse Electric Corporation), H. L. Maxwell (E. I. du Pont de Nemours & Company), H. R. Morrison (Linde Air Products Company) and E. H. Roper (Air Reduction Sales Company).

washed out of the cut as unconsumed or metallic iron. As a result of this fortunate circumstance, it is not uncommon to obtain satisfactory cuts with a consumption of cutting oxygen even somewhat less than one cubic foot of oxygen per cubic inch of material removed from the kerf. As may be seen from the above data, this rate of consumption is more than 30% better than the theoretical figure, based on chemical reaction alone.

Combustion of Fuel Gases. A number of fuel gases of higher flame temperature have been employed for cutting ferrous metals, with varying degrees of success. The more important of these are: acetylene, hydrogen, city gas, natural gases, coke-oven gas, ethylene, and the lighter petroleum distillates, including methane, ethane, propane and butane. Table I gives combustion constants for certain of these fuel gases.

Table I. Combustion Constants of Fuel Gases

Name of Gas	Chemical Equation for Complete Combustion	Heat Value, Btu per cu ft (net)	Flame Temp with O_2, deg Fahr
Acetylene	$C_2H_2 + 2\frac{1}{2}\ O_2 = 2\ CO_2 + H_2O$	1433	6300
Hydrogen	$H_2 + \frac{1}{2}\ O_2 = H_2O$	275.1	5400
City gas	Typical mixture	300 to 800	4600
Natural gas	Typical mixture	800 to 1200	4600
Coke-oven gas	Typical mixture	500 to 550	4600
Methane	$CH_4 + 2\ O_2 = CO_2 + 2\ H_2O$	913.8	5000
Ethane	$C_2H_6 + 3\frac{1}{2}\ O_2 = 2\ CO_2 + 3\ H_2O$	1631	5100
Propane	$C_3H_8 + 5\ O_2 = 3\ CO_2 + 4\ H_2O$	2309	5300
Butane	$C_4H_{10} + 6\frac{1}{2}\ O_2 = 4\ CO_2 + 5\ H_2O$	2999	5300
Ethylene	$C_2H_4 + 3\ O_2 = 2\ CO_2 + 2\ H_2O$	1530	5100

Aside from hydrogen, all these fuel gases are hydrocarbons and, as shown in Table I, give off carbon dioxide (CO_2) and water vapor (H_2O) as products of complete combustion. They may be burned in different manners but, when used for gas cutting, the combustion is made to take place in the way that will develop maximum flame temperatures. For quick starting and rapid progress of a cut, hot preheating flames are a prime essential. This requirement is fulfilled by designing cutting torches or blowpipes that burn the fuel gases according to the Bunsen principle and premix commercially pure oxygen instead of air with the gases before combustion. The substitution of oxygen for air, in the primary combustion, results in a notable increase of flame temperature of the fuel gas, because the nitrogen, constituting nearly four fifths of the air, does not need to be heated by the flame when oxygen is used. Acetylene produces a hot, short flame, with an easily distinguished, bright inner cone; the hottest point is at the tip of the inner cone. Flame structures of hydrocarbon gas are complex in nature, with a multiplicity of cones as a result of the successive chemical reactions that take place in different stages of combustion.

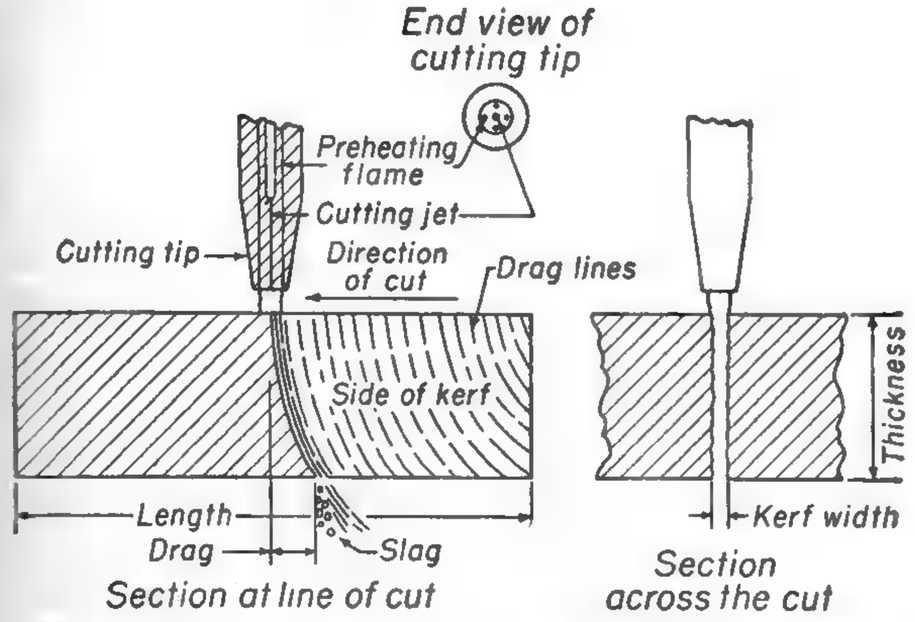

Fig. 1 Sections during oxyacetylene cutting

Depending on the ratio of oxygen to fuel gas in the mixture, the characteristic of the flame produced may be carburizing, neutral, or oxidizing. The neutral flame results when just sufficient oxygen is supplied to complete the primary combustion in the inner cone of flame, yielding carbon monoxide (CO) and hydrogen (H_2) as products. Neither of these two gases carburizes or oxidizes molten metal; in fact, both are neutral to it. Regardless of the amount of primary oxygen supplied, complete combustion in the inner cone of flame is impossible since, at such extremely high temperatures, carbon dioxide and water vapor are unstable and dissociate or revert in part to carbon monoxide, hydrogen and oxygen. This dissociation limits maximum temperatures attainable in a flame of oxy-fuel gas; otherwise these temperatures might go much higher.

Maximum flame temperatures are obtained with strongly oxidizing flames; therefore, this type is generally used for gas cutting. Oxidizing flames preserve the general appearance of neutral flames, but their inner cone is shorter, "necked in" on the sides and more sharply defined. Because of dissociation, the products of the primary combustion in the inner cone of excess oxygen flames consist of carbon monoxide, carbon dioxide, hydrogen, water vapor, and free oxygen, in proportions that depend on the amount of excess oxygen premixed with the fuel gas.

The secondary combustion of the fuel gas takes place in the outer or envelope flame. Here, any carbon monoxide and hydrogen contained in the primary combustion products complete their combustion to carbon dioxide and water vapor, respectively, since the lower temperature is insufficient to cause dissociation of these latter compounds. The necessary oxygen required for completing the secondary combustion in the envelope flame is taken from the surrounding air by diffusion into the zone.

Table II gives optimum gas ratios and equivalent volumes of oxygen and acetylene, city gas, natural gas, and propane required for gas cutting the same work at the same speed.

Table II. Equivalent Volumes of Fuel Gas and Preheating Oxygen for Cutting

Name of Fuel Gas	Optimum Ratio of Oxygen to Fuel Gas	Gas Consumption: Preheating Oxygen, cu ft per hr	Gas Consumption: Fuel Gas, cu ft per hr
Acetylene	1.7 to 1	17	10
City gas	0.75 to 1	56	75
Natural gas	2.0 to 1	56	28
Propane	4.5 to 1	54	12

The data in Table II apply only when each fuel gas is utilized at maximum efficiency. In practice it is difficult for the operator to adjust the ratio of gases other than acetylene to even approximately correct values. Because there is no definite starting point, such as the neutral flame in the burning of acetylene, even an experienced operator frequently adjusts the gas ratio of the flames that utilize other fuel gases, to much higher gas ratios than the best values indicated by Table II. Obviously this involves the use of much more oxygen than would otherwise be required. With acetylene, the change in the size and brilliance of the flame when adjusted to the oxidizing side of the neutral flame, is great enough to make it quite unlikely that any operator will employ oxygen-acetylene ratios appreciably higher than necessary.

Furthermore, when certain other fuel gases are used, the oxygen requirements for the cutting jet are greater than when acetylene is used. This is particularly true when the consumption of preheating gas is large and the resulting gases of combustion are sufficient to pollute the jet of cutting oxygen. In such instances a noticeable deterioration in the cutting efficiency may ensue.

Combustion of Acetylene. Because acetylene is the fuel gas most widely used for cutting, its combustion will be described in greater detail. Tables I and III show the reaction for complete combustion of acetylene as:

$$C_2H_2 + 2\frac{1}{2}\ O_2 = 2\ CO_2 + H_2O + 542{,}700\ \text{Btu}$$

In other words, 1 molecular volume of acetylene unites with 2½ molecular volumes of oxygen to form 2 molecular volumes of carbon dioxide and 1 of water vapor, with a liberation of 542,700 Btu of heat.

Most hydrocarbons are exothermic, generating heat during formation and absorbing the same amount of heat during combustion. But acetylene is highly endothermic, absorbing heat during formation and liberating it during burning or decomposing. The endothermic heat liberated by acetylene is in addition to that produced by the com-

bustion of its component elements. The total heat generated is given in Table III.

Table III
Heat Produced by Complete Combustion of Acetylene

Reaction Formula	Btu per Molecular Volume	Btu per cu ft at 60 F and 1 atm	Percentage of Total
Endothermic ... $C_2H_2 = 2\,C + H_2$	86,600	228	15.9
Carbon ..... $2\,C + 2\,O_2 = 2\,CO_2$	352,000	928	64.8
Hydrogen ..... $H_2 + \frac{1}{2}\,O_2 = H_2O$	104,100	277	19.3
Total heat of combustion.....	542,700	1433	100.0

Acetylene contains the highest percentage of carbon (92.3% by wt) of any common gaseous hydrocarbon compound. This, coupled with its exceptionally large endothermic heat, gives it the highest flame temperature of any known fuel gas, by a wide margin.

Oxygen Purity. High-purity oxygen is essential for rapid and efficient cutting. Even a small percentage of impurities in oxygen causes a great loss in the cutting quality. Tests made by machine cutting 12-in. mild steel billets in the laboratory, under identical conditions, using oxygen from 97.5 to 99.5% pure, gave results summarized in Table IV. The results demonstrate clearly the importance of using high-purity oxygen for cutting.

Table IV. Effect of Oxygen Purity on Consumption

Percentage Purity	Oxygen Consumption — Cubic Feet per Linear Foot Cut	Oxygen Consumption — Percentage Increase
99.5	45.5	...
99.0	49.5	8.8
98.5	55	20.9
98.0	63	38.5
97.5	73	60.5

Effect of Gas Cutting on Steel. In gas cutting, the temperature of a slight depth of metal immediately adjacent to the cut face is raised to considerably above the transformation range. As the cut progresses, the steel cools again through this range. The speed of cooling depends on the heat conductivity of the surrounding metal, radiation losses, and the fact that the heat is applied only momentarily at any given point, since the cutting torch is kept in constant motion while cutting. When the steel being cut is at room temperature, the rapidity of the cooling is sufficient to have an actual chilling or quenching effect on the cut edges, particularly in heavier cuts involving large masses of cold metal.

When polished and etched specimens are taken from gas-cut edges and examined under the microscope, the material is found to be altered when compared with the original metal. However, the change is largely a physical one, concerned with crystalline grain structure. The normal pearlitic steel is transformed into one or more of several structures ranging from spheroidized carbides in ferrite to the harder constituents, depending on the particular chemical composition of the steel cut and the rate of cooling after the cutting operation, as well as the carbon content and the alloying elements present. Also, the heat developed by the cutting makes the grains at the edge of the cut either larger or smaller than the unaffected grains behind the cut edge.

Low-Carbon and Mild Carbon Steels. At normal temperatures, gas cutting of carbon steels that contain less than 0.30 or 0.35% C is not detrimental unless alloying elements are present. Gas-cut edges of such steels are suitable for any uses where edges are employed that are prepared by any of the mechanical methods of severing; for example, planing, milling, shearing, friction sawing and grinding. Gas-cut edges are adapted to applications involving stresses, such as mechanical calking and holes in which tubes are to be expanded or rivets driven. Clean, smooth gas-cut edges of low-carbon or medium-carbon steel plates or forgings have physical properties that render them actually superior to edges that are sheared, planed, or otherwise prepared mechanically.

A few years ago when the ASME Boiler Code Committee conducted an investigation of the conditions that develop when the fusion welding process is applied to gas-cut edges, such conclusive results were produced that all restrictions pertaining to welding on gas-cut surfaces were removed from the Boiler Code. The wording of the Code requirement, adopted in 1935 for incorporation in the Power Boiler and Unfired Pressure Vessel Sections, follows:

> *"Preparation for Welding.* The plates may be cut to size and shape by machining or shearing, or by flame cutting if the carbon content does not exceed 0.35%. If shaped by flame cutting, the edges must be uniform and smooth and must be freed of all loose scale and slag accumulations before welding. The discoloration which may remain on the flame-cut surface is not considered to be detrimental oxidation."

Where edges are gas-beveled to form a V for welding, and later are welded together by either oxyacetylene blowpipe or electric arc, the heat of the welding operation acts to dissolve all marginal structures previously formed and operates to anneal the metal for an appreciable depth below the cut surface. Any change in structure that the preceding cutting may have produced in and adjacent to the cut surface is therefore obliterated.

Tests of flame-cut edges of low-carbon and medium-carbon steels to determine their physical properties (such as hardness, ductility, microstructure and resistance to impact) have shown that they are satisfactory for almost any type of mechanical treatment or character of service.

Higher-Carbon and Alloy Steels. Gas cutting of higher-carbon and alloy steels, particularly at room temperature, may produce a thin layer of hard material on the cut surfaces, which may not be sufficiently ductile to withstand the stresses set up in cooling, without cracking, or the stresses imposed by the subsequent use of the part cut. The torch heats the steel at the cut edges to a high temperature momentarily, but normal thermal expansion is prevented by the adjoining cold metal. The action called "upsetting" results. Later, when cooling occurs, contraction of the upset metal may develop severe stresses in tension along the cut edges. With these steels, the ductility may not be sufficient to prevent incipient cracks and checks that can prove dangerous in service, since they are likely to develop into large fractures.

Preheating and Annealing. Experience has shown that if these higher-carbon and alloy steels are preheated and, in certain instances, annealed afterward, no cracks will occur on the cut edges. Naturally, with the adjoining metal preheated, the difference in expansion is less between it and the metal heated during cutting, and "upsetting" is greatly reduced or eliminated.

Certain steels may be preheated as high as 1000 F or more for gas cutting. However, care must be taken not to carry the preheating too far, because the metal may develop too great an affinity for the jet of cutting oxygen at elevated temperatures, thus causing it to act erratically and prevent proper control of the cut. In cutting particularly thick preheated sections, special precautions should be taken to complete the work as quickly as possible after the piece has been withdrawn from the furnace, in order to avoid having the interior considerably hotter than the metal at the surface, a condition that may arise if the piece is allowed to cool partially in air before cutting. If partial cooling does occur, the oxygen jet may start to penetrate without much difficulty, but on entering the interior of the section the jet may fail to go through and may cause a flare-up in the cutting. The factor responsible for this stoppage is the hot center, which oxidizes so readily that a cavity or pocket may form on the inside of the piece. Where this occurs, a slight lowering of the cutting oxygen pressure will often rectify the trouble.

When equipment is used that delivers large volumes of oxygen through large tips at low pressures, large billets and rounds are successfully cut at rolling temperatures (1700 to 1800 F). Occasionally very high cutting speeds are obtained. Evidently, at temperatures above the transformation range, steel reacts more vigorously with the cutting oxygen, producing slags with great amounts of iron and relatively little Fe_3O_4.

To obtain the most efficient use of the oxygen and, at the same time, leave the steel in the best condition, a preheat temperature of 500 to 600 F should ordinarily suffice for carbon steels. The additional expense that accompanies preheating is compensated for by the more rapid rate at which preheated steel can be cut.

Annealing completely restores the original pearlitic structure of the steel at the cut edges, wherever this may be desired, and removes any residual stresses set up in the metal. The majority of steels do not require annealing if they have been preheated before the flame cutting.

Flame Softening. Flame softening is a localized and progressively applied oxyacetylene heat treatment, similar in physical aspects to flame hardening, but directly opposed in the objective. The results of flame softening are similar to those obtained by preheating in a furnace, but the effect can be restricted to a small area and the process is comparatively simple and economical. Flame softening is discussed in an article on page 651.

Mechanical Effects of Gas Cutting. Properly performed, gas cutting on carbon steels and low-alloy steel produces accurate results. Top and bottom edges of the cut are sharp and the width of the kerf is uniform. Surfaces of the cut may be smooth and square and may be produced without "drag" lines. The precision obtainable depends on (1) the cutting equipment and procedure employed and (2) the suitability of the material for cutting. Other mechanical effects of the gas cutting result from warping, caused by the expansion and contraction of the steel in heating and cooling.

When heated locally, as in gas cutting, a part may warp unless (*a*) its stiffness or cross-sectional strength is sufficient to resist the forces set up; (*b*) it is held in place by clamps or weights during cutting and cooling; (*c*) it is multiple-cut simultaneously or in rapid succession around its neutral axis, thus equalizing the forces set up and neutralizing their effect; (*d*) the cutting operation is followed immediately and progressively by rapid cooling or quenching in a suitable medium.

Plates ½ in. thick or more seldom warp or buckle from gas cutting, unless unduly long and narrow. In such simple operations as cutting off rods, bars, rails, piping, structural shapes, and similar materials of considerable length, warpage is not involved. So-called "skip-cutting" is frequently used in splitting narrow materials, such as flat bar stock and structural I-beams and channels to prevent warpage. In this method, the cut is made to skip at intervals, depending on the work, leaving a series of uncut sections along the line of cut, each about ½ in. to 1 in. long. These uncut ligaments hold the material in line until cooled; then they are cut through to separate the parts. Sometimes two or more torches are moved together along parallel lines, thus making simultaneous cuts, to eliminate warpage, increase production and reduce costs. During some operations, such as beam splitting, water quenching is an effective check to warpage. Where great accuracy is demanded in over-all dimensions of larger cut parts, suitable correction factors must be applied in making the cutting layout, particularly where the steel is preheated.

Gas-Cutting Equipment. Gas-cutting equipment consists ordinarily of the cutting torch or blowpipe with separate cutting tips of different sizes, oxygen and fuel-gas hose with connections, oxygen and fuel-gas pressure regulators, and gas cylinders. The pressure regulators are usually equipped with cylinder and working-pressure gages. Regulators for the cutting oxygen are designed especially to deliver oxygen in large volumes and at higher pressures and, hence, are usually fitted with gages that measure working pressures as high as 400 psi.

Where large quantities of oxygen are required, oxygen cylinders are often manifolded. Acetylene generators, rather than cylinders, are used where the consumption justifies it. In such installations, distribution pipe lines are frequently employed to carry both gases to the various points of consumption throughout the premises. For gas cutting by machine, the torch is held and operated mechanically, but its essential features and the accessory equipment remain unchanged. To ensure safety and efficient results, the manufacturer's instructions for setting up and operating the equipment should be followed closely.

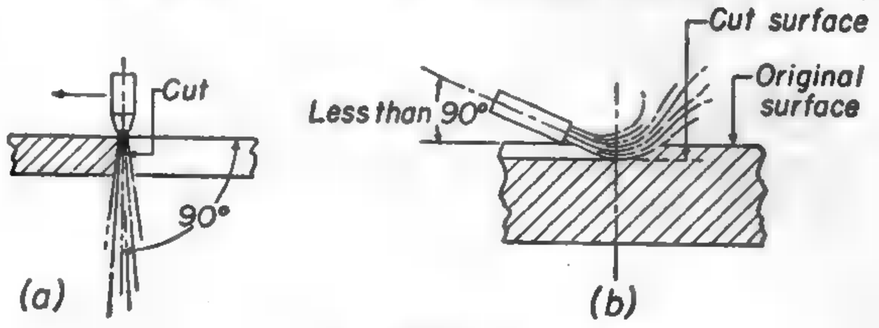

Fig. 2 Flame cutting

Gas-Cutting Processes. *Flame Cutting.* Gas cutting is used primarily for severing. With this process, the cut is made through the material as at (*a*), Fig. 2, leaving the cut edges in a plane usually at 90 deg to the surface of the part cut. The cutting tip is held preferably perpendicular to the surface, as shown, although in certain work it may be tilted somewhat along the line of cut. For bevel cutting, the tip is tilted to the required angle or a bent tip is used, but the cut still penetrates through the material. These processes are widely known as "flame cutting".

Flame Machining. This process utilizes the same fundamental principle of chemical reaction, but the cutting oxygen stream is made to impinge on the work at a more or less acute angle, as at (*b*), Fig. 2—in some instances almost tangentially. The cut is not permitted to penetrate through the work, as in severing, but is restricted to removal of a predetermined depth and width of material from the surface by oxidation. The various gas-cutting processes are classified in Fig. 3.

Fundamental Principles of Flame Cutting. In flame cutting, the jet of cutting oxygen usually enters the cut in line with the axis of the cutting oxygen orifice (*a*) in Fig. 2. After traversing about one-half the thickness of the cut, however, the jet may curve backward in a direction opposite to the travel (Fig. 1). When this occurs, the amount by which the oxygen jet falls behind the perpendicular in passing through the material is known as the "drag" of the cut. Faint markings or ridges called "drag lines", left on

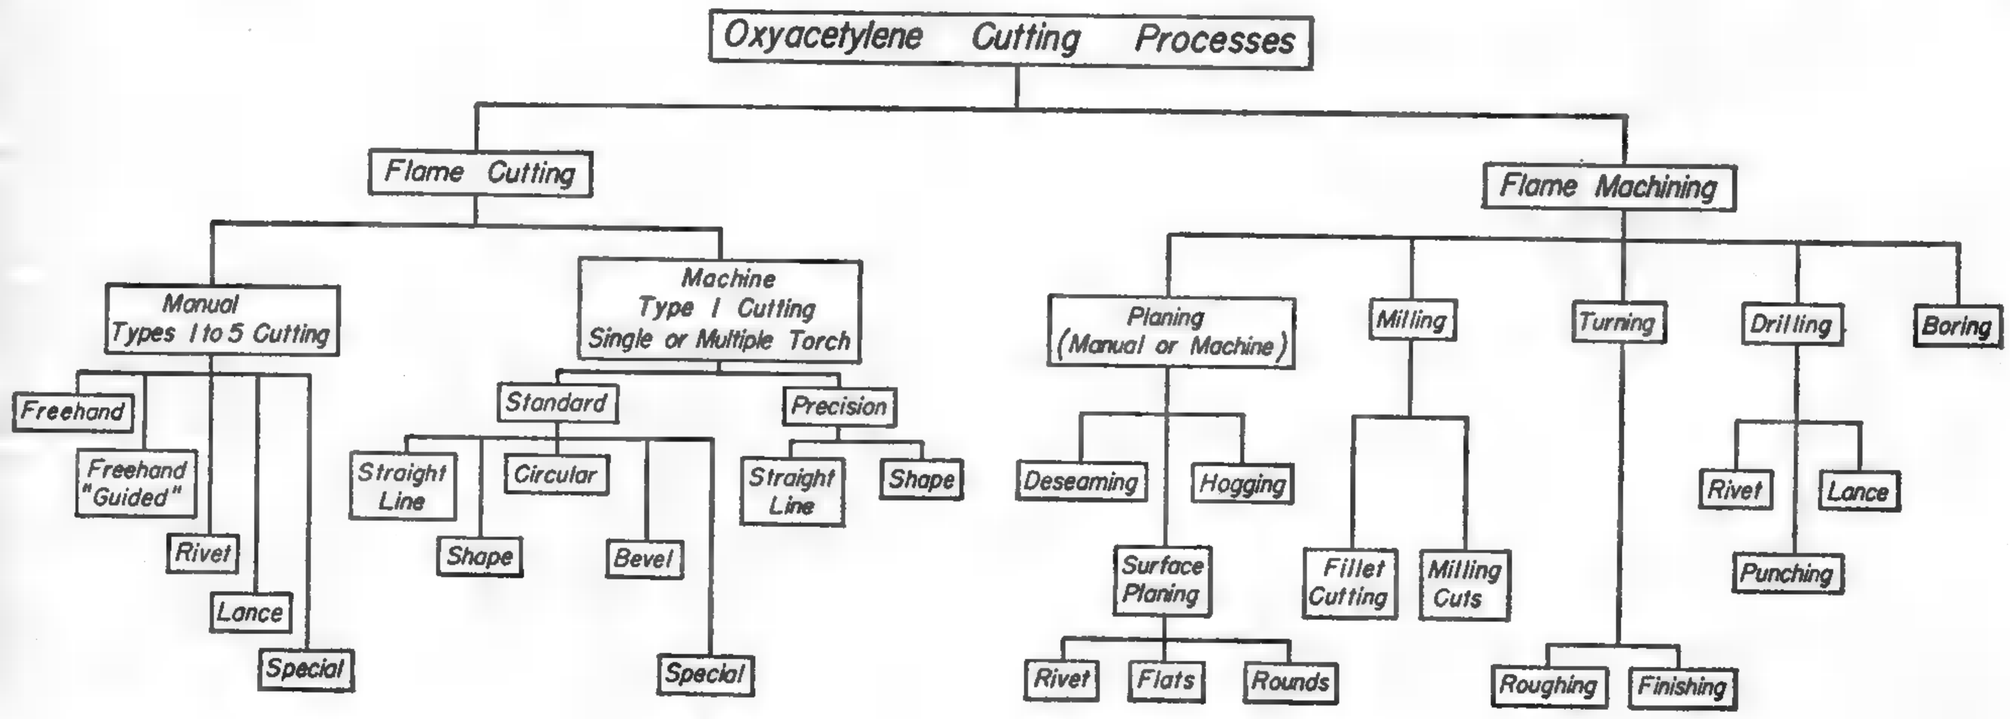

Fig. 3 Classification of gas cutting processes

the face of the cut, enable the drag to be measured, as shown in Fig. 1. In heavy cuts, these drag lines are more pronounced. Cuts with short or negligible drags are known as "high-quality" cuts; those with long drags are termed "low-quality" cuts.

Cutting studies have shown the following facts: (1) As the drag is decreased, the oxygen consumption is increased. For very short drags, a slight decrease in drag length can be procured at the expense of increased oxygen consumption. (2) Except for low cutting speeds, a certain minimum length of drag is characteristic of a given tip and speed regardless of the operating pressure (or the oxygen consumption). (3) An increased drag may result if an attempt is made to obtain a drag shorter than the minimum by increasing the operating pressure beyond that at which the minimum drag is obtained.

In considering the costs of flame cutting, therefore, it is essential to determine how short the drag must be to fulfill the requirements. If it is too long, a final corner will remain uncut and this is usually not permissible. Straight-line cuts can frequently be made with considerable drag, without a particularly detrimental effect, since the drag lines lie within the plane of the cut and do not prevent both top and bottom edges of the cut from being left clean and sharp. This procedure, which saves considerable oxygen, is also applied in cutting scrap, where cut quality is nonessential as long as severing is accomplished. However, in cutting shapes, when rounding curves or corners, less drag is permissible, because the bottom contour of the cut will tend to come out different from the top, with the edges not square. Such cuts must be made with short drag. They require a good deal more oxygen than long-drag cuts that barely penetrate the material. Precision-machine flame cuts are necessarily of high quality.

Satisfactory Commercial Flame Cuts. These must fulfill the following requirements: (*a*) The drag must be sufficiently short; that is, the line markings on the face of the cut should approach the straight up-and-down condition. The drag should not be long enough to prevent the final corner from being cut and the piece from dropping. (*b*) The sides of the cut should be sufficiently smooth—not grooved, fluted or ragged. (*c*) There should be no firmly adhering slag on the bottom of the cut, because considerable labor is required for its removal. With proper adjustments, only loose slag is obtained, or none at all. (*d*) The upper and lower edges of the cut should be sufficiently sharp to meet the requirements of the particular job. (*e*) The cost must be moderate.

The following conditions are necessary to obtain smooth cuts: (1) suitable cutting tip, with cutting orifice of correct size and proper degree of preheat; (2) suitable oxygen and fuel-gas pressures and uniform regulation of them; (3) correct cutting speed; (4) uniformity of torch movement; (5) smooth and uniform bore and proper type of cutting orifice; (6) cleanliness in the exit of the orifice; (7) cleanliness of preheat holes; no slag adhering to the end of the tip; (8) high-purity oxygen; (9) proper angle of incidence of the cutting oxygen stream in relation to the upper edge.

Selection of Cutting Tip or Nozzle. Widely varied cutting tips or nozzles of different styles and sizes are available for flame cutting. They provide for cutting various thicknesses of most ferrous materials, and for different surface conditions—clean, painted, rusty or scaly—as well as for various special types of work. The thickness of the material to be cut determines the diameter of cutting orifice of the tip to be selected. The condition of the surface and the composition of the metal determine the intensity of preheat flames that should be used. Rusty or scaly surfaces are often cleaned or "descaled" along the line of cut before cutting, by cracking the scale loose, either with the preheating flames or the torch, or mechanically with scrapers or chipping hammers.

Starting Flame Cuts. Flame cuts are usually started at the edge of the piece. The cutting torch is held so that the ends of the inner cones in the preheating flame just clear the surface of the material. When a spot of metal at the top of the edge has been heated to a bright red, the jet of cutting oxygen is turned on. The metal in the immediate path of the cutting jet oxidizes, and as the torch moves slowly and steadily along the line to be cut, separation is effected. In flame cutting ordinary steel, the tip should be held vertically at a correct distance above the surface and advanced steadily at the proper speed.

Piercing Holes. When starting a flame cut in the metal away from the edge, or when piercing a hole, more time is usually consumed in bringing the spot to the kindling temperature than in starting the edge. When a spot has been heated to a bright red, the torch is raised about ½ in. above the normal position for line cutting and the cutting oxygen is turned on slowly. As soon as the work material is perforated, the torch is lowered again to the normal height above the surface and the cutting is continued if necessary. Drilled holes are used for some work, particularly to form a straight, smooth starting edge for a heavy internal cut.

Cutting Round Bars. When round bars of steel are to be cut, gas pressures are set for the maximum thickness or diameter, and the cut is started at the side. As the cut progresses, the torch is raised to follow the circumference. Starting is facilitated by nicking the bar with a chisel to create a burr at the point where the cut is to begin, so that the oxygen can take hold more easily.

Heavy Cutting. In heavy cutting, the greatest care must be used in selecting the proper operating pressure. Not only is the range of suitable pressures considerably narrower for the heavier cuts, but the pressure decreases at the hose-line connections and a larger torch should be used with the increasingly greater flows of oxygen required for heavy cutting. The large volumes of oxygen needed are better supplied through the use of lower pressures and torches with large cutting orifices. Extreme preheating is necessary. Attempts to obtain the quantity of oxygen required by the use of high pressures in common machine cutting torches results in gouges and pockets in the kerf. Variations in the quality of steel are more important in heavy cutting.

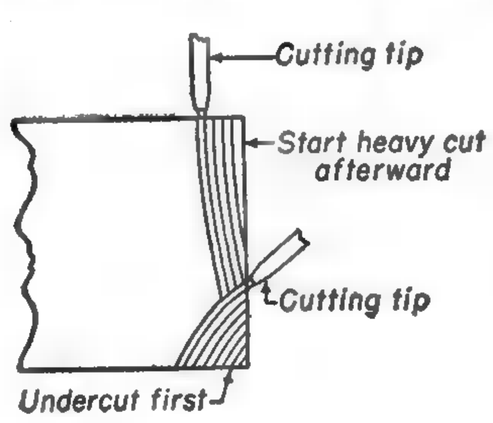

Fig. 4

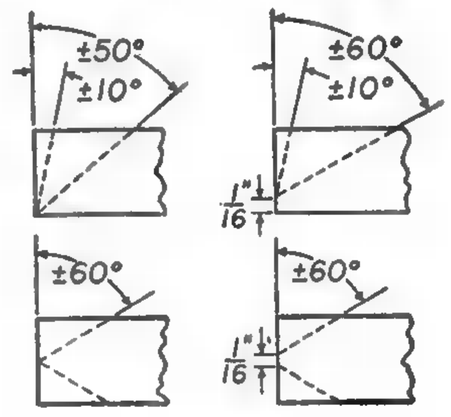

Fig. 5

Fig. 4 Undercutting as an aid in starting a cut
Fig. 5 Limits in the cutting of bevels and fillets

Considerable skill is sometimes required for starting a heavy cut, in order to sever the initial lower corner completely and to avoid pocketing the stream of cutting oxygen in the lower portion of the cut. It is essential that the front edge of the cut be very clean, particularly the lower portion of the front face. To align the axis of the tip with the front edge of the material, the stream of cutting oxygen should be turned on with preheating flames burning to render it visible. In starting the cut, the movement of the torch should be retarded just long enough to allow the cutting stream to attack the material actively throughout almost the entire depth. Then the torch is permitted to proceed normally. If the piece is very heavy, the lower portion of the front face is sometimes heated with a large welding flame. In certain instances, starting is facilitated by first undercutting the forward edge of the material with a hand cutting torch (Fig. 4). However, unless the operator is experienced, the resulting cuts may be poor and ragged.

Care is required also in completing the final corner of heavy cuts. A slight retardation of the forward movement of the torch is desirable here as well.

Scope of Flame Cutting. *Thickness.* When the standard cutting torches are not assisted by oxygen lances, present limits of penetration are about 36 in. for manual cuts and 54 in. for machine cuts. Particularly for freehand flame cutting, the upper limit depends largely on the skill and steadiness of the operator. With oxygen lances it is possible to penetrate virtually any thickness of metal.

Materials. Almost any ferrous material can be cut by gas; however, certain steels contain sufficient alloying elements to offer considerable resistance to the process. The uncombined carbon in cast iron has a similar effect. For such materials, special flame-cutting techniques must be applied, as described later. Oxygen lances permit penetration of virtually any metal, ferrous or nonferrous.

Cross-Cut Tolerances. Where the torch is held firmly and advanced at uniform speed, as in machine flame cutting, cross-cut tolerances can be kept within narrow limits. In ordinary steel 6 in. thick, cut surfaces can be held to cross-sectional squareness accurate within $\frac{1}{32}$ in. Cuts in thinner sections can be held to proportionately smaller limits. The degree of longitudinal precision of a machine cut depends on the trueness of the guide rails of the cutting machine, the clearance of the operating mechanism and the regularity of the propelling unit. Machine cuts can be made so smooth and square and can have such sharp edges that they require no further finishing of any kind.

Bevels. Angular or bevel flame cuts are accomplished by inclining the torch and tip sideways to the desired angle, or by using a bent tip. Such cuts may be either by hand or by machine, in straight or irregular lines, and with the same range of depth as in normal cutting at right angles. The usual angular limits of bevel and straight-faced fillet cutting are indicated in Fig. 5.

Shapes. Straight lines, circles or contours of the utmost complexity are flame-cut with equal ease by either mechanical or hand-guided torches. Flame cutting, in sharp contrast with most machine tool processes, has almost unlimited flexibility in this respect.

Multiple-Torch Cutting. In many applications of machine flame cutting, as many as 20 torches are used to cut a like number of identical shapes simultaneously. Concentric circles for flanges and the like are often cut in one operation, with two or more torches.

When the sheets are thin and level enough to be clamped economically into a tight pile, stack cutting is indicated for multiple production. When the plate is heavy or wavy, multiple cutting is used—sometimes along with stack cutting.

Stack Flame Cutting. The operation known as "stack flame cutting" offers a means of cutting several thicknesses of metal simultaneously with a single torch, instead of employing multiple-torch cutting.

The plates in the stack should be clean and flat, with edges in alignment where the cut is started. The number varies with the thickness of individual plates, to keep the thickness of the stack within reasonable limits. The plates should be clamped together firmly, as nearly as possible along the line of cut. When thin plates are to be flame cut in stacks, a "waster plate" that has sufficient rigidity to lie flat while the cut is being made, is usually clamped on to prevent the top thin plate from buckling with the heat. A waster plate serves also to maintain ignition in the cut by its own combustion, thereby increasing the speed of cutting in this kind of work.

Flame-Cutting Techniques. Several different flame-cutting techniques have been developed for performing various cutting operations and for cutting different grades of ferrous metals. The International Acetylene Association in its Oxyacetylene Committee Publication, Section I, entitled "Oxyacetylene Cutting", defines five distinct flame-cutting techniques. These are typified in Fig. 6 from the standpoint of flame movement and may be described as follows:

Type 1 Flame Cutting. This is the simple progressive type, widely used for carbon steels and other ferrous metals that are easily cut. The cut proceeds freely and regularly in a line and at the will of the operator. The technique consists in first preheating a spot to kindling temperature (1400 to 1600 F) with the several preheating flames surrounding the orifice for the cutting oxygen. Then the cutting oxygen is turned on and the cut is started. Theoretically, preheating should be necessary only for starting. In practice, however, preheating flames are maintained throughout the cutting operation, to ensure continuity of cutting and high speed. The torch is manipulated merely by holding it at correct height above the surface and advancing it at proper uniform speed along the line of cut (Fig. 6). The high velocity of the stream of cutting oxygen confines it to a narrow path and holds the oxidizing action within close limits. This makes accurate control possible. In practice, a considerable portion of the metal removed from the kerf is blown out in molten metallic form, unoxidized—particularly from heavier cuts. Figure 7 illustrates the relationship among thickness, metal removed and oxygen consumed in Type 1 flame cutting.

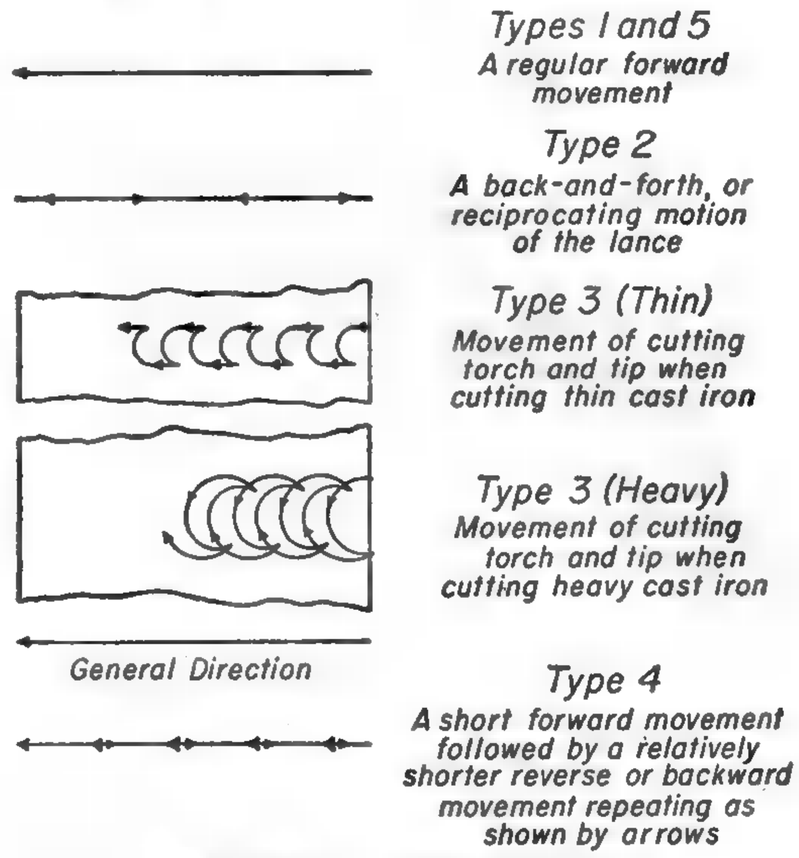

Fig. 6 Types of cutting techniques

Type 2 Flame Cutting. Commercially, this is known as "oxygen-lance cutting". Virtually all ferrous metals and many other materials can be cut or pierced with the oxygen lance. The lance ordinarily consists of a length of black iron pipe (¼ or ⅜ in. inside diam) with a globe valve on one end, connected to an oxygen hose, regulator and cylinder or manifold, so that only oxygen flows through the lance pipe.

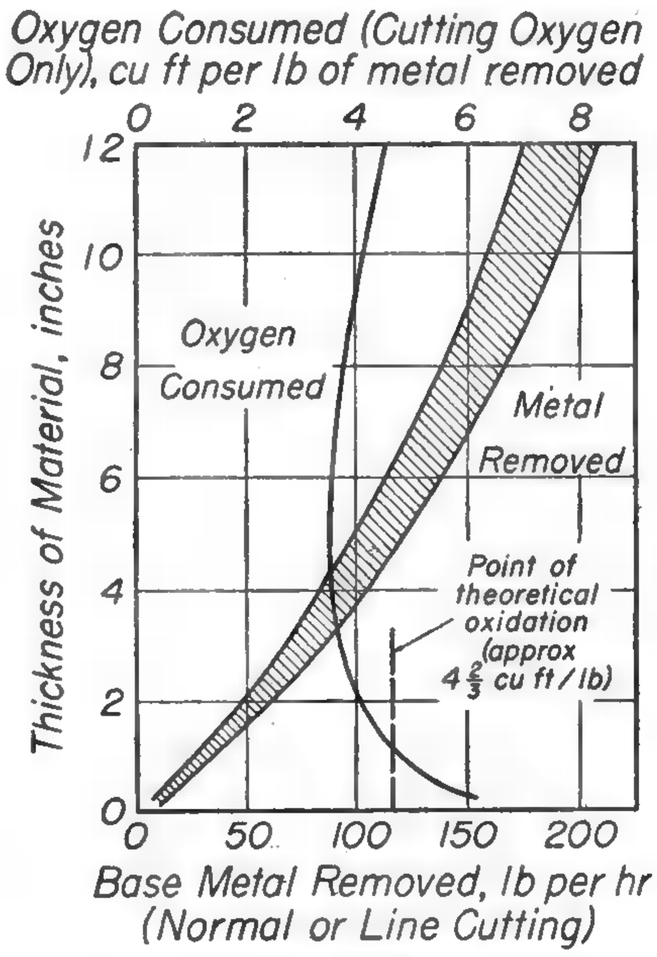

Fig. 7 Relationship among thickness, metal removed, and oxygen consumed

As in Type 1 flame cutting, a spot is first preheated to kindling temperature, usually by means of a welding torch with large tip. Then the end of the lance is brought against the heated area and oxygen is turned on at about 40 to 50 psi. This oxidizes the metal and sufficient heat is produced to continue the cut or hole with oxygen alone, without oxy-fuel gas flames to facilitate the progress. The end of the lance is held in the cut or hole so that the stream of cutting

oxygen emerges at the point of cutting or oxidation. This heats the end of the lance pipe, causing it to burn also. As the operation proceeds, the lance is consumed, ultimately requiring replacement by a new length of iron pipe. Oxidation of the lance itself requires only a minor portion of the oxygen consumed, while the heat of the burning lance assists in the cutting.

Once started, the oxidation reaction is vigorous. It may be intensified further, if desired, by using a lance pipe of greater wall thickness, or by inserting one or more steel rods into the pipe. Both the thicker pipe and the rod inserts furnish additional fuel and heat, while the rods decrease the area of the effective opening in the lance pipe, thereby imparting greater velocity to the oxygen stream and increasing the eroding effect.

Oxygen-lance cutting acts to extend the range of penetration in standard cutting-torch operations. This method is seldom used alone but is an aid to Type 1 flame cutting in severing thick or heavy masses of metal. However, under proper conditions and setup, oxygen lances can be employed independently. With various modifications, they are used for flame cutting large sections of cast iron, steel and other materials. For example, oxygen lances serve to burn holes in salamanders and ladle chills, in which, after cooling, dynamite is inserted and exploded for final demolition. It has become standard practice to open tap holes in blast furnaces and open hearth furnaces with the oxygen lance. In this operation, a spot of metal in the tap hole and the end of the lance pipe are both heated red hot with an oxy-acetylene welding torch. Oxygen is then allowed to flow through the pipe and impinge on the hot metal, which is quickly pierced, allowing the molten metal to flow out.

Lancing usually consumes more oxygen per pound of metal removed than other types of flame cutting. This, however, is offset by the greatly increased value of the cutting service as compared with other methods that can be used for such work. Obviously, the surface produced by Type 2 flame cutting, or lancing, is not so smooth as the surface obtained with Type 1 flame cutting. Nevertheless, surprisingly accurate holes can be pierced with the lance. Oxygen lance cuts should be made so that the slag and molten metal can flow out of the cut freely by gravity wherever possible.

Type 3 Flame Cutting. This technique was developed especially for cutting cast iron. Considerably more preheat is used than in Type 1 flame cutting, both in starting and in continuing the cut. A definite flame oscillation is used, which is necessary for cutting the cast irons, particularly those possessing carbon in the uncombined or graphitic state resistant to flame cutting. The sidewise motion or oscillation of the flame is approximately in the form of half circles or new moons, advancing in short and regular intervals, as shown in Fig. 6, Type 3 (heavy), when cutting heavy cast iron. A slight modification of the flame oscillation, shown in Fig. 6, Type 3 (thin), has been found more advantageous for cutting thin cast iron.

The resulting cut, therefore, may be termed a "worked cut", for the cast iron originally in the kerf has, in reality, been "worked out" by the oscillating technique. If this technique is regularly maintained, it causes a constant stream of slag and molten metal to flow through the kerf, preheating the base metal in the kerf and preparing it for further oxidation and displacement as the molten products are removed. The cut is naturally somewhat rougher than a Type 1 flame cut, because more of the metal has been removed by the mechanical eroding effect of the jet of cutting oxygen. A wider kerf is produced; therefore more metal must be oxidized and oxygen and acetylene consumptions are greater than for Type 1 flame cutting.

Highly carburizing preheating flames are used in Type 3 flame cutting of cast iron; that is, the flames are adjusted to carry a considerable excess of acetylene, which appears as a long whitish feather in the flames, beyond the small brilliant inner flame cone (Fig. 8). The length of the excess streamer of acetylene should be approximately equal to the thickness of the cast iron. This flame adjustment helps to maintain preheat in the cut, since the excess acetylene combines with cutting oxygen beyond the tip.

Type 3 flame cutting, or cast-iron cutting, appears to be limited at present to the alteration and repair of machinery and to the demolition of castings, usually in basements or other inaccessible locations where they must be broken up before removal, or otherwise reduced in size.

Type 4 Flame Cutting. For severing stainless steels, which resist ordinary techniques, a distinctive cutting technique has been developed, utilizing a flame motion or oscillation different from that in Type 3 flame cutting. In this method also the flame is moved continually while cutting, but in short strokes back and forth along the line of cut (Fig. 6) instead of sideways. When a cut is started in stainless steel, the entire face or leading edge of the cut is preheated from top to bottom, until the edge has been brought to a bright red color. The usual spot at the top edge is preheated also. Then the cutting operation is started. The forward and backward reciprocating motion already described, advances the cut through the part in short forward increments.

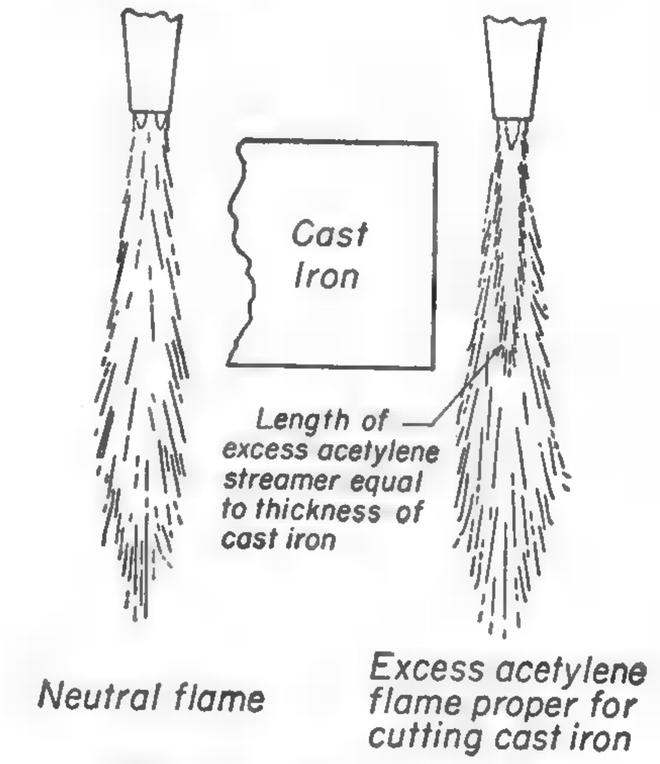

Fig. 8 Flame for Type 3 cutting

As in Type 3 flame cutting, the maintenance of a steady stream of liquid slag and molten metal is essential for a successful cut. Erosion by slag is probably as important as any other single factor in cutting stainless steels. It determines the degree of uniformity attainable in the cutting of these metals. Naturally, Type 4 cutting leaves a rough surface, necessitating subsequent machining or grinding if a smooth finish is desired.

Type 5 Flame Cutting. This technique involves the use of powdered additive materials in the cutting zone and supplants Type 4 cutting when the necessary equipment is available, enabling cuts of Type 1 to be made on metals such as stainless steels that are difficult to cut. The principal trouble in cutting these steels is the formation of highly refractory chromium oxide. One form of the Type 5 technique introduces iron powder into the reaction zone where it combusts with a portion of the oxygen, thus liberating intense heat that removes the oxides of chromium by a combination melting and fluxing action, and also permits cutting on very high alloy materials and cast iron in addition to stainless steels. Another type of equipment feeds a flux through the cutting oxygen stream. This flux combines with the chromium oxides to form a slag of low melting point—an action similar to that of the flux in oxy-acetylene welding of stainless steels.

The possibilities of this type of flame cutting have been investigated less thoroughly for cutting other metals than for cutting stainless steels. However, there are definite indications that cast iron, tungsten, and possibly other metals and alloys of low cuttability will yield to this technique.

Regardless of whether the iron-powder method or flux-injection method is used, the speed of cutting compares favorably with that reached in cutting mild steel and the cut faces are remarkably smooth. At times, the addition of flux enables resistant materials to be cut by Type 1 flame cutting instead of by a more tedious technique.

Cuttability of Ferrous Metals. Certain alloy steels contain chromium, nickel and other elements in amounts sufficient to render these steels considerably more difficult to

cut than carbon steels. The effect of various alloying elements on the cuttability of steel, as reported by various authorities, is summarized in Table V.

Types of flame-cutting techniques that are employed with various ferrous metals are given in Table VI.

Hand Flame Cutting. Many variables affect the performance of freehand flame cutting. However, the range of fair average practice in freehand oxyacetylene flame cutting of mild steel, not preheated, is given in Table VII. Oxygen and acetylene consumptions for cutting the various thicknesses as great as 12 in. are listed, both in cubic feet per hour and in cubic feet per linear foot of cut.

Freehand "Guided" Flame Cutting. This includes such operations as cutting circles and drawing the torch head along a bar or straight edge that acts as a guide. Circles or disks can be cut accurately with a hand torch that has a straight head, by using a circle-cutting attachment consisting of a clamp, radius rod and adjustable center point. Another attachment has small wheels that rest and roll on the surface of the work.

Flame-Cutting Machines. Flame-cutting machines are comparable with machine tools. As flexible as a jigsaw, flame-cutting machines are capable of making flame cuts of such high quality and accuracy that the edges frequently require no further finishing.

Straight-Line Machine Flame Cutting. Straight-line machine flame cutting is even simpler than freehand flame cutting. Once the machine and gas pressures have been set, the torch follows the line of cut automatically. As the cut progresses, the operator watches the drag and the flow of slag or oxide to prevent pocketing or other defects from developing. For oxyacetylene machine flame cutting of mild steel, speeds and gas pressures should be adjusted within the ranges given in Table VIII.

Machine Flame Cutting of Shapes. Regular or irregular shapes, of almost any size or thickness, no matter how complex, are flame-cut with ease by machine. The process has jigsaw flexibility. Most shape-cutting machines are driven by a motor. Some have tracing devices that are guided by hand around the outline of a drawing.

Circular Flame Cutting by Machine. Most flame-cutting machines can be adapted to circular cutting. A radius rod that has an adjustable center point is furnished with some of these machines. The point is placed in a punch mark at the center of the circle and the machine and cutting torch travel around the circumference at the radius set. Ordinarily a short "lead in" cut is made through the scrap, so as to have the finished cut smooth and unmarred at the starting point.

Precision Flame Cutting by Machine. One technique for machine flame cutting that produces especially high quality and accurate cuts is sometimes distinguished by the name "precision machine flame cutting". It will be noted in Fig. 3 that this type of cutting has been set up as a separate division of machine flame cutting, to distinguish it from standard machine flame cutting, which is a less refined process.

Although the technique described under Type 1 cutting is, in general, the one followed for precision machine flame cutting, closer adjustments of pressures and speed are required than for standard machine flame cutting. Cut surfaces have been attained by this method that have the cross-sectional squareness accurate within 0.003 in. for a 1-in. thickness. For thicker material, cross-cut tolerances increase approximately in proportion to the thickness. The cross-cut tolerances for thicknesses of 1, 2, 4 and 6 in. when precision flame-cut by machine, are shown in Fig. 9. These tolerances are not generally available commercially (1947).

Machine Flame-Cutting Table. The range of fair average practice in machine oxyacetylene flame cutting of mild steel, not preheated, is given in Table VIII.

Flame-Machining Operations. In flame machining, each operation is a problem in itself, calling for a co-ordination of nozzle tooling and metallurgical control. Various types of flame-machining operations have been included at the right-hand side of Fig. 3. It will be noted that these are termed planing, milling, turning, drilling and boring, like the corresponding machine tool operations. Subclassifications of these operations also are given in the chart. Not all these operations have been commercialized up to the present time; some are still in the development stage.

Flame Machining. Several types of tangential cuts may be classified under the heading of "flame machining". The principal differences are primarily the character of application and the tolerances or degrees of surface regularity attained or permitted. Flame machining can be either manual or mechanical. The subclassifications are:

1 *Deseaming or Scarfing.* This process of flame machining is used in the steel mills for removing cracks or seams in billets, slabs and rounds.* It is employed also in steel foundries for exploring and cleaning out cracks and sand holes in castings.
2 *Hogging.* This type of flame machining, applied to steel castings, removes superfluous metal that has been either provided purposely or caused by defective conditions at the time of pouring. Hogging also removes risers and sprues of such location or character as to make it difficult or impossible to dispose of them by ordinary or Type 1 flame cutting.
3 *Surface Planing.* This operation is a step beyond the practice of deseaming, in that the cuts are adjacent to one another, thus enabling the removal of wide surfaces. When surface planing is done mechanically, the tolerances as to depth and width of cut can be kept to within $\frac{1}{16}$ and $\frac{1}{8}$ in. of the surface.

* For information concerning torch scarfing, the reader may refer to the article "Conditioning of Semifinished Steel", page 343.

Table V. Effect of Alloying Elements in the Gas Cutting of Steel

Element	Effect
Aluminum	A low aluminum content does not hinder flame cutting. However, an aluminum content of 10 to 15% resists flame cutting either hot or cold, except where a special technique is used.
Carbon	In unalloyed steels, 2% C or less permits flame cutting by simple progressive procedure (Type 1 technique). However, steels containing more than 0.30% C should be preheated between 500 and 600 F before cutting, or heated after cutting, before the cut surface cools to normal temperature, in order to prevent hardening and cracking at edges. The quality of the cut is affected by both amount and form of carbon content. Graphite and cementite (Fe_3C) tend to hinder cutting, but cast irons containing 4% C are cut successfully by a special technique (Type 3).
Chromium	Chromium contents of 1½% or less have no adverse effect. Steels with 4 to 6% may also be cut by Type 1 technique, provided carburizing preheating flames of low intensity are used. Where the chromium content is 10% or more, a special cutting technique is required to produce a complete cut (Types 4 and 5).
Copper	Copper contents of 3% or less in steel permit easy flame cutting.
Manganese	Manganese contents of 14% or less, with 1.3% C, allow for good cutting. However, high-manganese steels require preheating before cutting, in order to prevent cracking.
Molybdenum	A molybdenum content of 0.25%, as in chromium-molybdenum aircraft steels, does not hinder cutting. But a steel with 5.5% Mo, 8% W and 1% C is uncuttable, either hot or cold, unless special techniques are employed.
Nickel	As much as 7% Ni in steel does not hinder good flame cutting. Steels with 34% Ni have been cut in instances where the carbon content was lower than 0.50%.
Phosphorus	Phosphorus contents of 2% or less do not prevent good gas cutting.
Silicon	Silicon contents of 2.90% or less permit cutting by the simple progressive method. Transformer iron, containing 4% Si or less, can be gas cut, but a high silicon content reduces speed. Precautions in preheating and cooling are necessary with certain of these steels in the higher ranges of carbon and manganese contents to prevent or modify tendencies toward air-hardening.
Sulfur	Small amounts, such as are normally present in steels, have no effect. With higher percentages of sulfur, the rate of gas cutting is reduced and sulfur dioxide (SO_2) fumes are produced.
Tungsten	Tungsten contents of 10% or less do not hinder flame cutting of steels that contain also 5% Cr, 0.2% Ni and as much as 0.8% C. A tungsten content of 17% necessitates preheating before cutting and a procedure similar to the cutting of cast iron (Type 5 technique).

Table VI. Data for Flame Cutting of Ferrous Metals,[a] Cutting Techniques[b] and Heat Treating Practices[c]

Metal	Approximate Carbon Content, %	Cutting Technique[b] Type 1	2[k]	3	4	5	Pre-heating Flames[d]

(a) The data apply to metal in the forged, rolled, and cast condition unless otherwise noted. Preheating of any steel will ordinarily improve the economy of cutting and prevent acute hardening. For carbon steels, heat treatment in one form or another is usually employed where the carbon content exceeds 0.30%, provided the cutting is conducted at normal temperatures (60 to 80 F). If the temperature of the metal is lower than this, heat treating may have to be employed at a lower carbon content to preserve or re-establish desired physical properties. The letters P or HT are used to designate material that is cuttable cold, but requires either preheating or reheating to prevent damaging the cut surface or to preserve or restore commercial properties.

(b) The technique of cutting varies for different grades of steel. See the description of the five distinct types in the text.

(c) Heat treating practices employed for grades that are unduly hardened by the normal application of flame cutting are listed in the table under the following classifications:

C denotes that metal may be safely cut at room temperatures.

P denotes that metal should be preheated before cutting in order to prevent hardening of the metal in the face of the cut. Usual preheating temperatures range from 500 to 900 F. Preheating is also used for certain grades to facilitate cutting.

HT denotes heat treatment, in a furnace or by other means, after cutting, in order to improve or recondition the structure of the cut surface, provided the material is kept warm between the time of cutting and the heat treatment.

Car denotes carburizing flame. A carburizing flame is one carrying more fuel gas than is required for complete combustion.

(d) Unless otherwise indicated, neutral preheating flames are desirable. However, appreciably higher preheating temperatures may be obtained by adjusting these flames for an excess of oxygen (oxidizing). Therefore, where additional preheating is desired, oxidizing preheating flames may be used wherever neutral flames are indicated. Considerable economies are sometimes obtainable with oxidizing flames in which the ratio of oxygen to acetylene is about 1.7 to 1 or 1.8 to 1.

(e) The addition of normal amounts of copper (3% or less) does not interfere with the type of cutting normally employed for the grade of steel in question. The addition of copper, however, does increase hardening of the cut surface, necessitating introduction of heat treatment at a lower point in the aggregate of hardening alloys than would otherwise prevail.

(f) Grades SAE X-1314 and X-1315 may harden perceptibly if carbon contents are high and the metal is cut at normal or lower temperatures.

(g) After cutting, heat treatment may be necessary if carbon contents are high.

(h) No data are available as to heat treatment, if necessary.

(i) Including SAE 4340 and 4315.

(j) Evidently the tungsten contents may be as high as 10% with Type 1 cutting technique.

(k) All grades that respond to Type 1 cutting technique will respond readily to Type 2 technique, either in conjunction with Type 1 technique or separately. The heat treatment for Type 2 corresponds to that for Type 1.

(l) Heat treatment is usually necessary to counteract harmful effects of the heating produced during the cutting operation, unless the metal contains a stabilizing element to prevent such heat effects.

(m) Aluminum steel containing approximately 1% Al, 1% Cr and 0.50% Mo is reported to be cuttable by Type 1 technique. Heat treatment would depend on the carbon content.

(n) The cut surfaces in heavy sections of cast iron are hardened by the cutting operation and should be heat treated if they are to be machined after cutting.

Flame Drilling and Punching. Figure 10 shows a method used for flame drilling a round hole in the end of a billet, for centering or piercing purposes. The dimensions of the finished hole can be made uniform and the walls straight if the nozzle or tip is held properly during drilling.

The oxygen lance, described under Type 2 flame cutting, is also a valuable tool for flame-drilling operations, particularly those too deep for a cutting tip to reach.

Rivet Cutting. Flame drilling has proved successful for rivet cutting by surface oxidation of heads. Cutting tips

(a) Because the pressure of acetylene for the preheating flames is more a function of blowpipe or torch design than of the thickness of the part being cut, the pressure data have been omitted from this table. For acetylene pressure data, see charts of manufacturers of apparatus.

(b) Lowest speeds and highest gas consumptions per linear foot are for inexperienced operators, short cuts, dirty or poor material. Highest speeds and lowest gas consumptions per linear foot are for experienced operators, long cuts, clean and good material.

(c) Beyond 12-in. thickness, the critical data of manual cutting practices are greatly affected by the condition of the metal and the skill of the operator, resulting in wide ranges of data. In view of this, the table has been terminated at the 12-in. thickness.

The reader is referred to Table VIII, which gives data on machine cutting wherein the range of thickness has been extended to 36 in.

(a) Because the pressure of acetylene for the preheating flames is more a function of blowpipe or torch design than of the thickness of the part being cut, the pressure data have been omitted from this table. For acetylene pressure data, see charts of manufacturers of apparatus.

(b) Lowest speeds and highest gas consumptions per linear foot are for inexperienced operators, short cuts, dirty or poor material. Highest speeds and lowest gas consumption per linear foot are for experienced operators, long cuts, clean and good material.

(c) The apparent inconsistencies that will be noted in some of the columns in the table result from the fact that straight-line relationships do not exist among pressure, speed, and orifice sizes for the range of apparatus data for which this table was devised.

(d) The generally accepted point at which heavy cutting begins is 12 in. The data for 12 to 36 in. are for torches with large tips, using large volumes of oxygen at low pressures. Because the speed depends on the conditions of the material being cut and the skill of the operator, no figures are given for gas consumption per linear foot.

(e) Cutting speeds per minute vary from 4 in. for light sections to 2 in. for heavy sections.

(f) These data are for divergent orifices that have controlled expansion tips, permitting the use of relatively high oxygen pressures so as to expand the cutting oxygen through the orifices. Thus the gas stream has high velocity and is relatively narrow. Higher speeds and lower specific consumption of oxygen result.

used for this operation have large cutting-oxygen orifices of the expanding type, low in pressure and velocity, together with preheating flames of high intensity. The tip is held in line with the rivet, close to the head, so that preheating flames impinge on the center. As soon as a spot is heated bright red, the cutting oxygen is turned on slowly. This quickly oxidizes a crater in the head and consumes the head. The rivet shank is then knocked from the hole.

Flame Boring. Rough boring can be accomplished by means of a compound setting of the cutting flame. Application of this process depends largely on tooling so that the slag and molten metal from the cuts will not interfere with the cutting and the operation of the cutting nozzle.

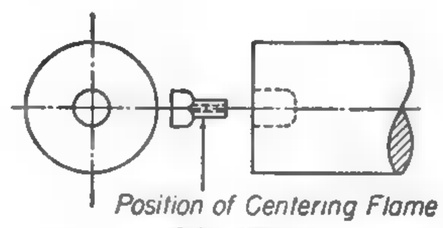

Fig. 10

Fig. 9 Cross-cut tolerance for precision machine-cutting practices
Fig. 10 Flame drilling

Underwater Cutting. Equipment for underwater cutting has been highly developed. Although oxyacetylene is used for shallow work, the pressure of acetylene needed soon rises to more than 15 psi because of the hydrostatic head. As a result oxyhydrogen torches are used at depths greater than 25 ft. Operation under water involves the creation of an artificial atmosphere or "bubble" in which the preheating flames burn and in which the actual cutting is done. Some torches create such a bubble by the use of a skirt around the tip. The skirt is filled with the combustion gases, in order to keep the water away from the flame. The most successful equipment for deep-water operation requires a supply of compressed air to form the bubble in the skirt.

Operating pressures are determined largely by the hydrostatic head to be overcome. The chilling effect of the water on the work requires heavier preheats. Because of the difficulties under which the diver must work—such as clumsy dress, darkness, insecure footing, cold, and high pressure—only severing cuts are made, and oxygen and acetylene consumption figures are meaningless, although the specific cutting speed may be higher than in the open air.

The torch may be lighted on the surface and lowered to the diver in that condition or it may be sent down unlighted, to be ignited by a spark.

Another form of underwater cutting equipment uses the electric arc for preheating. The apparatus embodies a holder with an oxygen valve and means for gripping a hollow electrode. In operation, the diver calls for current, draws an arc against the work and, as soon as there is a molten pool of metal, he opens the oxygen valve, permitting a stream of oxygen to flow down the hollow electrode. Simplicity is the chief advantage of this equipment, since only the oxygen hose and the cable carrying the current need to go to the surface. However, the diver's telephone must be in perfect order and elaborate precautions must be taken to protect him from the electric current.

Safety Rules. Certain precautions must be observed for the safe handling and operation of gas cutting tools and appurtenant equipment. Standard rules and regulations have been promulgated by the cutting industry in co-operation with regulatory bodies that deal with the safety of the public and of workers. In "Safe Practices Bulletin No. 23", published by the National Safety Council, and in "Regulations for the Installation and Operation of Gas Systems for Welding and Cutting", issued by the National Board of Fire Underwriters, the subject of general safety is well covered, with regard to gas-welding and gas-cutting processes. The American Standards Association pamphlet, War Standard Z 49.1, is also recommended.

Electric-Arc Cutting

The process of electric-arc cutting consists in applying the heat energy of the electric arc to melt the metal along the desired line of cut. Because of the extremely high temperature developed in the electric arc, it can be used to fuse almost any material that conducts electricity, and in this way it is employed for cutting metals. Arc cutting is not a true cutting process, since the metal is merely melted away. Arc cutting does not equal gas cutting from the standpoint of smoothness, quality, or accuracy of cut surfaces, and hence, is not used where high-quality, accurate cuts are required. However, it is useful where smooth, uniform cut surfaces are not essential and mere severing is the main object, as in scrapping operations. Arc cutting is used also for metals not easily cut in any other manner, such as cast iron, manganese steel, and large sections of nonferrous metals. It is applied particularly to the cutting of risers from large manganese steel castings. Arc cutting is also used for the cutting of rivets and piercing of holes.

Carbon-Arc Cutting. This process consists essentially of drawing an arc between a carbon or graphite electrode and the material to be cut. Direct current is generally used, with the carbon electrode negative (straight polarity), although alternating current can be used also. Graphite electrodes are preferred to carbon electrodes, because they have a much longer service life and retain a point longer. A point is essential for clean, smooth cuts. The heavy currents used for arc cutting make ordinary electrode holders unsuitable except for light work. Special holders are recommended that have a long shank, a special mechanism for gripping and a shield for protecting the hands.

Manipulation of the cutting arc, when cutting plates ½ in. thick or less, consists simply in advancing along the line of cut at a rate equal to that at which the metal is being melted away. The most smooth and uniform cuts are made when the plate is in a horizontal plane, but the operation may be performed when the plate is in an inclined or vertical position. For horizontal cutting, the electrode is held vertical or pointed slightly forward. For inclined or vertical cutting, the electrode is pointed downward. When materials heavier than ½ in. are being cut, the vertical face of the cut is melted away progressively from top to bottom. Thus the bottom of the cut is advanced slightly ahead of the top of the cut, producing an undercut that permits the molten metal to run out more easily. Skilled operators can make narrower cuts. The width and speed of the cut increase with the current and the diameter of the electrode. Recommended current values for graphite electrodes of different sizes are in Table IX.

Table IX. Current Values for Arc Cutting

Electrode Diameter, inch	Current, amperes
¼	200 or less
⅜	200 to 400
½	300 to 600
⅝	400 to 700
¾	600 to 800
⅞	700 to 1000
1	800 to 1200

Arc Cutting With Coated Electrodes. The application of heavily coated electrodes to cutting is not always an economical process, but has certain merits, particularly where no oxyacetylene cutting torch or graphite electrode is available. Electrodes with either a gaseous or slagging type of coating can be used, but the slagging type gives better results because it will handle higher current densities. Plates ⅜ in. thick or less can be cut simply by advancing the electrode along the line of cut. On heavier plates the electrode is pointed forward and moved from the top to the bottom of the cut, so as to keep the bottom slightly ahead. Electrodes smaller than $\frac{5}{32}$ in. in diam are not suitable for arc cutting. The width of the cut is approximately constant for all electrodes ¼ in. in diam or less. Alloy steels and many nonferrous metals can be cut readily by the coated-electrode cutting process.

Oxygen-Arc Cutting With Hollow Electrodes. Using the equipment and technique described for underwater cutting with an oxygen arc, rough cuts at high speeds can be made in air if the work piece is moderate in thickness. However, the electrode must be changed at frequent intervals and the speed decreases when the sections to be cut are heavy.

Macro-Etching of Iron and Steel

By the Subcommittee on Macro-Etching*

MACRO-ETCHING of iron and steel consists in subjecting the surface of the metal to the action of a reagent in order to bring out the internal and surface structure for visual examination.

Preparation of Sample. The preparation of the surface of the test specimen is governed by the intensity of the action of the reagent employed. Weak etching solutions require polished surfaces. Solutions strong enough to produce a deep attack require less care in sample preparation.

Unless otherwise noted, the samples should be in a soft, annealed condition. However, when hardened material is to be etched, great care should be taken to protect the metal from the effects of heat of grinding or cutting.

In Table I, the surface required for each reagent is designated by the letters *A*, *B*, or *C* under the heading "Remarks". Type *A* represents a saw-cut or machined surface; *B*, an average ground surface; and *C*, a polished surface. When type *A* surface is used, consideration must be given to the type of steel. For the higher-carbon steels and for tool steels in general, a cleanly sawed disk will produce very good results. On the very soft steels, it is desirable to have a machined surface, not too coarsely cut, or a sawed surface, rough ground to remove all traces of flowed metal. It is important to make sure that the metal has not been smeared or flowed over the surface in order to conceal internal defects.

The compilation of etching solutions for macro-etching (Table I) has been taken largely from Berglund's "Metallographers' Handbook of Etching". In the present compilation an effort has been made to list the reagents alphabetically according to the purposes for which they are intended. Different conditions will be revealed in the same steel by etching with different solutions, and it is well to be familiar with each reagent in order to interpret the results correctly.

Recommended Practice for a Standard Macro-Etch Test for Routine Inspection of Iron and Steel

The macro-etch test reveals readily and quickly many of the characteristics of steel but, in some instances, further examination by standard testing methods is required to evaluate the characteristics properly. The knowledge that a piece of steel is dendritic or that it contains metallic and nonmetallic segregates is not sufficient evidence on which to base definite conclusions concerning the properties of the steel. The macro-etch test is of real value in separating metals that are obviously defective from those that are not. The test is easily made, but experience and judgment are required to interpret results.

Preparation of Sample. When it is desired to reveal surface defects, such as seams, laps and grinding checks, preparation of the sample is frequently unnecessary. Any oil or grease on the surface should be removed for best results. Scale on the surface of the material will be removed by the acid, so that the surface defects will become visible. In order to reveal the internal structure or defects, a section must be prepared by cutting through the metal at a point where inspection is desired. For best results, the samples to be etched should be in a soft, annealed condition, and the method of preparation such that no metal is smeared or flowed over the surface.

The surface finish necessary for the specimen depends on the etching solution to be used. A machined surface is recommended as the standard in this practice. A smooth ground and polished surface is not necessary and in many instances a fairly smooth sawed cut is satisfactory—for example, on the higher-carbon steels and tool steels in general. On the very soft steels, a machined surface is desirable, if not too coarsely cut, or a sawed surface, rough ground to remove all traces of flowed metal.

Etching Solution. A solution of one part commercial hydrochloric acid and one part water is recommended. The advantage is that this solution can be heated with little or no change in concentration. The fumes of this mixture are corrosive so the work should be done under a hood. A solution consisting of 38% hydrochloric acid, 12% sulfuric acid and 50% water, is sometimes used in the same manner as the recommended hydrochloric acid solution. This solution has been used extensively by a number of forging manufacturers, and was suggested originally by the Watertown Arsenal. The advantages appear to be a more sharply defined etched pattern and less susceptibility to rusting.

It is not necessary to throw away the acid after each test, but for the best results, a fresh solution should be used for each test. Irregular etching effects are obtained if the etching solution is dirty or contaminated, or if the sample is oily.

For containers, pyrex glass, porcelain dishes, or corrosion-resistant metals can be used. Satisfactory results have been obtained with hydrochloric acid and particularly with sulfuric acid in a lead-lined iron pan or wooden tank, provided care is used in the application of heat. However, a wooden tank is the least satisfactory type of container and should not be employed unless absolutely necessary. For heating the solution, the method that permits the best control of temperature should be used.

Temperature of Acid. A temperature of 160 F is recommended. At this temperature the reaction of etching is vigorous and the solution does not evaporate too rapidly.

* The members of this subcommittee are C. B. Post, *Chairman* (The Carpenter Steel Company), C. T. Hewitt (The Fafnir Bearing Company), T. B. Reynolds (Ingersoll-Rand Company), E. S. Rowland (The Timken Roller Bearing Company) and A. O. Schaefer (The Midvale Company).

Table I. Etching Solutions and Recommendations for Macro-Etching

The compositions of various etching solutions are given below. When acids are mentioned, the concentrated strengths are intended. Muriatic acid may be used satisfactorily where hydrochloric acid is mentioned. When the ingredients of an etchant are all liquids, the proportions are by volume. When one or more of the ingredients is a solid, the proportions are by weight unless the actual weights and volumes are given.

Water or alcohol should never be poured into an acid; rather, the acid should always be poured into the other liquid. Unless otherwise stated, the etching should be done at room temperature.

After the etchant has been removed by washing and drying, the etched surface may be preserved by covering it with clear lacquer. The lacquer should be removed if it is desired to study the macro-etched specimens further.

"Surface A" in the column headed Remarks, means a saw-cut or machined surface; "Surface B", an average ground surface; "Surface C", a polished surface.

Purpose	Composition	Remarks	Uses
Blowholes	10% sulfuric acid in water	Use cold on large sections for 24 hr. Surface B	Shows blowholes, porosity, pipe, and inclusions.
Blowholes	50% hydrochloric acid in water	Use at 160 to 175 F for ½ hr. Surface A	Shows blowholes, porosity, pipe, and inclusions.
Carburized case	5% solution of nitric acid in alcohol	Etch at room temperature. Surface B	Shows depth of carburized case
Contrast	1 part iodine, 2 parts potassium iodide, and 10 parts water	Use at room temperature. Surface B	Produces contrast for photographing
Cracks	5% solution of nitric acid in alcohol	Etch at room temperature. Etches within ½ hr. Surface B	Detects fatigue, service, hardening and grinding cracks
Cracks	Hydrochloric acid	Apply cold with swab	Detects embrittlement cracks in steam boiler drum
Cracks	50% hydrochloric acid in water	Use at 160 to 175 F for ½ hr. Surface B	Detects fatigue, service, hardening, grinding, and internal cracks. If hardened, material should be softened before etch.
Cracks	Kerosene and whiting test	Wash surface with kerosene. Wipe off. Paint with thin mixture of whiting and water. Let dry. Kerosene in cracks, if present, will discolor whiting. Surface B	Detects fatigue, service, hardening and grinding cracks
Cracks	120 g copper ammonium chloride, 50 ml conc hydrochloric acid, 1000 ml water	Etch first with a neutral solution to remove machine marks. Use cold for 20 min to ½ hr. Surface B	Produces a strong relief effect. Shows up dendrites and may indicate cracks
Decarburization	5% nitric acid in alcohol	Etch at room temperature. Surface C	The decarburized areas will be light. Area not decarburized dark
Defects	10% sulfuric acid in water	Use cold on large sections for 24 hr. Surface B	Shows porosity, pipe, blowholes, and inclusions
Defects	50% hydrochloric acid in water	Use at 160 to 175 F for ½ hr. Surface A or B	Shows porosity, pipe, blowholes, and inclusions
Defects	2 parts conc sulfuric acid, 1 part conc hydrochloric acid, 3 parts water	Use at 160 to 175 F for at least ½ hr. Surface A	Shows general structure and defects
Dendrites	2 parts conc sulfuric acid, 1 part conc hydrochloric acid, 3 parts water	Use at 160 to 175 F for at least ½ hr. Surface A	Shows general dendritic structure and defects
Dendrites	50% hydrochloric acid in water	Use at 160 to 175 F for at least ½ hr. Surface A	Shows general dendritic structure and defects
Dendritic pattern	25% sulfuric acid in water	Use cold, 8 to 16 hr. Surface B	Shows dendritic pattern and flow lines
Dendritic pattern	40 g ferric chloride, 3 ■ cupric chloride, 40 ml hydrochloric acid, 500 ml water	Etch first with 10% nitric acid. Surface B	Shows dendritic pattern or structure
Etch, universal	500 ml hydrochloric acid, 70 ml sulfuric acid, 180 ml water	Use at 160 to 175 F for 1 to 2 hr. Surface A	Good universal etch
Fiber	10 to 20% solution of ammonium persulfate in water	Swab on freshly made solution for ½ min. Surface B	Shows fiber and grain contrast
Flow lines	25% sulfuric acid in water	Use cold, 8 to 16 hr. Surface B	Shows flow lines and dendritic pattern
Flow lines	50% hydrochloric acid in water	Use at 160 to 175 F. Surface A	Shows flow lines
Ghost lines	10 to 20% solution of ammonium persulfate in water	Swab on freshly made solution for ½ min. Surface C	Shows ghost lines
Grain contrast	10 to 20% solution ammonium persulfate in water	Swab on freshly made solution for 1 to 2 min. Surface B	Shows grain contrast and fiber
Grain contrast	1.5 g cupric chloride, 30 ml hydrochloric acid, 95 ml water, 30 ml ethyl alcohol	Polish specimen carefully. Surface C	Shows good grain contrast
Grain size	10 to 20% solution ammonium persulfate in water	Swab on freshly made solution for 1 to 2 min. Surface B	Shows grain size especially in low carbon steels, wrought iron, and welded sections
Hardness penetration	5% nitric acid in alcohol	Etch at room temperature on smooth ground surface. Surface B	Shows depth of hardness penetration of heat treated samples
Hardness penetration	50% hydrochloric acid in water		(*See* NOTE A)
Heterogeneity	50% hydrochloric acid in water	Immerse specimen in solution at 160 to 175 F from ½ to 1 hr. Surface A	Shows heterogeneity in general
Heterogeneity	Undiluted hydrochloric acid	Use hot (212 F). Surface A	Shows heterogeneity in 3 to 3.5% Ni steels
Impurities in ferrite	1 g cupric chloride, 0.5 g stannous chloride, 30 g ferric chloride, 30 ml hydrochloric acid, 500 ml distilled water, 500 ml ethyl alcohol	Etch only well polished surface that has been thoroughly dried. Surface C	Plates out copper on ferrite containing impurities. Gives a good even etch
Internal cracks	50% hydrochloric acid in water	Use at 160 to 175 F for ½ hr or longer. Surface B	Shows internal cracks or thermal checks
Inclusions	10% sulfuric acid in water	Use cold on large sections for 24 hr. Surface B	Shows inclusions, porosity, pipe, and blowholes
Inclusions	10 to 20% sulfuric acid in water	Use at 160 to 175 F. Surface B	Etches sulfide inclusions
Inclusions	50% hydrochloric acid in water	Use at 160 to 175 F. Surface B	Etches sulfide inclusions

Purpose	Composition	Remarks	Uses
Pipe and porosity	10% sulfuric acid in water	Use cold on large sections for 24 hr. Surface B	Shows pipe, porosity, blowholes, and inclusions
Pipe and porosity	50% hydrochloric acid in water	Use at 160 to 175 F. Surface B	Shows pipe, porosity, blowholes, and inclusions
Rail Sections	9 parts hydrochloric acid, 3 parts sulfuric, 1 part water	Use at 160 to 175 F for 2 hr. Surface A	Use for etching rail sections.
Segregation	3% solution picric acid in ethyl alcohol	Etch at room temperature for 4 to 5 hr. Surface B	Shows segregation
Segregation	1 g picric acid, 1 drop conc hydrochloric acid in 25 ml alcohol	Use hot. Surface B	Shows segregation
Segregation	10 to 15% solution nitric acid in water or alcohol	Etch at room temperature. Surface B.	Shows heavy segregation
Segregation	5% solution nitric acid in water or alcohol	Etches within ½ hr. Surface is black when etched. Surface B	Shows segregation in low-carbon, low-chromium, nickel steels
Segregation	2 to 10% solution nitric acid in water	Etch first with weak acid to remove machine marks and then increase concentration for structure. Surface B	Shows segregation in ingot sections and large pieces
Segregation	50% hydrochloric acid in water	Use at 160 to 175 F. Surface A	Shows segregation in ingot sections and large pieces.
Segregation	1 g cupric chloride, 0.5 g picric acid, 1.5 to 2.5 ml hydrochloric acid, 10 ml water, 100 ml ethyl alcohol	May be used for electrolytic etching. Surface B	Shows segregation
Segregation, carbide	2% nitric acid in alcohol. For high speed steel, use 5% nitric acid in alcohol.	Use cold on a polished longitudinal section. For high speed steel, etch until matrix is darkened. Surface C	To detect carbide segregations, particularly in high speed steels
Segregation, carbon and phosphorus	1 part copper ammonium chloride, 12 parts water	Immerse finely ground, clean sample in solution for 1 min, wash with water, and rub off copper. Surface C	Shows phosphorus and carbon segregation
Segregation, phosphorus	0.5% solution picric acid in water	Etch at room temperature until staining occurs. Surface C	Uneven staining represents phosphorus segregation
Segregation, phosphorus	30 g ferric chloride, 100 g hydrochloric acid, 1 g cupric chloride, 0.5 g stannous chloride, 1000 ml water	Polish as for microscopic work, use etch cold for 10 sec to 2 min. Surface C	Shows phosphorus segregation
Segregation, phosphorus	10 ■ cupric chloride, 40 g magnesium chloride, 20 ml hydrochloric acid; 1000 ml ethyl alcohol (Steads No. 1 reagent)	Dissolve salts in small amount of hot water, then add alcohol. Apply solution to polished surface drop by drop. Surface C	Areas not coated by copper show phosphorus segregation
Segregation, phosphorus	5 ■ cupric chloride, 4 ■ magnesium chloride, 1 ml hydrochloric acid, 20 ml water, 100 ml alcohol (Steads No. 2)	Etch for 1 min. Surface C	Shows phosphorus segregation
Segregation, phosphorus	4 ■ cupric chloride, 20 ml hydrochloric acid, 40 ml water, 20 ml ethyl alcohol	Polish specimen carefully. Surface C	Shows phosphorus segregation
Segregation, phosphorus	1.5 g cupric chloride, 5 g nickel nitrate crystals, 6 g ferric chloride, 12 ml water	Immerse specimen for 90 sec or more. Surface C	Shows phosphorus segregation
Segregation, sulfur		(*See* NOTE B)	
Segregation, sulfide inclusions	10 to 20% sulfuric acid in water	Use at 160 to 175 F. Surface A	Etches sulfide inclusions
Soft spots	5% nitric acid in alcohol	Etch at room temperature. Surface B	Nondestructive test for hardened tools
Soft spots	50% hydrochloric acid in water	Use cold on ground surface. Surface B	Shows soft spots
Strains	90 g cupric chloride, 120 ml hydrochloric acid, 100 ml water	(*See* NOTE C)	Shows strain lines
Strains	6 ■ cupric chloride, 6 g ferric chloride, 10 ml hydrochloric acid, 100 ml ethyl alcohol	Heat specimen to 400 F and immerse ground surface. Surface B	Shows strain lines
Strauss test	3% cupric sulfate; 10% sulfuric acid, 87% distilled water	(*See* NOTE D)	To measure intergranular corrosion of 18-8 Cr-Ni corrosion-resisting steel
Structure	25% nitric acid in water	Etch at room temperature. Surface B	Shows general structure
Structure	50% hydrochloric acid in water	Use at 160 to 175 F for at least ½ hr. Surface A	Shows general structure and defects
Structure	2 parts conc sulfuric acid, 1 part conc hydrochloric acid, 3 parts water	Use at 160 to 175 F for at least ½ hr. Surface A	Shows general structure and defects
Thermal cracks	50% hydrochloric acid in water	Use at 160 to 175 F for ½ hr or longer. Surface B	Shows thermal checks or internal cracks
Weld examination	50% hydrochloric acid in water	In testing large sections, the acid may be added by building a dam with paraffin wax around the part to be tested. Surface A	For testing the soundness of welds

NOTE A. *Hardness penetration.* Use at 160 to 175 F for about 15 to 60 sec. To preserve surface after etching, scrub in running water, dip in weak NH_4OH, dip in solution of soluble cutting oil, dry with a rag and compressed air. Surface B or C

Shows depth of hardening, especially in carbon steels; produces distinct contrast between martensitic and troostitic zones

NOTE B. *Segregation, sulfur.* Soak ordinary sensitized photographic silver bromide paper in a 2% aqueous solution of sulfuric acid. Apply emulsion side of paper to smooth-ground, clean sample for a minute or two. Do not move the paper once in contact with the specimen. Air bubbles should be rubbed out with a squeegee or roller. Rinse paper, fix in hypo, wash thoroughly.

The brown pattern formed on the paper indicates the relative distribution of sulfides. The darker and heavier the marks, the more sulfur is indicated to be present. Surface B. Best results are obtained only on the first or second prints made from a surface.

Shows the distribution of sulfur. Can also be used to distinguish machinery steel from screw stock.

NOTE C. *Strains.* Copper does not precipitate with this etch. Heat specimen to between 400 and 475 F for ½ hr, then etch ground surface for 1 to 3 min. Rub with powdered cupric chloride, then rinse with alcohol. Surface B

NOTE D. *Strauss test.* Specimen ½ by 1 by 4 in. is sensitized by actual welding, or artificially by heating to between 900 and 1300 F (generally 1250 F). Immerse in the boiling cupric sulfate solution for 72 hr. Specimen is then bent 180 deg around a ½-in. pin. Cracking indicates disintegration, caused by migration of carbides to grain boundaries. Surface B. (120° fine emery)

If the temperature rises much above 175 F, the etching solution may lose selectivity and a reaction may occur over the entire surface rather than only at the localized points of attack that it is desired to reveal. On the other hand if the solution is at a temperature below 160 F, the etching operation will generally be prolonged unnecessarily with little gain in the results. A suitable thermometer should be used for determining the temperature.

The ordinary procedure is to put the cold specimens into hot acid at 160 F and then to adjust the process carefully so that a temperature of about 160 F is maintained at all times. Methods for maintaining this temperature are different in different laboratories and depend on the number of specimens that are etched in the pan at one time, the volume of etching solution used, and the heat conductivity of the container. For extreme consistency of results, it is advisable to clean the specimens first and then to heat them in hot water to the same temperature as the acid. The specimens are then transferred to the acid bath, which has first been heated to the proper temperature. This practice makes the duration of etching much easier to control than if the specimens were put into cold acid and brought up to temperature with the solution, or if cold specimens were put into hot acid, with resulting fluctuation in the temperature of the acid.

Duration of Etching. The duration of etching depends on the type of steel to be etched, the condition of the surface, and the physical condition of the steel—for instance, whether it has been annealed or hardened. For best reproducibility of results, it is extremely important that the time be measured accurately and maintained from batch to batch. If the steel is not etched long enough, the sample will not reveal all the information desired; if the steel is etched too long, some of the more delicate details will be masked by the general destruction of the surface.

When the specimens are in a soft, annealed condition, the etching periods listed in Table II have been found to produce good average results. However, this table has a limited value, and should serve only as a guide in determining the length of time that may be required for producing a properly etched surface. Marked variation in the susceptibility of steels to attack by acid, will be found among different heats of steel and among different methods of heat treatment. This variation in susceptibility to acid attack depends also on the position of the specimen in the ingot as influenced by the extent of segregation, and depends particularly on the machined finish of the specimen. A little practice with the macro-etch test will enable the operator to develop a surface that will be macro-etched deeply enough to bring out the structure fully, but not overetched with consequent development of excessive pitting that masks the structure and frequently deceives the examiner.

Washing and Preserving Specimens. After the test specimen has been etched, it should be removed from the hot acid, washed under running water, and then scrubbed with a stiff brush in order to remove the deposit of "smut" from the surface. Live steam is also an excellent medium for washing etched pieces. The piece is first rinsed thoroughly and then placed under the nozzle that directs the steam. By this method the specimen can be dried rapidly and completely with freedom from rust. After being washed, the specimen can be blotted with a paper or cloth towel or dried with a blower.

As a simple temporary means of avoiding rust, the specimen may be rinsed in water to remove the acid, then dipped in ammonia and washed in hot water. For longer preservation, after the specimen has been dried, it should be covered with a thin coat of transparent lacquer or with a film of oil that may be applied with the palm of the hand. Rusting may be delayed temporarily and small amounts of rust may be removed from a dried sample by the application of a solution of 50-50 syrup of phosphoric acid and water to which a little sugar has been added. The excess solution may be blotted up with a cloth or paper towels. Caution is recommended because this solution will roughen the hands and disintegrate cloth, if allowed to remain in contact for an extended time.

Interpretation of Results.* The results obtained on properly etched samples are of great value if interpreted correctly. Surface seams, internal cracks and pipe are easily recognized. It is the incorrect interpretation of the evidences of segregation and dendritic structures, as revealed by deep etching, that affords the greatest possibility of expensive errors and the needless rejection of material. For instance, every pit does not indicate an inclusion, since pitting may also result from acid attack around carbide particles. Irregular etching effects are obtained if the surface being examined has retained any oil or

* The article on page 412 includes macrographs that illustrate most of the defects discussed here.

Table II. Recommended Duration of Macro-Etching for Various Steels

(See text for recommended composition and temperature of the etching solution.)

Steel	Duration of Etching, minutes
SAE Carbon Steels	
1010	60 (%S <0.020)
1050	20 (%S <0.020)
1070	20 (%S <0.020)
1095	20 (%S <0.020)

grease; if the surface was prepared by an unsuitable machining method that caused a smearing or rubbing action of the metal; if the piece was in contact with other specimens in the etching bath; or if the etching solution was dirty or contaminated.

Cracks from Etching. Before etching, hardened or otherwise highly stressed steels should be tempered sufficiently to prevent cracking, since otherwise sound steel may crack in the etching solution and thus lead to false conclusions.

Grinding Cracks. Grinding cracks can be distinguished easily in a short-time macro-etch test and are usually, but not always, identified by a pattern of some symmetry. Again it must be emphasized that hardened pieces should be softened by tempering before hot etching.

Surface Cracks. As revealed by deep etching, surface cracks usually follow an irregular path and may result from wrong handling during heating, forging, rolling, or cooling from the finishing temperature. On heat treated material, surface cracks may be caused by incorrect treatment, by improper grinding, or by surface stresses.

Seams. Seams in rolled material are of varying depth and usually extend in a straight path parallel to the direction of rolling. In forged material, seams generally follow the contour of the forging and the flow of the metal. The most detrimental result of seams is that they may serve as a point of origin for fatigue failures or may open into deep cracks if the metal is subsequently quenched during heat treatment. This detrimental effect may be avoided if, during manufacture, the surface is machined to a sufficient depth to remove the seams.

Surface Appearance. Steels may be etched with a comparatively smooth surface or with a very rough or pitted surface, depending on variables in manufacture and composition. Therefore, a highly roughened surface is not necessarily detrimental. It has been found that smoother surfaces can be obtained by adding to the hot etching solution several drops of triamylamine, an organic inhibitor. Inclusions are then attacked in preference to the metal, thereby eliminating the general roughness and consequently producing better etch patterns.

Irregularity in pitting may usually be attributed to one or more of the defects described below. Certain manganese, oil-hardening steels are attacked more readily by the acid and are often decidedly roughened without being defective in any way.

Center Porosity. If porosity is the result of an actual discontinuity within the metal, it is probably more accurate to classify the defect as a pipe. Usually, however, the porosity is not visible until the specimen has been etched. This condition may be found in widely varying degrees, and the question of whether the steel should or should not be used is one for experienced judgment. The term "porosity" is generally restricted to segregations that are partially torn open during hot rolling, or forging.

Pipes and Bursts. Pipes are internal cavities formed during solidification of the ingot and carried through the various manufacturing processes to the finished product. Pipe is invariably associated with segregated impurities, which are deeply attacked by the etching reagent. Cavities in the center that are not associated with deeply etched impurities, are often mistaken for pipe but such cavities can usually be traced to bursts caused by incorrect processing of the steel during forging or rolling. Either pipes or bursts should be visible after deep etching; they can generally be distinguished from each other by the degree of sponginess surrounding the defect. Piped material usually shows considerably more sponginess than burst material.

Unsound Steel. Numerous blowholes and nonmetallic inclusions visible as the result of the deep etch usually indicate that both gases and oxides were distributed throughout the steel at the time of casting.

*Nonmetallic Inclusions and Metallic Segregates.** Nonmetallic inclusions usually appear as pits and must not be confused with pits that result from the etching out of metallic segregates. When nonmetallic inclusions are suspected in highly alloyed steels that may contain metallic segregates, a comparison should be made of an annealed specimen and a hardened specimen, etched in the same way. If the etching pits are the result of nonmetallic inclusions, they will appear similarly in both the annealed and the hardened specimens. If they are the result of a metallic segregate they will differ. The macro-etch test is not recommended as a test for "cleanliness" of steel, since unambiguous results are obtained only when large slag inclusions are present in the steel.

Segregations are revealed by the severity of the acid attack on the affected areas. Segregations at the center may be attacked so deeply after etching that they appear as a pipe, or the segregation may be grouped in some fairly regular form about the center, depending on the shape of the ingot and the mechanical work done on it.

Segregation at the corners of ingots can sometimes be detected in macro-etched disks obtained from large forgings. It should be emphasized that evidences of this type of segregation sometimes appear as cracks, whereas actually they may represent a segregate that has been dissolved by the acid during the test.

Segregation, as revealed by macro-etching, is not always an indication of defective material. A polished specimen should be examined under the microscope to determine whether the revealed segregation is metallic, a crystalline arrangement, or a concentration of impurities. The microscopic identification of segregation may be supplemented by chemical means, such as analysis of center drillings for carbon, phosphorus and sulfur, or analysis of inclusions separated chemically from the metallic matrix of the steel.

Internal Cracks. Internal cracks, sometimes called "flakes", "cooling cracks", or "thermal cracks", can be detected by the macro-etch test and their identity can be verified by a fracture test of a hardened specimen in which the cracks are revealed as brightly crystalline spots. These cracks are an actual discontinuity in the metal and, depending on their nature and distribution, may make the steel unfit for use unless closed by further hot reduction.

Dendritic Pattern. Etching often reveals a dendritic structure that results from the crystalline characteristics of the ingot. Dendritic patterns are detected even in steel that has been subjected to repeated mechanical reduction. It has not been proved that dendritic patterns are associated with surface failures, provided the material has been subjected to sufficient mechanical working and provided the segregation accompanying the dendritic formation is not in the form of nonmetallic inclusions incapable of being dispersed.

In the formation of dendritic crystals, the intercrystalline material contains minute metallic segregations that can be eliminated by diffusion. However, nonmetallic inclusions thus segregated cannot be eliminated by diffusion. The microscope should be used in conjunction with macro-etching for distinguishing metallic from nonmetallic segregates.

Pattern Effect. Pattern effect is almost entirely the result of the crystallization of the ingot, and is found in the part of the bar that was the columnar structure of the ingot. This part of the bar etches differently from the part that was the granular structure of the ingot. If the steel contains considerable inclusions of sulfide and silicate, then the area of contact between the columnar structure and the granular structure may be particularly noticeable. In the absence of large amounts of sulfides and silicates, the pattern effect is probably of no serious consequence.

Grain Size. Although the deep-etch test is of no definite value in determining grain size, nevertheless the manner in which many specimens etch may provide some indication of the grain size. Generally the larger the grain size, the coarser the appearance of the etched surface.

Decarburization and Carburization. Ordinarily areas that have been either decarburized or carburized, etch differently from the remainder of the specimen; the chief difference is in color. Decarburized parts appear lighter in color and carburized parts, darker.

If the section to be examined is small enough, it can be given a final polished finish and then etched cold for ▮ to 30 sec in nital (3% nitric acid, 97% ethyl alcohol). This will usually result in excellent contrast and if the polish is good enough, the same sample can be examined microscopically as well as visually.

* *See also* "Nonmetallic Inclusions in Steel", page 445.

Etching to Determine Soft Spots and Penetration of Hardness. The hardened case and the unhardened core of a heat treated section of shallow-hardening steel will contrast in color after etching. This fact is valuable in determining the depth to which a sample has hardened.

To show the penetration of hardness best, the sample should have a finish equivalent to that produced by polishing with 00 emery cloth, or finer. The sample can then be etched in either hot or cold acid. If hot acid is used, the ground sample is dipped for 15 to 60 sec in a solution of 50% hydrochloric acid in water at 160 to 175 F. If it is desired to etch cold, the ground sample is etched for 5 to 10 min in a cold solution, 10% nitric acid in water. On a polished surface, nital produces excellent results. After either method of etching, the sample should be washed thoroughly in warm water with a cloth or sponge, and then dried with an air blast. If it is desired to preserve the etched surface of the specimen, the procedure suggested earlier in this article should be followed.

Soft spots, which often result during the hardening of carbon or low-alloy tool steels, can generally be distinguished by either of the macro-etching methods mentioned above. The soft spots invariably etch in relief and are not so dark as the harder surrounding areas. Troostitic areas on hardened alloy steels appear darker than the surrounding areas when etched in nital.

Etching to Reveal Flow Lines. When macro-etched, a longitudinal section will show more or less well-defined flow lines, which result from elongation of structural constituents. These flow lines indicate the directions in which the steel was worked during rolling or forging, and do not signify defective material. The longitudinal face on which the flow lines are to be developed, should have a smooth surface, either machined or ground. The etching procedure is carried out in a solution of 50% hydrochloric acid in water at 160 to 175 F, in the same manner as outlined under Recommended Practice. The length of time required for development of flow lines is variable; therefore it is necessary to inspect the piece from time to time while it is etching, in order to determine when the etch has progressed far enough.

When it is difficult to develop flow lines on a particular piece, the etched surface may be painted with India ink. Then, when the ink is dry, the surface may be rubbed lightly with fine abrasive cloth. This procedure removes the ink from the high portions of the surface and leaves the "valleys" darkened, thus providing the contrast needed to show up flow lines.

Etched surfaces that reveal flow lines can be preserved in the same manner as other etched surfaces, as noted above. For an illustration of flow lines revealed by macro-etching, see page 416.

Etching Reagents for the Microscopic Examination of Iron and Steel

COMPILED BY THE SUBCOMMITTEE ON ETCHING REAGENTS FOR IRON AND STEEL*

IN THE preparation of etching solutions that are listed in Tables I to V, only reagents of high analytical purity should be used.

Etchants that are used for more than one purpose are listed in more than one of the tables; for example, chromic acid (Reagent 4) is included in Tables I, II and V, with explanatory remarks concerning the use of the reagent for each of three purposes.

The references listed after Table V, may be consulted for more detailed discussion of the recommended reagents, and for information concerning reagents that are used less commonly than those listed in the tables.

Table I. General Reagents for Irons and Steels (Carbon, Low-Alloy and Medium-Alloy Steels)

No.	Etching Reagent	Composition	Uses	Remarks
1	Nitric acid (Nital)	Nitric acid (sp gr 1.42) ..... 1–5 ml Ethyl or methyl alcohol (95% or absolute) ..... 100 ml (also amyl alcohol)	(1) To darken pearlite and give contrast between pearlite colonies; (2) to reveal ferrite boundaries; (3) to differentiate ferrite from martensite. Extensively used in studies of microstructures of medium-alloy as well as low-alloy and plain carbon steels.	Etching rate is increased, selectivity decreased with increasing percentages of HNO_3. 4% in amyl alcohol useful for grain boundary and contrast of low-carbon steels. Etching time, a few seconds to a minute.
2	Picric acid (Picral)	Picric acid ..... 4 g Ethyl or methyl alcohol (95% or absolute) ..... 100 ml (Use absolute alcohol only when picric acid contains at least 10% moisture.)	For carbon steels and some low-alloy steels (1) annealed (2) normalized (3) quenched (4) quenched and tempered (5) spheroidized (6) austempered	More dilute solutions occasionally useful. Does not reveal ferrite grain boundaries as readily as No. 1. (Reference 2)
3	Hydrochloric and picric acids	Hydrochloric acid .. 5 ml Picric acid ..... 1 g Ethyl or methyl alcohol (95% or absolute) ..... 100 ml	For revealing the austenitic grain size in quenched, and quenched and tempered steels	Best results are obtained when the martensite is tempered for 15 min at 400-475 F.
4	Chromic acid	Chromic acid ..... 10 g Water ..... 100 ml	For various structures except grain boundaries of ferrite. Attacks cementite very rapidly, austenite less rapidly, ferrite and phosphide very slowly, if at all.	Used electrolytically, the specimen as anode, the cathode stainless steel or platinum, ¾ to 1 in. apart; 6 volts usually used. Time of etching 30–90 sec depending on specimen. (Reference 5)
5	Heat tinting	Heat only	Pearlite first to pass through a given color, followed by ferrite; cementite less affected, iron phosphide still less. Especially useful for cast irons.	Clean, dry, polished specimen heated face up on hot plate to 400–700 F. Time and temperature both have decided effects. Bath of sand or molten metal may be used. (Reference 1)

* The members of this subcommittee are W. D. Forgeng, *Chairman* (Union Carbide and Carbon Research Laboratories, Inc.), M. Baeyertz (Armour Research Foundation), G. F. Comstock (Titanium Alloy Manufacturing Company), G. A. Ellinger (National Bureau of Standards), A. R. Elsea (Battelle Memorial Institute), C. F. Lottier (Chicago), M. R. Norton (Watertown Arsenal) and J. R. Vilella (United States Steel Corporation Research Laboratory).

Table II. General Reagents for Alloy Steels, Including Heat-Resisting, Stainless and High Speed Steels

No.	Etching Reagent	Composition	Uses	Remarks
6	Mixed acids in glycerol...	(A) Nitric acid ..... 10 ml Hydrochloric acid .....20-30 ml Glycerol .....20-30 ml	Structure of iron-chromium base alloys, high speed steels, and austenitic manganese steel. Etches nickel-chromium alloys satisfactorily.	Warm specimen in water before etching. For best results use method of alternate polishing and etching. If given sufficient time, will etch totally austenitic alloys, but better results are obtained by using Reagent 6 C.
		(B) Nitric acid ..... 10 ml Hydrofluoric acid. 20 ml Glycerol .....20-40 ml	Structure of high-silicon alloys of the Duriron type	Amount of glycerol may be varied to suit metal.
		(C) Nitric acid ..... 10 ml Hydrochloric acid. 20 ml Glycerol ..... 20 ml Hydrogen peroxide (30%) . 10 ml	For etching iron-chromium-nickel, iron-chromium-manganese, and all other iron-chromium base alloys	Amount of hydrochloric acid may be varied if reagent acts too rapidly or slowly. For best results employ method of alternate polishing and etching.
7	Chrome regia	Hydrochloric acid. 25 ml Chromic acid (10% water solution) 5-50 ml	Heat treated 18-8 stainless steels	Activity is controlled by amount of chromic acid. Can also be used electrolytically by diluting with 2 parts of alcohol and 2 parts of glycerine.
8	Acid ferric chloride.....	(A) Saturated solution of ferric chloride in hydrochloric acid, to which a little nitric acid is added	Structure of stainless steel	Use full strength.
		(B) Ferric chloride .. 5 g Hydrochloric acid 50 ml Water ..... 100 ml	Structure of austenitic nickel steels	
9	Oxalic acid	Oxalic acid..... 10 g Water ..... 100 ml	For austenitic stainless steels and high-nickel alloys. Carbides and general structure revealed, depending on etching time	Used electrolytically, the specimen as anode, the cathode stainless steel or platinum, about 1 in. apart; 6 volts usually used. Precipitated carbides in stainless steels may be revealed in 10-15 sec, the general structure in about 1 min. For study of carbides 1.5-3 volts may be used, thus increasing the etching time and improving control of etch.
10	Mixed acids and cupric chloride	Hydrochloric acid 30 ml Nitric acid ..... 10 ml Saturate with cupric chloride and let stand for 20-30 min. before use.	For stainless alloys and others high in nickel or cobalt	Apply by swabbing.
11	Cupric chloride and hydrochloric acid in alcohol	Hydrochloric acid 100 ml Cupric chloride.. 5 g Ethyl Alcohol... 100 ml	For austenitic and ferritic steels	Kalling's Reagent. In mixed structures, ferrite is most easily attacked, carbides are not attacked and austenite is attacked appreciably only when it has begun to decompose to martensite.
12	Hydrochloric acid in alcohol	Hydrochloric acid 10 ml Ethyl alcohol ... 90 ml	For chromium and chromium-nickel steels	Used electrolytically to show delta ferrite and the general microstructure
13	Hydrochloric and lactic acids in alcohol.....	Hydrochloric acid 10 ml Lactic acid ..... 45 ml Ethyl alcohol.... 45 ml	For chromium steels	Used electrolytically for general microstructure
14	Ammonium persulfate....	Ammonium persulfate .... 10 g Water ..... 100 ml	For austenitic stainless steels and high nickel alloys. Carbides and general structure revealed depending on etching time	Used electrolytically. Similar to oxalic acid, Reagent No. 9, but slower in action and provides better control in the case of fast-etching steels.
15	Nitric and acetic acids....	Nitric acid ..... 30 ml Acetic acid ..... 20 ml	For stainless alloys and others high in nickel or cobalt	Apply by swabbing.
16	Hydrochloric and nitric acids in alcohol.....	Hydrochloric acid 10 ml Nitric acid ..... 3 ml Methyl alcohol .. 100 ml	To reveal the grain size of quenched, or quenched and tempered high speed steel	Etch 2–10 min. (Reference 6)
17	Ferricyanide solution.....	Potassium ferricyanide ... 30 g Potassium hydroxide .... 30 g Water ..... 60 ml	To distinguish between ferrite and sigma phase in iron-chromium, iron-chromium-nickel, iron-chromium-manganese and related alloys. Colors sigma phase light blue, ferrite yellow	Must be fresh. Use boiling. (Reference 7)
18	Cupric sulfate.....	Cupric sulfate... 4 g Hydrochloric acid 20 ml Water ..... 20 ml	Structure of stainless steels	Marble's reagent
3	Hydrochloric and picric acids	Hydrochloric acid 5 ml Picric acid ..... 1 g Ethyl or methyl alcohol (95% or absolute) ..... 100 ml	For etching many steels of the iron-chromium, iron-chromium-nickel, and iron-chromium-manganese types	(Reference 2)
4	Chromic acid	Chromic acid.... 10 g Water ..... 100 ml	For austenitic steels. Attacks carbides very rapidly, austenite less rapidly and ferrite very slowly, if at all. Attacks the sigma phase more rapidly than carbides in iron-chromium base alloys	Used electrolytically (Referenee 5)
5	Heat tinting	Heat only	For identifying constituents in high-alloy steels. Carbides remain white while ferrite is darkened more rapidly than austenite.	Clean dry polished specimen, heated face up on hot plate to 1000–1400 F. for 10–60 sec. For distinguishing between austenite and ferrite, it is often useful to apply a chemical etch first.

Table III. Reagents for Revealing Segregation, Phosphides and Strain Lines

No.	Etching Reagent	Composition	Uses	Remarks
19	Cupric chloride	(A) Cupric chloride.. 1 g Magnesium chloride ..... 4 g Hydrochloric acid 1 ml Water ..... 20 ml Ethyl alcohol (absolute) .... 100 ml	For showing segregation of phosphorus or other elements in solid solution; copper tends to deposit first on areas lowest in phosphorus	Dissolve salts in least possible quantity of hot water. Etch for about 1 min, repeating if necessary. Stead's reagent.
		(B) Cupric chloride.. 5 g Hydrochloric acid 40 ml Water ..... 30 ml Ethyl alcohol.... 25 ml	To reveal strain lines, microstructure, and precipitation hardening in steel	May be used cold. Etching time, about 10 sec. Fry's reagent
20	Sodium picrate, neutral..	Sodium picrate .. 1 g Water ..... 100 ml (Wash salt well with alcohol to remove excess acid or alkali)	In cast iron, shows difference between phosphides and cementite. Iron phosphide attacked, cementite unattacked.	Use boiling. Etching time 20 min
21	Chromic acid and heat tinting	Chromic acid.... 8 g Water ..... 100 ml Followed by heat tinting.	Distinguishes between iron phosphide and cementite in phosphide eutectic of cast iron. Iron phosphide is colored darker.	Etch first in picric acid (No. 2) then for 1 min in chromic acid; heat tint by heating face up on hot plate at about 500 F for 1 min.
22	Alkaline chromate	Chromic acid .... 16 g Distilled water.. 145 ml Sodium hydroxide 80 g	Shows oxygen segregation. Darkens martensite rapidly, ferrite more slowly, and zones of high oxygen content much more slowly	Add sodium hydroxide slowly, and use when not over 1 day old by boiling at 118–120 C. for 7–20 min. (Reference 8)

Table IV. Reagents for Revealing the Structure and Depth of Case of Nitrided Steels

No.	Etching Reagent	Composition	Uses	Remarks
23	Cupric sulfate and cupric chloride	Cupric sulfate .....1.25 g Cupric chloride.....2.50 g Magnesium chloride 10 g Hydrochloric acid .. 2 ml Water ..... 100 ml Dilute above solution to 1000 ml with 95% ethyl alcohol.	For showing total depth, structure, and various zones of nitrided chromium-vanadium steels and nitralloy	Proportions must be accurate. Etch by immersion to avoid confusing edge effects.
24	Picric and nitric acids	4% picral (Reagent No. 2) 10 parts 4% nital (Reagent No. 1) 1 part	For depth of case and structure of nitralloy	Best results are obtained when specimen is annealed in lead at 1475 F before etching.
1	Nitric acid (Nital)	Nitric acid ..... 2 ml Ethyl or methyl alcohol (95% or absolute) ..... 100 ml	For structure and depth of case of nitrided steels	
18	Cupric sulfate	Cupric sulfate ..... 4 g Hydrochloric acid .. 20 ml Water ..... 20 ml	Total depth of nitrided case	Marble's reagent

Table V. Reagents for Differentiating Carbides, Nitrides and Tungstides

No.	Etching Reagent	Composition	Uses	Remarks
25	Alkaline sodium picrate	Picric acid ..... 2 g Sodium hydroxide ..... 25 g Water ..... 100 ml (Add sodium hydroxide slowly to picric acid and water.)	Colors cementite but not carbides high in chromium; in tungsten steels, iron tungstide and iron tungsten carbide are colored more rapidly than cementite, but tungsten carbide is unaffected; attacks sulfides. Delineates grain boundaries in hypereutectoid steels in slowly cooled condition	Use boiling, 5–10 min, or preferably, electrolytically at room temperature; for the latter, the specimen is the anode, cathode is stainless steel or platinum, with 6 volts about 40 sec is usually sufficient.
26	Hydrogen peroxide and sodium hydroxide	Hydrogen peroxide 10 ml Sodium hydroxide (10% solution in water ..... 20 ml	Attacks and darkens iron tungstide in carbon-free iron tungsten alloys; tungsten carbide is darkened.	Must be fresh. Etching time 10–12 min
27	Ferricyanide solution	(A) Potassium ferricyanide ... 1–4 g Potassium hydroxide .... 10 g Water ..... 100 ml (7 g of sodium hydroxide may be substituted for the potassium hydroxide.)	Differentiates between carbides and nitrides; cementite is blackened, pearlite turned brown, and massive nitrides remain unchanged.	Must be freshly made; etch 15 min. in boiling solution.
		(B) Potassium ferricyanide .. 10 g Potassium hydroxide ..... 10 g Water ..... 100 ml (7 g of sodium hydroxide may be substituted for the potassium hydroxide.)	Darkens carbide containing chromium, carbides and tungstides in tungsten and high speed steels. At room temperature colors ternary carbide (Fe_3W_2C or Fe_4W_2C) in a few seconds, iron tungstide (Fe_3W_2) in several minutes, and barely colors cementite	May be used cold, but preferably hot, should be freshly made, etching time 5–10 min. Murakami's reagent

(*continued*)

Table V. (continued)

No.	Etching Reagent	Composition	Uses	Remarks
28	Sodium cyanide	Sodium cyanide.. 10 g Water ..... 90 ml	Darkens carbides without attacking austenite or grain boundaries	Used electrolytically, the specimen as anode, cathode, similar material, about 1 in. apart; 6 volts (not less than 5). Etching time 5 min or more. (Reference 9)
29	Potassium permanganate.	Potassium permanganate .. 4 g Sodium hydroxide 1-4 g Water ..... 100 ml	For high speed steels, and alloys high in chromium or cobalt. Causes a differential attack on carbides and tungstides	Use boiling 1–10 min. (Reference 10)
4	Chromic acid	Chromic acid .... 10 g Water ..... 100 ml	Attacks carbides in stainless steels very rapidly, austenite less rapidly, and ferrite very slowly if at all. For various structures of stainless steels	See solution No. 4 in Table I.
9	Oxalic acid	Oxalic acid ..... 10 g Water ..... 100 ml	To reveal carbides in stainless steels	See No. 9 in Table II. If strongly etched, general structure is revealed; therefore for study of carbides reduced voltage is used for etching, giving better control of etch.

The Spark Testing of Steel

By W. G. Hildorf* and C. H. McCollam*

THE spark test is a method for the classification of steels according to their chemical composition, by visual examination of the sparks that are thrown off when the steels are held against a high-speed grinding wheel. The test is valuable as a safeguard against the accidental mixing of steels of different compositions, or as a method for separating steels known to be mixed. Spark testing is fast, convenient, economical and, when applied with proper regard for its limitations, reliable and accurate.

Spark testing is essentially a method for the separation of steels that have different compositions. It is not a substitute for chemical analysis, and is not intended for the identification of "unknown" samples. The character of sparks should be similar when spark streams are examined from a number of specimens supposedly of the same material. If one or more of the specimens exhibits a spark stream of different character, the presence of "foreign" material is indicated. Chemical analysis can be used for positive identification in such instances.

One of the advantages of the spark test is that it can be applied to steels in virtually all stages of production, as billets, as bar stock in the racks, as partly machined forgings, or frequently even as finished parts. Because spark testing is performed directly on the pieces themselves, expensive sampling methods are avoided, along with attendant possibilities of mix-ups in numbering and handling. Small pieces of mixed material that could not be sampled, even if the cost of analysis were not prohibitive, are frequently salvaged quite economically by the spark test.

Theory. When a piece of steel is held in contact with a moving abrasive wheel, small particles of the metal are torn loose. With a high-speed wheel, this tearing process is so rapid that the temperature of the particles is raised to incandescence. As the particles are hurled through the air, the trajectory is quite easily followed, particularly against a dark background. This trajectory is called a "carrier line". If the metal is either ingot iron or wrought iron, the result is a small sheaf of single lines, termed a "spark picture". If a piece of carbon steel of about 0.20% C is held in contact with the wheel, a lightening of the color of the line will be noted, as well as a number of short single "forks" or "primary bursts", caused by the presence of carbon (Fig. 1).

While a spark is incandescent and in contact with the oxygen of the air, the carbon present in the particle is burned to carbon dioxide. The transition of solid carbon to gaseous carbon dioxide is accompanied by an increase in volume. Although the particle of hot steel is plastic, it offers resistance to this volume increase, thus building up an internal pressure that is relieved only by an explosion of the particle. There are some observations to support this explanation of the bursts. For instance, the examination of the small steel particles when they are cold, reveals in the residue numerous hollow spheres with one end completely blown away. The relation of carbon content to the frequency of bursts also marks carbon as the element responsible for the forking of the carrier line. A 0.20% C steel exhibits a slight forking effect (Fig. 1); a 0.40% C steel, a pronounced burst (Fig. 2); and steel that contains about 1.00% C, a minute explosion (Fig. 3). Moreover, greater intensity of bursting is noticed as the carbon content of the steel is increased.

Examination of the Spark Stream. The technique of the visual examination of the spark stream is quite important. When this technique is properly learned, variations in the stream become more readily distinguishable.

Wheel Pressure for Spark Testing. When using the spark cabinet, which will be described later, the operator should hold the pieces on the wheel in such a manner as to throw the spark stream about 12 in. horizontally and at a right angle to his line of vision. At this point, it is well to spend a little time in determining precisely the pressure required for maintaining a stream about 12 in. long, without reducing the speed for most efficient performance of the wheel. Wheel pressure is important, whether the piece is held against the wheel, as in cabinet work, or the wheel against the piece, because increasing the pressure will raise the temperature of the spark stream and bursts, and will give the appearance, to the inexperienced eye, of a higher carbon content. Experience will dictate later, to the trained spark tester, the length and volume of the spark stream required for the various steels that will be encountered.

* Chief Metallurgist, Western Division and * General Manager of Sales, Steel and Tube Division, The Timken Roller Bearing Company

When the optimum wheel pressure has been determined, it is suggested, for the introductory tests, that the operator select two steels of widely different carbon content, preferably plain carbon steels. An SAE 1020 and 1050 (or a steel of higher carbon content) will be satisfactory. First one and then the other should be held against the wheel. The operator should always be careful to strike the same portion of the wheel with each piece. When the eyes of the operator are focused on a point about one-third of the distance from the tail end of the stream, and are watching only the sparks that cross the line of vision, he will find that after a short while a mental image of the individual spark will be formed. As soon as an operator can fix spark images in this manner, he is prepared to examine the character of the "spark picture".

Sections of Sparks. The entire sheaf of sparks may be divided into three equal sections: (1) the wheel sparks, which are the third of the stream nearest the wheel; (2) the center area; and (3) the tail sparks, which represent the third of the stream farthest from the wheel.

The components to be observed are the carrier lines, the spark bursts and the "characteristic sparks". The carrier lines will vary in length, breadth, color and number. The spark bursts will vary in intensity, size, number, shape, and distance from the wheel or from the end of the carrier lines. Carrier lines are the incandescent streaks that trace the trajectory of every glowing particle. They are discussed more fully in connection with the characteristic sparks to which they are closely related.

The Spark Burst. The spark burst, that is, the "carbon spark", is the most useful characteristic of the spark picture, since the variations in the number and intensity of the bursts indicate the changes in the carbon content. Steels that have the same carbon content but different amounts of alloying elements are not always so easily identified; most of the alloying elements have some influence on the spark picture. They may affect the carrier lines, the bursts, or the form of characteristic sparks. Their effect may be, for example, to retard or to accelerate the carbon spark, or to make the carrier line lighter or darker.

Effect of Molybdenum. One of the most easily recognized of all the characteristic sparks is that of molybdenum, which appears as an orange-colored spearhead on the end of every carrier line. Other features of the molybdenum spark are that the spearheads are detached from the carrier lines, and that they are always present, regardless of the length of the lines (Fig. 4). Sometimes, when the carbon content is high, the spearhead is difficult to distinguish; but if a decarburized surface can be found, the characteristic spark immediately becomes quite distinct. Low-carbon high-sulfur screw stock will generally show a spearhead at the end of the carrier line; however, with practice, this grade can be distinguished from the molybdenum steels with little difficulty.

Effect of Nickel. Nickel gives a characteristic spark identified by tiny blocks of brilliant white light. This characteristic spark from nickel steel may be the result of the suppressing effect of nickel on the carbon burst. In low-carbon steels (0.10 to 0.20% C and 3.5 to 5% Ni) these blocks are located in the spark stream quite near the wheel, but in higher-carbon steels they are located in the burst. When present with molybdenum, nickel partly suppresses the carbon spark, and the nickel spark is in turn suppressed in the 4600-series steels. The chemical spot-test method is generally used for distinguishing among various nickel contents because of inherent difficulties in spark testing for this element.

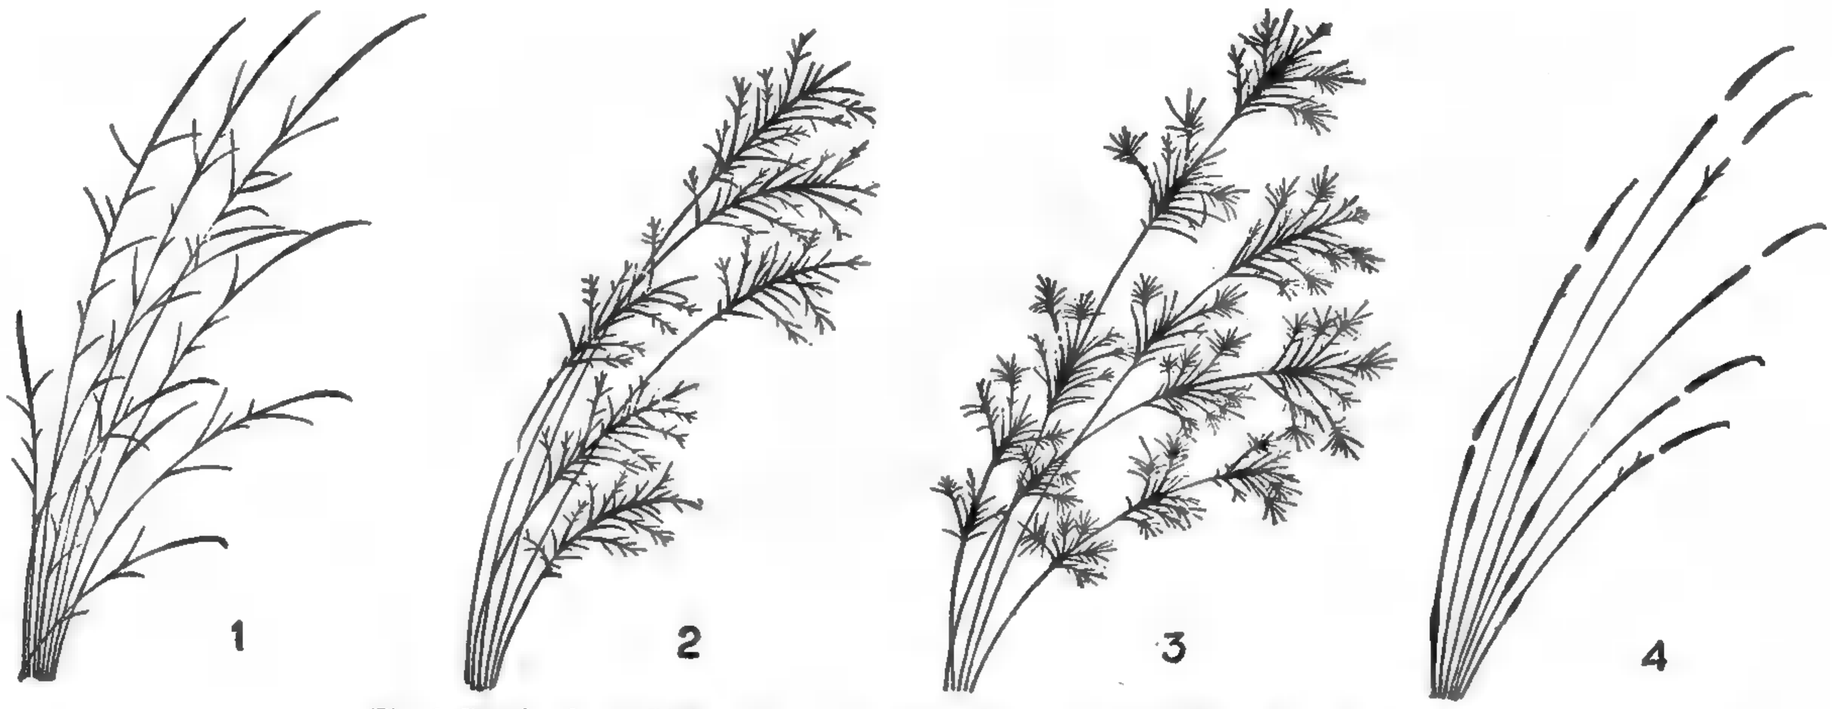

Fig. 1 Sparks from SAE 1015 steel (0.15% C), showing simple "forking effect"
Fig. 2 Sparks from SAE 1045 steel (0.45% C), showing "secondary burst"
Fig. 3 Sparks from SAE 1095 steel (1.0% C), showing the intensity of bursts that is characteristic of high-carbon steel
Fig. 4 Sparks from SAE 4615 steel (0.15% C, 1.75% Ni, 0.25% Mo), showing a detached "spearhead" that is characteristic of molybdenum, and the swelling in the spark line indicating nickel with molybdenum

Effect of Silicon. Silicon suppresses the carbon spark to a more marked degree. The carrier line from silicon steels of the SAE 9200 series is much shorter than from a plain carbon steel of the same carbon content, and usually ends abruptly in a white flash of light.

Effect of Tungsten. The spark streams for 18-4-1 and molybdenum high speed steels, as shown in Fig. 5 and 6, were prepared by J. V. Emmons. He states: "18-4-2 high speed steel sparks the same as the 18-4-1 type. With light wheel pressure, 4% W steel is similar in appearance to 18-4-1, but with heavy pressure the 4% grade shows an occasional secondary burst not found in the 18% W type. Observations are based on a 9-in. Alundum wheel, grade 46M, 1750 rpm."

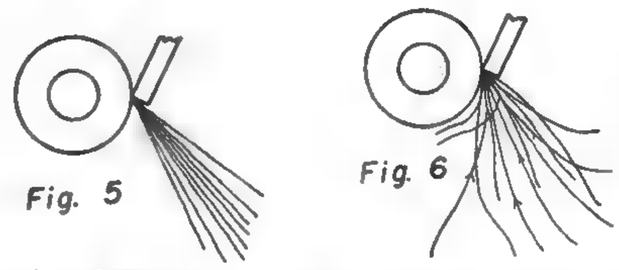

Fig. 5 Sparks from 18-4-1 high speed steel. Red color with numerous red lines
Fig. 6 Sparks from molybdenum high speed steel. Red and orange. Numerous orange spearheads have a few primary bursts.

Equipment for the Spark Test. *The Spark Cabinet.* A cabinet makes possible the examination of spark streams under ideal conditions. It is convenient both in training men for spark testing and in examining spark streams from steels that have spark characteristics still unknown to the operator.

A substantial wooden cabinet, about 40 in. long, 36 in. wide and 36 in. deep, will be suitable for this purpose. The cabinet should be placed on a bench or table at a

height convenient for the operator. The inside should be stained a flat black and should be equipped for artificial illumination. The spark cabinet should be located where no direct light will strike either the operator's eyes or the inside of the cabinet. The grinder may be mounted in the left front of the cabinet, and should throw a spark stream across the front of the cabinet at right angles to the operator's line of vision.

The Grinder. If the spark stream is to be satisfactory for examination, a grinder for spark testing should have a peripheral wheel speed of not less than 4500 fpm.

If parts in production are to be lightly ground, the grinding wheels should be of small diameter. Since the operator should not be handicapped by unnecessary fatigue, the weight, bulk and balance of the grinder are important considerations. Portable grinding equipment, with approximately 7 lb of well-distributed weight, has been found very satisfactory. The shaft bearings should be readily replaceable.

The grinding wheels should be rather coarse, very hard and approximately 1¼ by ⅜ by ¼ in. in size. Norton's wheel No. A 46-PV is suggested for general use, including testing of hard steels, and A 46-SV for soft steels.*

Spark-Test Goggles. Protection of eyes during spark testing is very important, both to avoid injury from steel and abrasive particles and to minimize the effects of certain light rays. Several optical companies have developed goggles that satisfy these requirements of spark testing.

Standard Spark-Test Specimens. Standard specimens can be prepared from bar steel. A convenient size is 1 in. in diam by 3 in. long. One end should be stamped with the identification marking of the steel, and a specimen number. Chemical compositions of these specimens should be kept for reference. Specimens should cover as wide a range of chemical compositions as possible, to permit the operator to familiarize himself with the manner in which the character of sparks is affected by various carbon contents and alloying elements.

For training purposes, a dozen or more specimens should be cut from bars of the materials with which the spark tester will have occasion to do most of his work. For example, if experience in identifying the molybdenum spark is desired, 12 pieces of SAE 1020 steel, 1 in. in diam, stamped **1**, and 12 pieces of SAE 4615 steel of like size and appearance, stamped 2, will provide the standard specimens necessary. These specimens are consulted only as a means of verifying the correctness of the classification of the "unknown" samples.

Spark-Testing Personnel. Personnel for spark testing should be selected with care. It is advisable to select a man whose eyes are sensitive to light and who has a fair knowledge of the compositions of various steels.

If a spark tester possesses the necessary physical and mental attributes, his efficiency should develop with experience in the examination of sparks. The more rapidly that experience is acquired, the sooner he will be available for duty.

Strict supervision of spark-testing work is advisable. The spark tester should be held at his highest possible efficiency. It should be understood by each operator that his work must be 100%, that not a single piece of foreign steel can be passed in error. Occasional decisions must be made as to when the spark test can be used safely, and also when it must not be used. The reputation of the spark test for reliability depends largely on the wisdom of such decisions.

Plant Spark Testing. Proper lighting conditions are necessary for satisfactory spark testing. Strong direct light, either natural or artificial, is a distinct disadvantage. Spark testing should be done in a shadow, and against a dark background.

It is advisable to protect the spark stream from heavy drafts of air, since this will cause a decided hooking of the tail sparks, which may be confusing.

Bar and tube stock, carefully racked, can frequently be spark tested without removal from the racks. Similar material in bundles can be spread out on inspection benches; small pieces of regular size and shape are generally placed on work benches. If a large number of pieces must be tested in a limited time, laborers can be used to arrange the parts in uniform rows for the spark tester, so that his time can be applied entirely to examination of sparks.

In tests of hot rolled or heavily scaled material, care must be used to make certain that the spark stream is not from a decarburized area. Bar stock is more safely ground on the cut end, and forgings are ground preferably at the point from which the tong-hold was removed.

Austenitic Grain Size in Steel

By E. C. Bain* and J. R. Vilella†

PROBABLY no other subject relating to the heat treatment of steel received more attention at one time than did austenitic grain size. This interest in grain size developed in response to the need for a better understanding of those subtle but important factors of steel quality that cannot be explained by the composition of the steel as ordinarily reported in the usual analysis. In brief, the explanation was found to lie largely in the grain size of the austenite, established during the final heating above the transformation range. The *extra-analytical* properties finally secured depend largely on the actual grain size of the austenite that transforms to set up the microscopic structure existing in heat treated steels as tested and used. Once the trends of austenitic grain growth in steel were understood, it was apparent that a clear-cut, positive correlation existed between properties or behavior and the austenitic grain size established in the final heating. This relationship seems not to exist between the securable properties and any grain size that might have been established at some other temperature, or with some treatment not used in the final heat treatment that is responsible for the properties. This reasonable circumstance was seemingly overlooked for a time, perhaps because of a lack of confidence in means of ascertaining quickly the austenitic grain size of any specimen of steel about to be quenched in any suitable manner. Yet this is the grain size that would be expected to have a direct, rather than fortuitous, significance. Throughout this article, *grain size* will always mean the actual austenitic grain size established at elevated temperature in an indicated significant heating.

†Metallurgist, United States Steel Corporation Research Laboratories, Kearny, N. J.

The pioneer contributions to this advance in the technology of heat treated steels, both in manufacture and in use, came from several sources. In Sweden the study[1] progressed as an inquiry into the characteristic attributes, particularly of acid open hearth tool steel. Another approach[2] was that which related to the hardenability of comparatively low-alloy, low-carbon, carburizing steels quenched directly from the carburizing box. A more advanced development[3] of this subject, on the part of manufacturer and user, was that of carbon tool steels of controlled hardenability (and toughness) produced without significant changes in composition, and the subsequent extension of these achievements to the steels of greater tonnage. All these studies converge, building a simple concept of grain-size effects and the purpose of this article is to set forth this simplification as applied to medium- and high-carbon and low-alloy steels that are heat treated.

The Usefulness of the Older Observations. It has been known for decades that a coarse fracture of a hardened and broken piece of steel accompanies excessive brittleness, and that equally hardened steel which requires greater effort in breaking, exhibits a finer, "silky" fracture. The many individual facets of the broken surface are large in the first instance and small in the second. With what the size of the individual facets is related, and on what this corresponding coarseness or fineness depends, was not

Table I

Effects of Previously Existing Austenitic Grain Size

Property	Trends in Heat Treated Steel Products: From Coarse-Grained Austenite (No. 5 and Above)	From Fine-Grained Austenite (Finer than No. 5, 5 to 8)
Hardenability	Deeper hardening	Shallower hardening
Toughness at same hardness	Less tough	Tougher
Distortion	More distortion	Less distortion
Quenching cracks	More prevalent	Usually absent
Grinding cracks	More susceptible	Less susceptible
Residual stress	Higher	Lower
Retained austenite	More	Less
For Annealed and Normalized Products		
Machinability	(Rough) better	(Rough) inferior
Machinability (special cases)	(Fine finish) inferior	(Fine finish) better
Formability (special cases)	Superior	Inferior

obvious, however, and was not understood until more recently. Another observation was probably made long ago; similar steels, in sections too large to be hardened throughout, harden more deeply, in a given medium, whenever the fracture appearance is coarse, and less deeply when the fracture is fine. Some twenty-five years ago certain manufacturers were introducing an alloying element to preserve the fine fracture and its attendant toughness, and were adding extra manganese to restore the deeper hardening characteristics. When a single bar or heat of steel was under consideration, it was observed long ago that high heating temperatures, as in the Metcalf test, induced the deeper hardening and the attendant coarser fracture, but any cause-and-effect relationship between coarseness and depth of hardness penetration in the quenched piece was not specifically mentioned until more recently. Indeed it was erroneously supposed by some that the quenching rate in any medium was accelerated if the steel was quenched from a higher temperature. This is now known to be untrue[4] in any general sense. Since steels of almost identical composition (as far as ordinary chemical analysis is concerned) are available, each of which will develop its own particular grain size at a certain temperature, grain-size variation may be studied independent of the heating temperature, which may thus be the same for all. When interest centers in a particular steel, then heating temperature or heating schedule is varied to produce the grain-size contrast. By the use of both methods of grain-size control, the broad effects have become familiar.[5] In a general way the effects of the previously existing austenitic grain size can be summed up in Table I.

The Formation and Growth of Austenite Grains. When a piece of carbon or low-alloy steel is heated above the so-called critical point, the ferrite and carbide react with each other to form austenite. The austenite is a crystalline phase differing distinctly from both the carbide and ferrite of which the steels under consideration are inevitably composed. Like any metal composed of a solid solution, austenite exists in the form of polyhedral grains. This reaction begins at a number of points, in the interface of the carbide (particles or plates) and the ferrite. In each such growing particle of newly formed austenite, carbon and iron and other elements from the carbide particles are dissolved, as well as iron and other elements from the ferrite. Each little island of austenite grows until finally it reaches its similarly growing neighbors.[6] In an ideally simplified formation there would be just as many grains of austenite as there were separate original nuclei, and this is nearly realized in a fairly coarsely spheroidized steel. In actuality, some of the islands of austenite grow more rapidly than others; therefore, when a large grain encounters a small one, the small one is forced to shift its orientation, layer by layer, thus losing its identity while being absorbed into the larger grain. Probably this happens frequently in certain steels and rarely in others. Now if the steel is far from eutectoid in composition and is heated below the Ac_3 or Ac_{cm} temperature, some islands of ferrite or cementite will remain unabsorbed regardless of the period of heating. These undissolved proeutectoid constituents appear to block grain growth so that this initial set of austenite grains is preserved even after long heating. When the temperature of heating is above Ac_3 or Ac_{cm}, any ferrite usually disappears quickly enough, but the carbide, although ultimately soluble, dissolves rather slowly so that, depending on its coarseness, more or less of the carbide persists even after surprisingly long intervals of time. It is important to note here that the first grain size of the austenite depends largely on the number of nuclei and that as long as any moderate amount of carbide remains these grains do not change greatly.

In pearlitic steels the effective nuclei are often located in the interior of a region of lamellae; in spheroidized steel each spheroid of carbide is a potential nucleus. When the spheroidization is fine, many such nuclei are ineffective because of the mechanism mentioned above. However, at ordinary quenching temperatures the original pattern of austenitic grain size is largely retained; this is termed the "uncoarsened grain size" to which almost all practical heat treating of carbon steel relates. The number of nuclei seems to depend on the following factors:

1 Previous mechanical and heat treatment, as it affects
   (*a*) Distribution of carbide, lamellar or spheroidal; that is, the structure
   (*b*) Fineness of carbide dispersion
   (*c*) Homogeneity of steel
   (*d*) State of stress or deformation
2 Composition of ferrite and carbide
3 Nonmetallic inclusions
   (*a*) Submicroscopic
   (*b*) Microscopic

Subsequent changes in the grain size of the austenite occur when heating reaches toward and beyond the normalizing range of temperature. Many steels not made in a way to restrict grain growth begin to undergo mild coarsening about as soon as the major part of the carbide (or ferrite) is dissolved. With rising temperature, such steels appear to coarsen rather regularly without any abrupt changes, presumably by the successive coalescence, here and there, of two or sometimes three grains to form one new grain. There is no marked disparity of grain size at any point. When a special, less soluble carbide exists, as for example in vanadium steels, the carbide particles persist to high temperatures such as 1750 to 1800 F, and little grain growth occurs as long as many such vanadium-rich carbide particles remain.

In similar manner certain nonmetallic substances appear to accomplish this same inhibition to grain growth. This broad effect of inert particles has long been known in the manufacture of tungsten filament wire, in which the extremely inert and refractory oxide of thorium present as visible particles, at least in part, acts as the grain-growth inhibitor.

An interesting effect of these so-called "grain-growth inhibitors" is that when they finally become ineffective at some elevated temperature, as a result either of solution or of coalescence, or by mere inefficacy or insufficiency, the amount of grain growth is then likely to be greater than in a steel free from such restraint. Such steels retain a fine grain almost unchanged during heating at successively higher temperatures until abruptly, here and there, a single large grain forms from as many as 100 or more former small grains. Prolonged heating, or a rise in temperature, will ordinarily convert the remaining fine grains to the same type of large grain as first formed upon reaching the coarsening temperature. Inhomogeneities of the steel tend to broaden the temperature range of two distinct grain sizes. This state of affairs in the range of marked grain growth is sometimes spoken of as "duplexing". It has no special significance, merely marking a natural transition stage from fine to coarse grains, when the change is large, fairly abrupt and unfinished.

It should be remembered that the persistence of carbide and attendant retention of small grains is often a matter not of equilibrium but of rate of solution, and carbide frequently remains undissolved for 30 min or more in eutectoid or even hypoeutectoid steel heated well into the austenite temperature range (above Ae_3).

Determination of Austenitic Grain Size

The grain size established in austenite at various temperatures has been discussed above in a qualitative or comparative way. It now becomes necessary to go into greater detail and to choose some quantitative basis for estimating grain size. Grains are solid bodies, and to be entirely correct one should speak of an average grain size in terms of volume, such as fractions of a cubic inch or a cubic millimeter; or one could better use the reciprocal, a certain number of grains per cubic inch or cubic millimeter. Actually, this is unnecessary and probably confusing. Estimation of grain size or grain counting is finally accomplished by viewing a polished *plane* section under the microscope; the boundaries of the grains as viewed lay out a network on a *plane* surface. The number of grains per unit area so sectioned on a plane, or the average area of these rough polygons, serves as well, as a measure of grain size, as would a number based on three dimensions or volume. It is possible to consider the grains as solid bodies while reporting in terms of their mean sections on a representative plane. The actual units employed in such estimates of grain size are not uniform for different metals in different countries. The common terms for reporting grain size are:

1 Grains per sq mm
2 Average area of grain (in sq mm)
3 Mean diameter of grain (in mm)
4 Arbitrary numbers (exponential), Timken, ASTM, index based on the formula Number of grains per sq in. at × 100 = 2^{N-1}, in which the index of grain size = N

The designation "mean diameter" (3) is fortunately not much used, since it is not easily estimated directly and, as a derived number, is ambiguous and less useful than the direct observation. Any scheme showing number of grains per unit area (either of specimen or microscopic image at known magnification) is vastly preferable.

In America, virtually all studies and specifications of austenitic grain size refer to the Timken, ASTM index numbers. For convenience they are tabulated with corresponding dimensions in Table II, and extended somewhat beyond the usual range employed. In Table II, the last column, headed "Grain Boundary Area, sq mm per cu mm", shows the minimum possible interface area. The effective intergranular surface will be greater, particularly in the finer grain sizes, because of the surfaces of undissolved carbide particles and because of irregularities in the boundaries of austenite grains.

It is often desirable to match the microscopic image discussed below with the standard network charts, such as are included herewith (Fig. 1 to 8), using a magnification either lower or higher than ×100, respectively, for coarse or fine grains. These rules apply:

For × 50, report ■ numbers lower than matching chart.
For × 200, report 2 numbers higher than matching chart.
For ×400, report 4 numbers higher than matching chart.
For × 800, report 6 numbers higher than matching chart.

Idealized grain boundaries in a hypothetical hexagonal network are shown in Fig. 1 to 8 for the corresponding ASTM grain sizes as tabulated in Table II. These are probably the best standards for general comparison and estimation of grain size.

Preparation and Microscopic Examination of Specimens for Grain-Size Rating. Thus far it has been assumed that the grains could be rendered clearly visible in a microscopic specimen and an estimate of their size arrived at either by counting over a known area of image at known magnification, or by comparing such images on the ground glass of the microscope with charts that have standard graded patterns of grain size marked out. In general, this is easily done, especially for grain sizes No. 6 or coarser. For finer grain sizes counting or comparing is more time-consuming but never impossible. In principle, the problem of determining grain size of austenite is rendered more complex than in brass, for example, because it is necessary to estimate the grain size of a constituent which is no longer present. If it were possible to examine under a microscope the heated steel ready to be quenched, this complication would not arise, but such technique is not practical. Fortunately, austenite transforms in such a way as to reveal the former grain boundaries unequivocally. This comes about because:

1 Proeutectoid rejections in either hypereutectoid or hypoeutectoid steels can usually be forced to the grain boundaries to form a complete, or nearly complete, network.
2 Transformation reactions, even in eutectoid steel, begin dominantly in the grain boundaries and may be interrupted when a network is developed.
3 Martensite has limits of orientation that depend on the orientation of the parent austenite grain and hence can, with suitable agents, be etched much like a pure metal to develop contrast among grains.

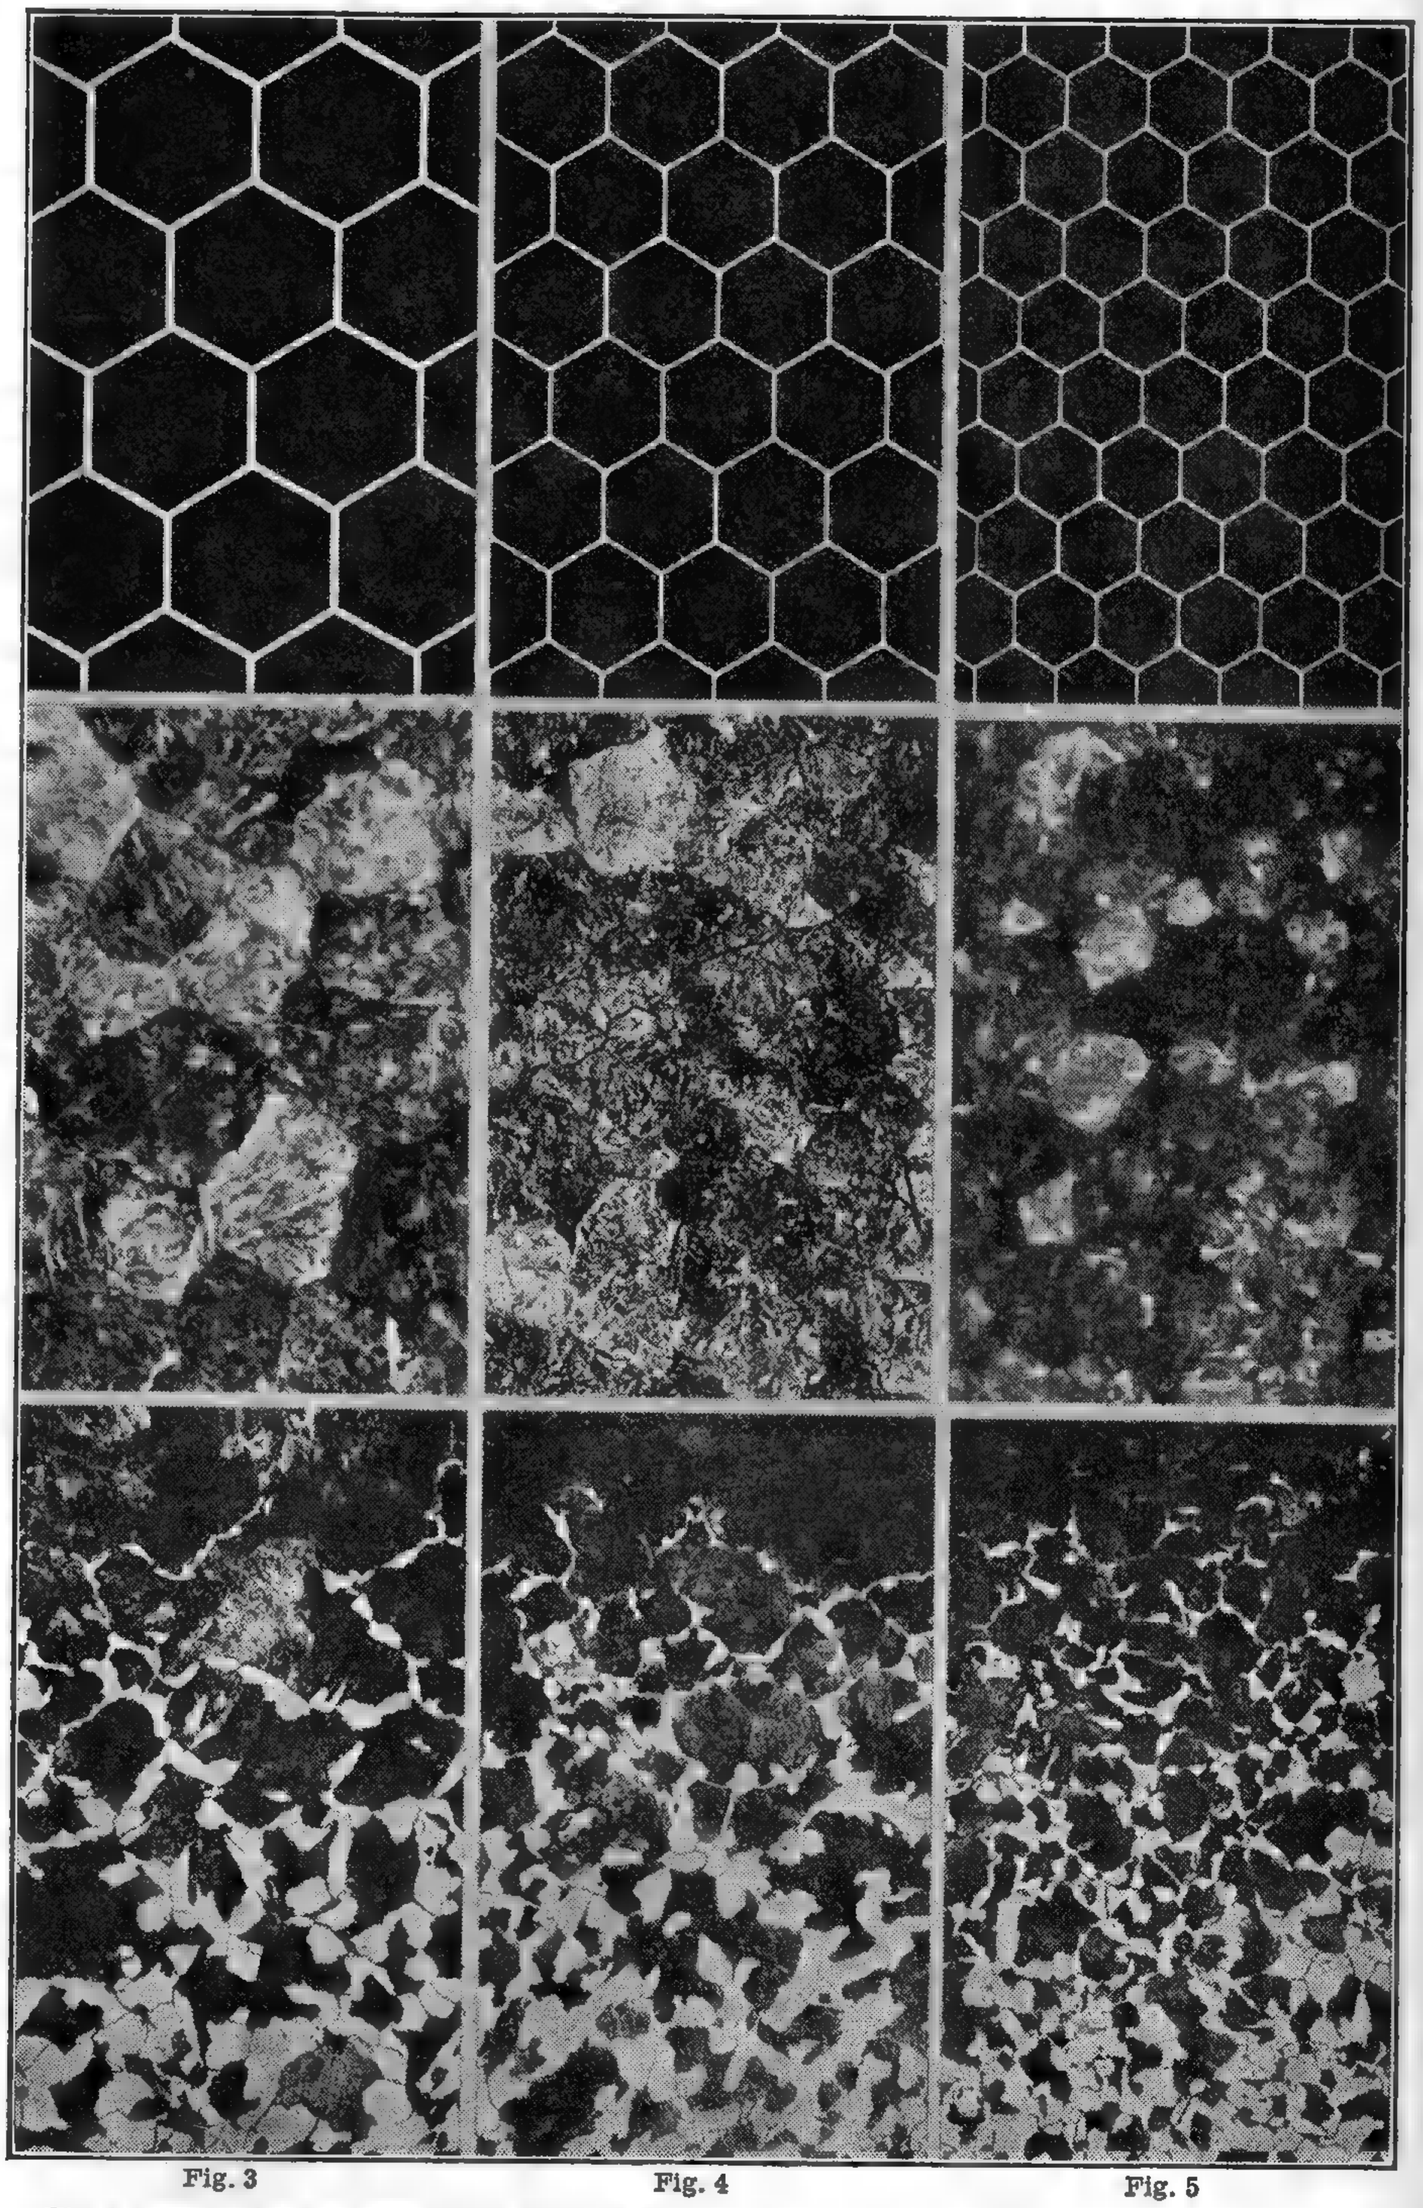

Fig. 3 Fig. 4 Fig. 5

Fig. 3 *Upper*, idealized hexagonal network for mean grain size 3, ASTM scale. *Center*, austenitic grain size 3, that is, 3 to 6 grains per sq in. of image at × 100 as revealed in quenched and lightly tempered structure. Etched with Vilella's martensite reagent. *Lower*, from ASTM specification E 19-33, hypoeutectoid structure in carburized steel (8 hr at 1700 F) having 3 to 6 grains per sq in. at × 100.

Fig. 4 *Upper*, same as Fig. 3, but for mean grain size 4. *Center and lower*, same as Fig. 3, but for 6 to 12 grains per sq in.

Fig. 5 *Upper*, same as Fig. 3 and 4, but for mean grain size 5. *Center and lower*, same as Fig. 3 and 4, but for 12 to 24 grains per ■ in.

In some respects it is advantageous that the grain size of austenite is estimated on the basis of its decomposition products and not of the constituent itself, for this circumstance permits outlining the grain boundaries with constituents that may have great visual contrast with the main portion of the grains. Even under the worst conditions the problem, however unique, is not more difficult than for brass or other single-constituent metals. It happens that while cooling slowly through the transformation range, carbon or low-alloy steels with a carbon content somewhat remote from the eutectoid (that is, distinctly hypoeutectoid or hypereutectoid) reject either ferrite or carbide, respectively; the rejection of these proeutectoid constituents occurs largely at the grain boundaries, after which the remainder of the austenite transforms to a black-etching pearlite. The transformation of eutectoid austenite, beginning characteristically in the grain boundaries, makes possible the formation of some fine pearlite (nodular troostite) in the grain boundaries, after which the remainder of the austenite may be caused to transform to light-etching martensite. Thus eutectoid steels, from which no separate boundary constituent can be rejected, may have the grain boundaries clearly outlined. It is obviously of no consequence which is darker, the boundary or the interior body of the grain.

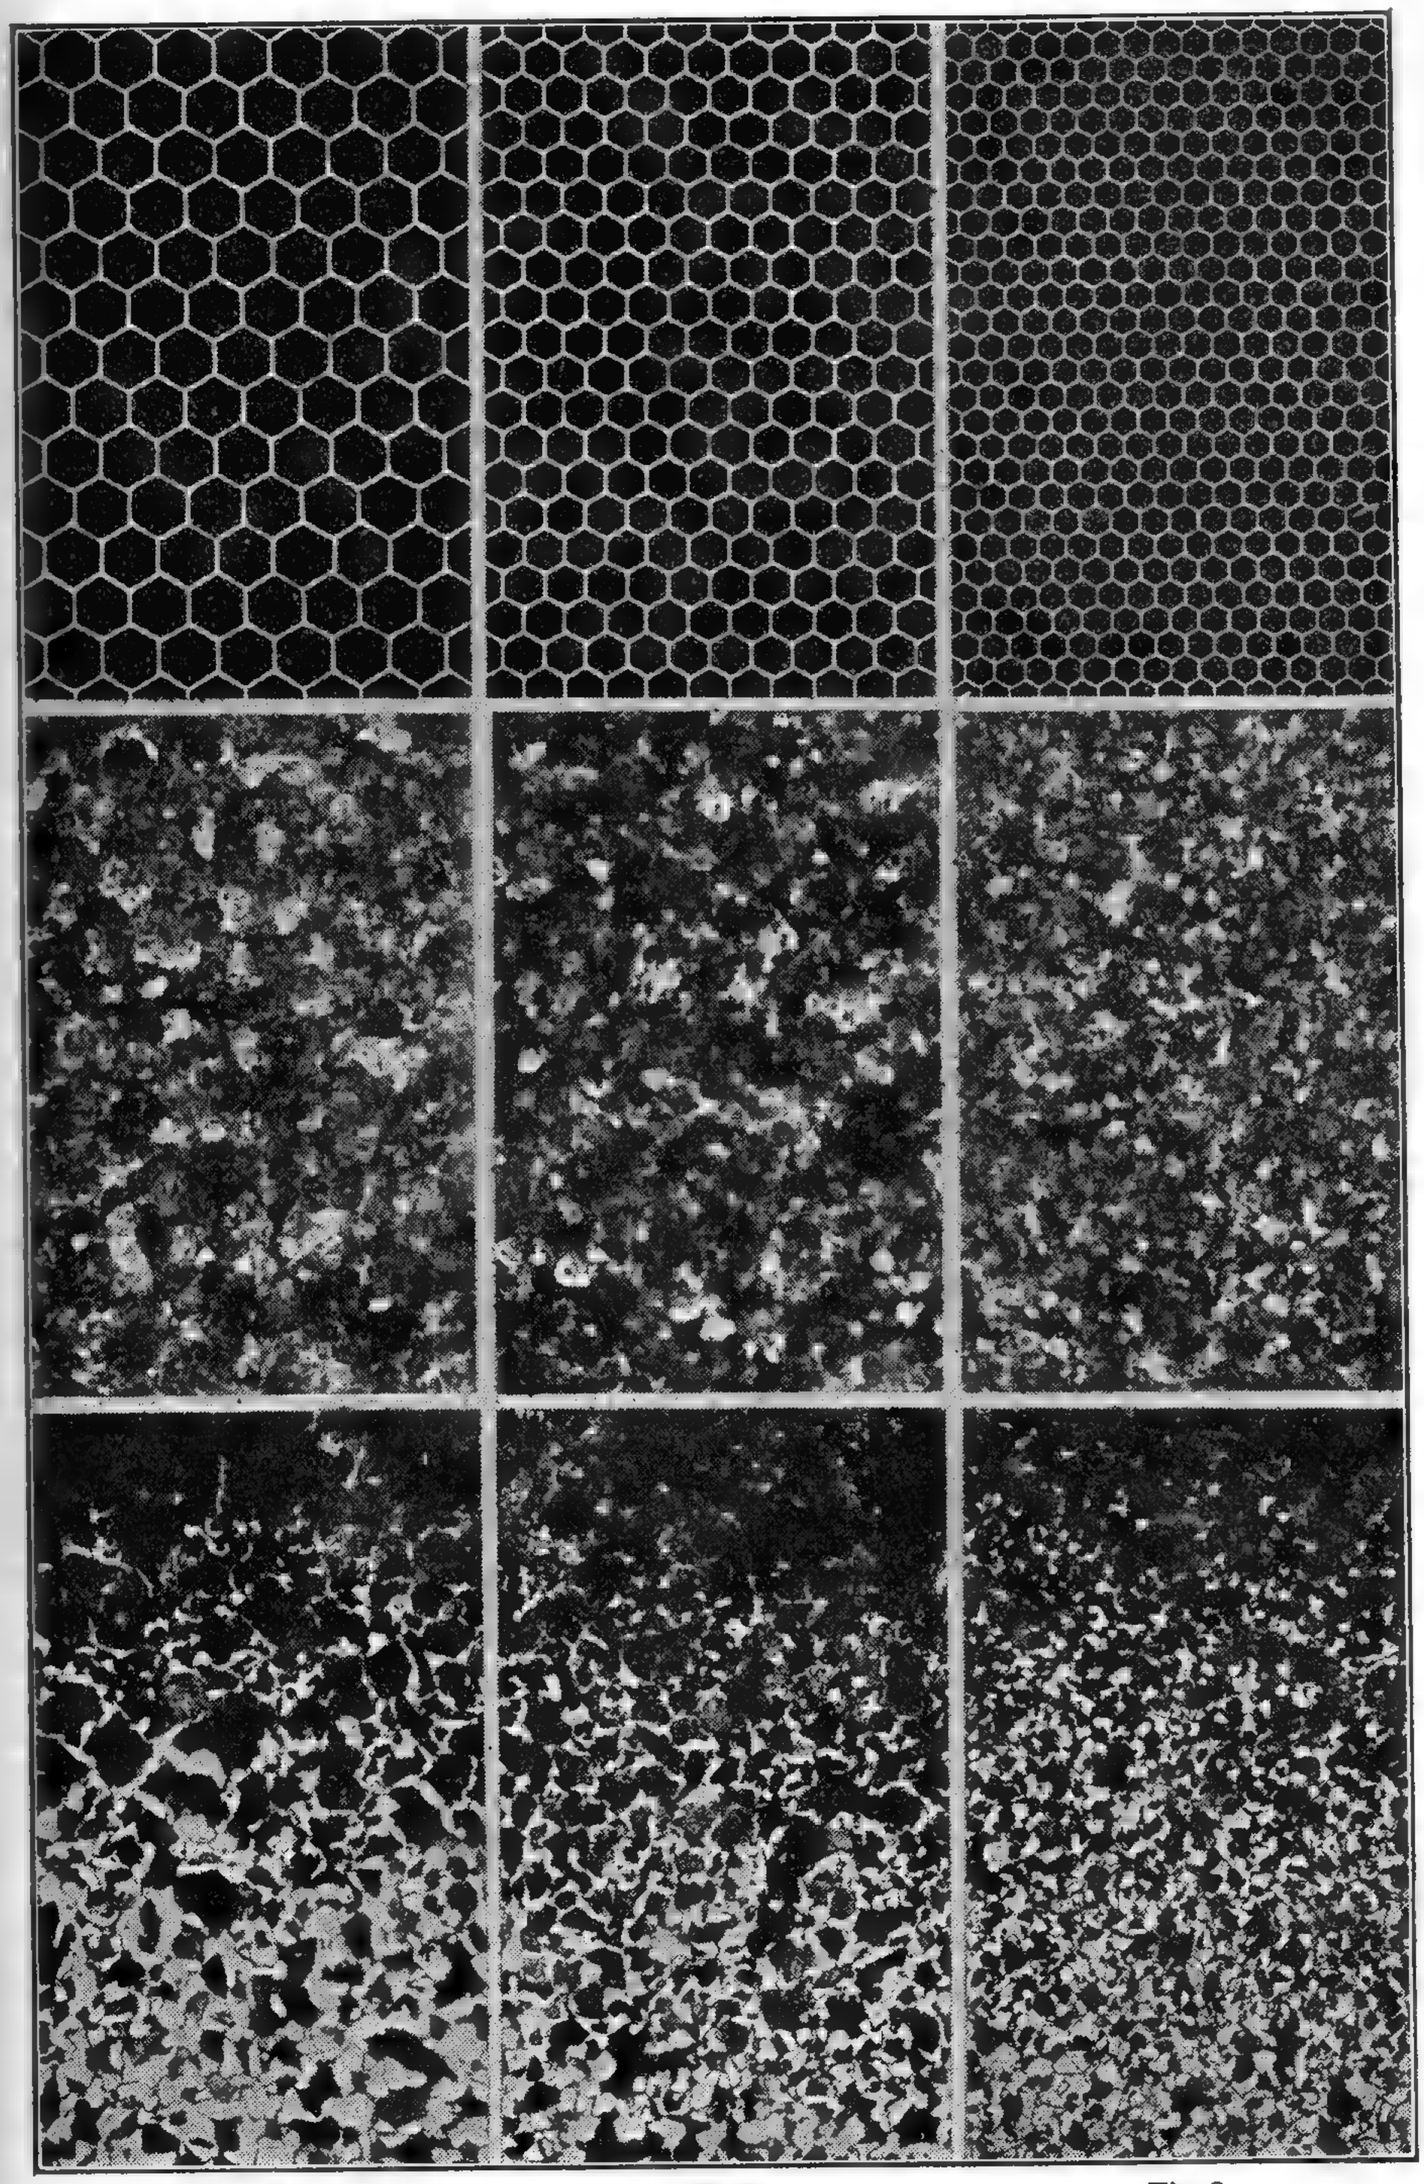

Fig. 6 Fig. 7 Fig. 8

Fig. 6 *Upper,* idealized hexagonal network for mean grain size 6, ASTM scale. *Center,* austenitic grain size 6, that is, 24 to 48 grains per sq in. of image at × 100 as revealed in quenched and lightly tempered structure. Etched with Vilella's martensite reagent. *Lower,* from ASTM Specification E 19-33, hypoeutectoid structure in carburized steel (8 hr at 1700 F) with 24 to 48 grains per sq in. at × 100.

Fig. 7 *Upper,* same as Fig. 6, but for mean grain size 7. *Center and lower,* same as Fig. 6, but for 48 to 96 grains per sq in.

Fig. 8 *Upper,* same as Fig. 6 and 7, but for mean grain size 8. *Center and lower,* same as Fig 6 and 7, but for 96 grains or more per sq in.

Any sample of steel heated at any temperature, depending on carbon content, above Ac_3, Ac_1 or Ac_{cm}, is made of austenite (in which carbide may be present or not), composed of grains, and an interest may exist in the size of those grains; the foregoing paragraph shows how it is always possible to learn what this grain size is. Often the steel may be normalized in handling; then it will be the high-temperature austenitic grain size in which interest centers. If so, it is possible either to simulate the normalizing treatment in a small laboratory furnace, thus establishing the grain size in question, or to carry a piece along in the commercial furnace. The grain size is established at the conclusion of either type of heating and the only problem thereafter lies in cooling the specimen in a manner that will make the grain size clearly readable under the microscope. More often the interest lies in the grain size in the steel as heated for the final quench (water, oil, or air). Only the austenitic grain size actually established in the particular heat treatment under consideration can be correlated with the steel properties to be secured. The austenite grain size is not affected in any way by the kind of cooling applied; however, a specimen selected from the heating furnace for examination should be cooled so that the grain size will be made apparent.

For example, if a steel is desired which will not coarsen beyond a No. 5 grain size, and the customary austenitizing temperature is from 1475 to 1500 F, then it is advisable to cut a specimen of dimensions suitable for the application and to heat it, either along with a commercial batch or in a small furnace for the same period, and then to cool it, as indicated below, in a way that will give the best

delineation of grain size. If the steel is normalized or homogenized prior to such heating for hardening, then this treatment should preferably precede the heating for test. To take care of possible furnace irregularities, some prefer to heat to a temperature 50 F or even 100 F higher than the commercial schedule, assuming that if a steel does not coarsen at 1550 F, it certainly will not do so at 1475 F, a conclusion that is generally true. Testing at much higher temperatures than those employed in practice is not helpful in the study of grain size, because the test then departs too far from the conditions in which interest centers and valuable information is lost.

Another example might be cited in which a certain degree of coarsening is desired in the normalizing range. Then the proper preferred normalizing temperature should be used either in the commercial furnace or in a laboratory furnace, for the customary period of time.

The essential point is that for pertinent information regarding quenching and tempering and the final properties of heat treated steel, the grain size should be established at the approximate quenching temperature. For useful information concerning grain size effects in other heating operations, such as normalizing or forging, the higher temperatures employed therein should be used in the determination of grain size also. Failure to observe this consistent procedure may result in erroneous conclusions.

When the grain size has been developed in the properly heated —and therefore austenitic—steel, the steel is cooled in whatever way will best reveal this grain size. The procedure will vary with the type and carbon content.

Hypoeutectoid Carbon Steels. In most steels with a carbon content between 0.25 and 0.60%, it will be sufficient merely to cool a specimen about ½ in. in diam in air. The ferrite will form chiefly in the grain boundaries and mark out the grains as in Fig. 9. When the grain size is small, complete envelopes (particularly of ferrite) ordinarily will not form, but this offers no difficulty. Generally one austenite grain still forms only one area of dark pearlite so that the eye readily recognizes the grains either for counting or for comparison.

When the composition is only slightly hypoeutectoid, the steel may be treated according to directions below for eutectoid steel, or may be cooled to about 1340 F and held there for 10 or 15 min before final cooling. This cooling will usually form a very good network of ferrite.

Hypoeutectoid Alloy Steels. With the exception of carburizing steels (discussed below) these steels should generally be cooled by the second method for hypoeutectoid carbon steels, allowing still more time at about 1340 F. Otherwise they may be treated as for eutectoid steels (below). An excellent improvement of this method is to hold at some temperature near 1300 F long enough to establish a ferrite network, and then quench. Subsequent tempering at approximately 800 F (one minute is sufficient) develops a black-etching "sorbite" in the body of the grains. The most brilliant contrast develops during etching. Higher alloy steels require longer holding time; the optimum can be determined once for all by a series of specimens held for three or four different periods.

Hypereutectoid Steels. These steels are easily cooled to develop a fine carbide network; the best rate depends on composition. Unless the carbon content is more than 1.10%, they are best treated as eutectoid steels (below). Equally satisfactory results are secured by the method of holding at 1300 to 1340 F, quenching, and reheating at approximately 800 F. The hypereutectoid zone of a carburized steel is handled in the same way, as discussed below. Figure 10 shows a carbide network marking out the grains.

Eutectoid Carbon Steel. A specimen of ⅝ to 1 in. in diam is properly heated in the range in question and quenched in water; one end may be kept out of the water. The center, or the unquenched end, will be uniform fine pearlite, in which grain size is not discernible; the outer zones will be martensitic. Between the two will be a zone in which the martensitic body of the grains will etch lightly, while the many nodules of fine pearlite in the grain boundaries will etch black and mark out the grains. When this method becomes somewhat ambiguous in the

(a) Some of the data of this table are from unpublished work of R. H. Aborn and J. J. B. Rutherford.

finest grain sizes, and it is still desired to have an accuracy of one grain size number, the estimation should be made in the fully hardened zone as for hardened steel. Figure 11 shows grain size marked out by black etching fine pearlite in the boundaries in the transition zone.

Fully Hardened Steel. It may be desirable to know the grain size established in heating a steel that has already been quenched—and even perhaps tempered, which would make the problem more difficult. This determination can be accomplished also by suitable etching of the wholly martensitic structure. Two or more slight repolishings and etches may be necessary. The etching agent (Vilella's martensite reagent) that develops contrast between the martensite of individual austenite grains, is made up as follows: Dissolve in 95 ml of ethyl alcohol 1 g of picric acid and 5 ml of concentrated hydrochloric acid.

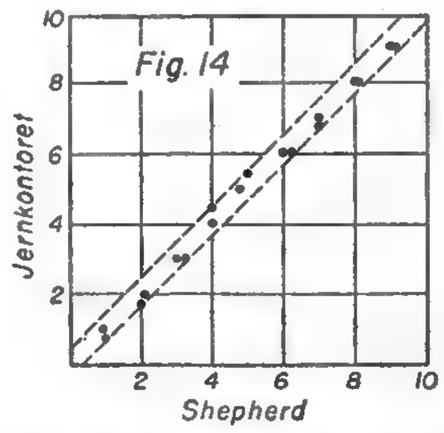
The prior austenitic grain size may be determined in hardened steel that has been tempered definitely and softened moderately. Indeed, there is an optimum degree of tempering that provides the greatest contrast among the grains. Figure 12 shows the structure of hardened steel etched for estimation of grain size, and Fig. 13 shows a hardened and tempered steel.

Carburizing Steels. When the steel under consideration is to be case carburized and quenched directly from the carburizing box, the important grain size is that established under conditions precisely like those that prevail when the steel is removed from the carburizer; the grain-growth characteristics of the steel are often greatly altered by the infusion of carbon, and an examination of the original low-carbon steel heated to the carburizing temperature would be misleading (that is, the core of carburized pieces). Accordingly the specimen should be properly cooled, so as to develop a carbide network in the high-carbon zone when removed at the conclusion of carburization; in brief, the specimen should be handled thereafter exactly as for any hypereutectoid steel. When, however, the carburized steel is to be reheated, the carburized grain is not significant and the specimen should be reheated according to the practice before cooling to mark out the grains.

Observations on the grain size of the hypereutectoid zone of carburizing steels are interesting. In the first place, estimation of grain size under the microscope is, perhaps, easiest in hypereutectoid compositions because of the extra contrast of the usually clear carbide envelopes or network. Certain other features* of the carburized structure are metallographically fascinating, and the examination of carburized specimens of various steels not commercially carburized has sometimes been carried out as a regular test. For details of this procedure the reader is referred to page 407. The only point that must be remembered is that steels indistinguishable in properties and grain size when properly heat treated may possess vast differences in grain size when carburized.

Section-Size Distribution. Inevitably some grains of the mean size or larger will be sectioned in such a way as to show a small polygonal surface in the image. Hence an occasional small polygon should not be reported as indicating mixed structure. When, however, a cluster of small grains is found, they should be taken into consideration, because it is not possible to section more than about three adjacent large grains to yield small plane grain sections. Generally speaking, when grain size is uniform, about three-fourths of the field will show "grains" within one grain-size bracket. Most of the remaining quarter of the field will consist of the next smaller size with a few still smaller polygons.

Austenitic Grain Size from Fracture. In the first section, mention was made that long ago the properties of hardened steel had been correlated with the coarseness or fineness of the fracture surface of a break on the hardened steel. As early as 1926 this relationship was used at the Uddeholm Steel Works in Sweden, as a quantitative measure of certain aspects of steel quality. At first only five recognized grades of fracture were employed, but later the work was extended through the supervision of Jernkontoret, and in 1927 a 10-step scale was recommended as a suitable measure of tool steel quality; sets of standard fractures in specimens 22 mm sq were prepared under the direction of Dr. Ragnar Arpi. These specimens covered the full range of coarseness and fineness usually encountered, by steps which to the eye appeared evenly spaced.



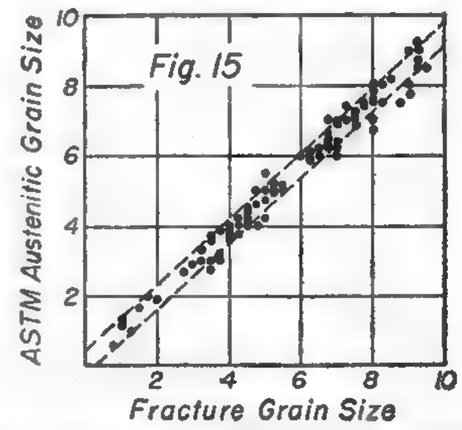


Fig. 14 A comparison of the Jernkontoret and Shepherd fracture standards 1 to 10, each in terms of the other. Note similarity.

Fig. 15 Relation between fracture rating and the true prior austenitic grain size in hardened and broken specimens.

In America, also, B. F. Shepherd employed an examination of hardenability and fracture appearance as a measure of the probable suitability of steels for certain purposes. Shepherd prepared a set of graded standard fractures in which the entire cross section of the standard

* An interesting structural feature of carburized steels becomes apparent when they are cooled in exactly the same way. It has to do with the regularity of the pearlite and the extent to which this pearlite fills the envelopes of the grains marked out by proeutectoid carbide and is designated "normality" or "abnormality". It is sufficient to note here that this feature is controlled by composition and grain size in the carburized condition of steels amenable to the classification. When composition is constant, fine grains infallibly favor abnormality; coarse grains favor normality. With constant grain size the normality is then a measure of effective content of deep hardening elements in solution, these elements favoring normality.

bars was hardened. To gain an adequate impression of different bars of steel, he generally hardened the specimens (of definite section) from four heating temperatures, 1450, 1500, 1550 and 1600 F, and secured thereby a pattern for the coarsening of the steel at increasing temperatures. The fracture was compared with the series of standards similar indeed to the Swedish standards. The latest standard fractures (hardened throughout in both instances) of Shepherd and Jernkontoret, numbered serially 1 to 10, each as compared with the other, are shown in Fig. 14. For most practical purposes these standards may be regarded as the same.

It will have become almost obvious by this time that there is a marked degree of parallelism, more than fortuitous, between coarseness of fracture and the austenitic grain size that existed in the fracture specimen before it was quenched and broken. This relationship proves to be closer than was at first supposed. The estimation of a great many fractures shows that the relationship between the Shepherd or Jernkontoret fracture numbers and the austenitic grain size responsible for the fracture appearance is about as shown in Fig. 15. It should be remembered that the eye is able to arrive at a mean value of the coarseness of a fracture and that for correlating fracture number with austenitic grain size, the mean value of the austenitic grain size should be used. Thus, if a specimen were accurately rated 65% No. 6 and 35% No. 4, its mean grain size would be about 5.3 and it would exhibit a fracture about midway between 5 and 6. There is one interesting fact about estimating prior austenitic grain size by fracture. The eye is more *sensitive* to slight changes in fracture appearance than is the corresponding mean grain size estimation on the microscope. Experienced observers of fractures will agree within one-half, and often within one-quarter, of a single step in the fracture series. There is probably no urgent need even for as many steps as exist in either the ASTM grain size rating or the fracture rating. The properties that are influenced by grain size are not sufficiently modified by small changes to warrant great accuracy in reporting grain size either by fracture or by microscopic examination.

A word should be said about the fracture appearance from mixed grain sizes. Actually there will be large facets mixed with the fine on the fracture surface but the eye does not recognize this at once unless the fracture is fairly coarse; instead, undue influence is exerted by the few coarse facets. Nevertheless, an experienced observer can distinguish "duplexed" specimens reliably from fracture appearance, once he acquaints himself with a few known specimens of mixed grain size. (The mixed grains must really have existed at the time of quenching, and not have been found only after some other unrelated heating.) A few rare anomalous instances are found, in which considerable experience is necessary to estimate actual grain size from fracture. The most notable of these is an austenite grain that coarsens abnormally at elevated temperature, having been inhibited until high temperature is reached. The surface of each grain is slightly matte, not brilliant, suggesting a fine grain size, while the large grain size is also apparent from a faint appearance of large facets. This condition occurs too rarely to be serious. The reasons for it have been suggested.[5]

It is easy and practical to combine a hardenability test with the evaluation of grain size by fracture as Shepherd has done. A standard size of specimen must then be adopted and rigidly maintained and the grain size at the fracture must be estimated on the fully hardened or martensitic rim. The depth of this rim can be measured (by 64ths of an inch in Shepherd's technique) after it is rendered visible by etching. Shepherd reports eight numbers that largely classify certain grades of carbon steel as to their suitability for hardened parts. The first four numbers are depths of hardened zone in 64ths of an inch as quenched from 1450, 1500, 1550 and 1600 F, respectively, while the second four numbers are the fracture numbers (Shepherd or Jernkontoret scale) of the hardened zone of the same specimens. It should be stressed that the information secured by this *P-F* (*P* = penetration of hardened structure; *F* = fracture rating) test goes far toward giving a full account of the behavior of carbon steel. Obviously alloy steels may harden throughout such large sections that the hardenability feature is inapplicable; the estimation of fracture grain size is still valid, however.

The most rapid examination of a steel for significant grain size characteristics consists of rating the fracture first;* if it is not indicative of mixed grain size, the ASTM grain size may be reported at once, or if the fracture shows the probability of such a condition, it may be polished, etched and rated microscopically by the charts of Fig. 1 to 8 inclusive. (*See also* page 413.)

Summary. The grain size established in the austenite of a bar of steel ready to be cooled or quenched plays an important part in determining the properties secured. This grain size is generally fine at ordinary quenching temperatures but is coarser at higher temperatures; for example, normalizing temperature, or higher.

Grain size is not altered by the method of cooling; hence estimation may be made for any suitably heated specimen cooled in such a manner as to reveal the grain size in the transformed microstructure.

The cooling schedule for best estimation of grain size depends on the composition of the steel. Either hypo- or hypereutectoid steels may be cooled slowly enough during the first part of the transformation to cause proeutectoid ferrite or carbide to be rejected in the grain boundaries as a thin network. Eutectoid carbon steels have the grain boundaries nicely marked out by black-etching fine pearlite (nodular troostite) in the zone not quite fully hardened; or in any fully hardened steel a special etch may be given the polished specimen to differentiate by selective attack the separate original austenite grains now converted to martensite.

A close approximate estimate of austenitic grain size in any hardened steel may be made by examining its fracture surface. A chart showing approximate relation between austenitic grain size and either Shepherd or Jernkontoret standard fracture number is included here (Fig. 15).

Eutectoid or hypereutectoid carbon steels (and even hypoeutectoid alloy steels) usually retain considerable undissolved carbide at low temperatures employed for hardening by best practice. Such austenites are fine grained, making it somewhat difficult to estimate actual grain size. This is not serious since the grains are obviously fine and since the carbide-ferrite interface has all the influences that grain boundaries exert on hardening characteristics.

Interest focuses principally on the grain size established in the temperature range of the operation to be carried out and correlated with grain size effects. It is therefore recommended that the grain size be estimated on regular pieces heated according to commercial operations up to the time of cooling or quenching.

The McQuaid-Ehn Test

By H. W. McQuaid*

THE McQuaid-Ehn test was developed in 1922 as a result of an extensive investigation into the effect of melting furnace practice on the hardenability of plain carbon case-hardening steels. It was found that by carburizing at 1700 F in a solid carburizer that would develop a definite hypereutectoid zone, and then permitting the material to cool slowly enough to develop a pearlite structure with free cementite in the hypereutectoid zone, a definite structure would be developed, depending on the practice used in the melting furnace. By this means it became possible to predict from the carburized specimen the reaction of the final carburized product to quenching.

Since this test was first introduced, it has been extended to cover not only plain carbon carburizing steels, but also alloy steels in all the commercial grades, and the plain carbon steels, including the tool steel ranges.

The importance of having methods of associating properties inherent in a given heat of steel with the results to be expected in heat treatment and in the finished product, has resulted in many investigations into the characteristics developed by the McQuaid-Ehn test. Other methods developed for the same purpose are given on page 399.

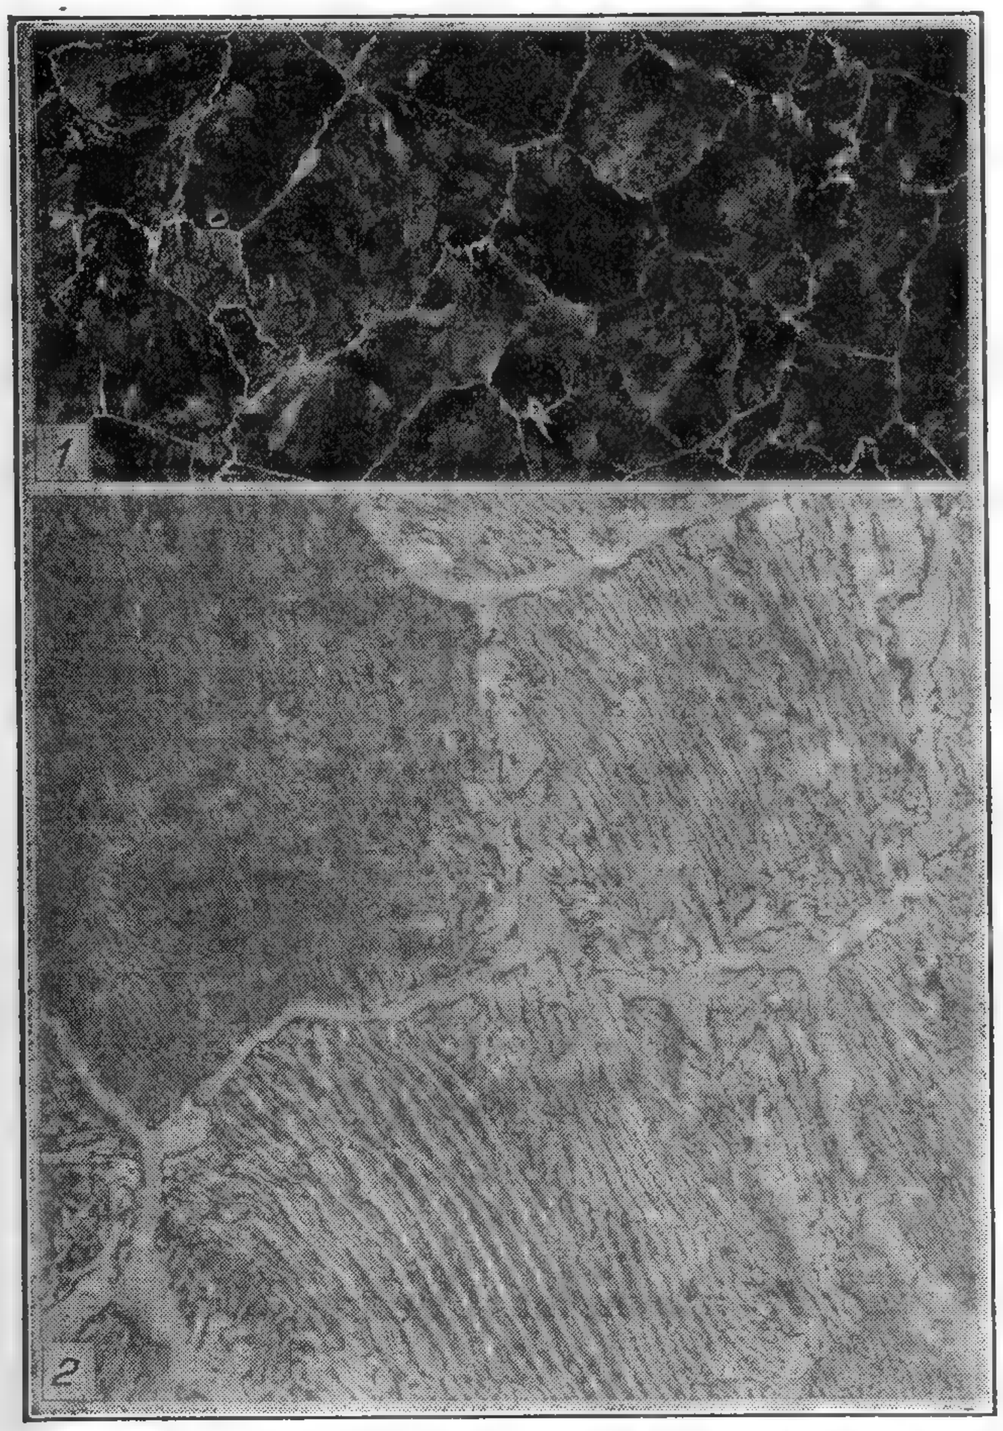

Fig. 1 Case structure of normal steel after McQuaid-Ehn test. White cementite network around dark pearlitic grains (× 100).
Fig. 2 Same as Fig. 1, at × 1000.

Pearlitic Structure Required. In order to make the McQuaid-Ehn test properly, it is necessary to develop a pearlitic structure within the grain of the hypereutectoid zone after case carburizing. This requires the use of a carburizing compound that will develop an excess of cementite sufficient to permit a clear indication of the disposition of the proeutectoid cementite after the formation of pearlite within the grain. The work to be tested should, therefore, be carburized in a solid carburizer containing sufficient energizer to give a carbon content in the case, well above the eutectoid range. Many available commercial carburizing compounds can be used for this purpose. The compound used in the average plant will be found satisfactory.

Carburizing Temperature and Time. The work material should be carburized at a temperature as near 1700 F as is commercially possible. However, little difference will be found with variation in temperature from 1675 to 1725 F.

The time at temperature is determined by the depth of case desired; for most purposes it is necessary to hold at temperature only long enough to develop a hypereutectoid zone sufficient to be studied readily at ×100 magnification. It is better, for most purposes, to carburize until a case approximately 0.050 in. deep is obtained, which will provide a hypereutectoid zone ample for satisfactory study.

Cooling from Carburizing Temperature. The cooling time is governed to a large extent by the alloy content. In order to develop a satisfactory pearlitic structure in the hypereutectoid zone, the cooling rate must be very slow for high-alloy air-hardening steels, but it can be relatively fast for the low-carbon, low-manganese steels containing no other alloying elements. The cooling rate can be determined only by experience, and depends not only on the composition of the steel but also on such factors as the size

Fig. 3 Case structure of abnormal steel after McQuaid-Ehn test. White cementite network with free ferrite (white) around dark lamellar pearlitic grains (× 100).

* Consulting Engineer, Cleveland

of carburizing container, size of specimen and of heating furnace. Plain carbon steels can be carburized in a commercial furnace and air-cooled in the standard carburizing container. The air-hardening steels, such as the high-nickel and Cr-Ni-Mo series, must be cooled in the furnace. Where the work material is carburized in a laboratory furnace, it is quite common to cool all test specimens in the furnace, and it has been found necessary to cool high-alloy steels in the furnace at a definite maximum rate.

The following minimum cooling periods through the transformation range may be found satisfactory: 4 hr for SAE 2315 and 4615; 8 hr for SAE 2512; 16 hr for Krupp steel (Ni 4%, Cr 1.5%); and 3 hr for the other steels, such as the plain carbon, 3115 and 6115.

Interpretation of Results. The interpretation of the test results depends on the examination of the pearlite and cementite in the hypereutectoid zone. In a strictly normal steel, the structure within the grain boundaries is completely pearlitic and, if the grain is coarse, the cementite exists as well-defined lines of fine but continuous formation at the crystal boundary, as shown in Fig. 1 and 2. In a strictly abnormal steel, the pearlite, if present at all as such, will be very coarsely and irregularly lamellar and will have broken down completely at the grain boundaries to form massive cementite and free ferrite (Fig. 3 and 4). Here the cementite will be distinguished as ridges, having a white background of ferrite. Between these two extremes will be found many types in which the pearlite becomes more coarsely lamellar as the steels become more abnormal and an increasing amount of free ferrite surrounds the cementite at the grain boundaries. It will also be noted that there is a tendency for the cementite to become thicker and, in some steels, to become a discontinuous series of elongated particles.

Consideration of Grain Size. It was noticed, at the time when this test was first developed, that variation occurred in the size of the grain in the hypereutectoid zone from one heat to another, and that this variation in grain size also served as an indication of the characteristics of the finished heat treated piece, with regard to hardenability, distortion and mechanical properties.

Usually coarse-grained steel (Fig. 5) will be quite normal—particularly plain carbon steel—with an increasing tendency toward abnormality as the grain size decreases. The coarse-grained normal steels respond better to quenching, harden more deeply and tend to distort considerably more than the finer-grained, more abnormal steels. The coarse-grained normal steels usually have much lower resistance to impact and for this reason the finer-grained steels (Fig. 6) are preferred for applications where resistance to shock-loading is necessary. Because fine-grained steels exhibit a greatly reduced tendency toward grain growth, they are usually preferred, especially in the alloy grades, for quenching directly from the carburizing temperature. In the plain carbon grades, the probability of having soft spots after hardening, is greatly increased with the fine-grained, more abnormal steels, so it is often necessary to quench these steels in a caustic or similar solution after carburizing.

The steels of coarser grain respond more readily to the usual normalizing temperature by forming a coarsely lamellar pearlite; hence they are preferred in some plants because of the improved finish obtained in machining. By using a higher normalizing temperature, approximately 1800 F, to overcome the inherent resistance to grain growth in steels of finer grain, it is possible to improve the machinability of the fine-grained steels so that it equals that of the coarse-grained steels.

At present there is some difference in opinions concerning the relative effects of normality and grain size. It is evident that normality and grain size are two independent characteristics and that steel can be made, if desired, which is fine-grained normal or coarse-grained abnormal. This is entirely a matter of furnace practice, but under present conditions most of the fine-grained steels are slightly abnormal, the coarse-grained steels are normal, and the desired characteristics can be obtained commercially by proper selection according to grain size. For this purpose grain-size charts are available, permitting classification according to grain size as revealed by the McQuaid-Ehn test.

The Determination of Oxygen, Nitrogen and Hydrogen in Ferrous Metals

BY THE SUBCOMMITTEE ON GASES IN METALS*

OXYGEN, nitrogen and hydrogen exist in solid steel in small amounts but in a variety of forms. Oxygen occurs chiefly as inclusions, that is, as oxides and silicates of iron and other elements, but small amounts may exist in solid solution in the iron, or in special cases—in rimmed ingots and certain castings, for example—as gaseous compounds trapped in small pockets in the metal. Oxygen contents normally encountered in ferrous materials range from about 0.1% by weight (chiefly as FeO) in open hearth ingot iron to negligible amounts in completely deoxidized clean steel, with 0.005 to 0.020% of oxygen usually present in the general run of tonnage steels.

Nitrogen occurs chiefly as nitrides of iron and the alloying elements. The nitrogen content of ferrous materials normally will be about 0.005% for open hearth carbon

* The members of this subcommittee are J. G. Thompson, *Chairman* (National Bureau of Standards), J. B. Austin (United States Steel Corporation), B. M. Larsen (United States Steel Corporation), D. W. Murphy (Bethlehem Steel Company), M. A. Scheil (A. O. Smith Corporation), and F. W. Scott (Marquette Manufacturing Co., Inc.).

steels and about 0.015% for Bessemer steels. Alloying elements such as chromium absorb nitrogen readily, with the result that alloy steels ordinarily contain more nitrogen than the plain carbon steels. Furthermore, nitrogen may be intentionally added to high-chromium steels, so that nitrogen contents of 0.2% or more may be encountered.

The hydrogen content of ferrous materials is usually less than 0.001%. The mode of occurrence of these small amounts of hydrogen is not definitely known, but stable compounds or stable solutions of hydrogen apparently do not exist in steel.

In such a situation it is natural that methods of analysis differ widely in basic principles and in intent. In the determination of oxygen, for example, some methods are intended for the isolation and separate determination of one or more individual oxides, whereas others yield a single value for total oxygen without attempting to determine its distribution among the various combinations that are present. An effort to correlate results obtained by different methods, and thereby to establish the accuracy and limitations of the different methods, was the basis for a project of co-operative analysis, international in scope, which was completed in 1937. The results of the co-operative analysis[1] have been extended by further work in this country and abroad, particularly as described in the Reports of the Oxygen Subcommittee[2] of the Committee on the Heterogeneity of Steel Ingots, of the British Iron and Steel Institute.

The present discussion is confined to individual methods for the quantitative determination of oxygen, nitrogen and hydrogen in ferrous materials. Methods that yield qualitative rather than quantitative data—for example, microscopic and petrographic methods—are discussed elsewhere in this Handbook. (*See* page 445.)

Sampling. When the material under investigation is solid steel, sampling is a routine matter of selecting chips, millings or solid pieces that will be truly representative of the mass of material. However, if the investigation is concerned with the composition of molten steel, sampling is more difficult. Proposed expedients for sampling molten steel without loss of gaseous elements include using a spoon or bomb sample killed with an excess of aluminum,[3,4] arranging for the sample of molten metal to solidify in an evacuated steel tube,[5] and casting the sample in a heavily chilled, wedge-shaped mold.[6] These procedures and the determination of finely divided Al_2O_3 by measurements of turbidity have been discussed by Brower and Larsen.[20]

Methods for the Determination of Oxygen and Oxides. Methods for the quantitative determination of oxygen and oxides in solid steel fall into two groups: reduction methods and residue methods. The first group includes vacuum fusion, hydrogen reduction and aluminum reduction methods, involving reduction of the oxide constituents of the sample at elevated temperatures, with subsequent analysis of the products of the reduction. The second group includes several procedures for solution of the metallic constituents of the sample, leaving an insoluble residue from which individual compounds can be isolated and determined.

Vacuum Fusion Method. The vacuum fusion or hot extraction method consists of heating the sample to temperatures well above the melting point, in a previously degassed graphite crucible in a highly evacuated furnace. Under these conditions, all the oxides in the sample are reduced to gaseous oxides of carbon, which are removed from the melting chamber and analyzed for oxygen.

Samples for analysis by vacuum fusion usually consist of 5 to 20 g of clean material, preferably in one piece of minimum surface area, to reduce errors caused by the presence of an oxide film on the surface of all ferrous materials. For example, recent work by Sloman and Rooney[2d] shows that this surface film varies from about 1 to approximately 100×10^{-6} grams of oxygen per sq cm of surface, depending on the composition of the metal and the manner of preparation of the sample.

Minor variations in details of construction and operation of the different vacuum fusion installations[1,2] are matters of personal preference and do not affect the accuracy of results, as long as certain basic principles are observed. The blank correction should be as low and as constant as possible. The pumping system should maintain a pressure of less than 0.001 mm Hg in the furnace at operating temperature, and should extract the evolved gases from the furnace rapidly and completely.

The vacuum fusion method, properly operated, yields accurate results for the total oxygen content of a wide variety of plain carbon and alloy steels, and is generally accepted as the standard with which the results of other methods are compared. Its principal limitation arises from the presence, in the sample, of volatile elements, the vapors of which react with carbon oxides in the upper portions of the furnace chamber and thus lead to low recoveries of oxygen evolved from the sample. Manganese and aluminum are the principal offenders; other elements, such as zinc and calcium, would cause interference but are not usually encountered in ferrous materials; high sulfur contents, that is, more than 0.05%, contaminate the copper oxide and may necessitate frequent renewal. The maximum permissible amount of manganese or aluminum varies with different installations; some operators believe that as much as 3% Mn or 2% Al can be tolerated, whereas others have reported interference from manganese or aluminum contents of less than 0.5%. In some laboratories, tin is added to the melt to reduce the manganese effect. Another possible source of error is the spattering that frequently occurs during the melting of a sample with high gas content and results in a loss of sample material before the reduction is completed. A third source of error is the occasional presence of unusually large particles of alumina, silica or other refractory compounds that may require extended operation for their complete reduction.

Two attempts to develop rapid methods for determining oxygen content, based on the principles of vacuum fusion, have been reported recently. Singer[7] suggested melting the sample in nitrogen instead of in a vacuum, to simplify maintenance of high-vacuum apparatus, and Derge[6] described a modified apparatus and procedure for rapid analysis. In both instances it appears that increased speed has been obtained at the expense of accuracy and reliability.

Fractional Vacuum Fusion Method. The method was developed to obtain more information than the single value for total oxygen, which is derived from the "standard" vacuum fusion operation. In the fractional procedure, tin is added to the sample in the graphite crucible to lower the melting point. The temperature of the molten metal is then raised in stages and the gases evolved in each stage are collected and analyzed separately. The carbon oxides evolved at the lowest temperature are ascribed to the reduction of FeO, and the gases evolved at progressively higher temperatures to MnO, SiO_2 and Al_2O_3, respectively.

The fractional procedure developed by Reeve and by Hoyt and Scheil[1] in this country has been studied recently by workers in England. Operation is correspondingly slower than a single determination of total oxygen and the accuracy of the various fractions has been questioned. After extended study of the fractional procedure, Swinden, Stevenson and Speight[2c,2d] concluded that the total content of oxygen is equal to that obtained by direct vacuum fusion, and the separation of easily reducible oxides from SiO_2 and Al_2O_3 is complete, but the separation of FeO and MnO is uncertain.

Hydrogen Reduction Method. The oxides present in steel can be reduced by hydrogen at temperatures of about 1200 C, and determination of the oxygen content of the exit gases indicates the amount of oxides reduced.

A major difficulty in the operation of the hydrogen reduction method is to insure exposure of all the oxides in the sample to the action of hydrogen. Early workers added antimony and tin to obtain the sample in the molten state, but this was unsatisfactory because of uncertainty in the blank correction. If solid samples are used, reduction of oxides in the interior depends on diffusion of hydrogen through the metal. Consequently the sample must be very finely divided to insure completion of the reaction in a reasonable time.

Brower, Larsen and Shenk[1] recommended the use of very fine millings, a preliminary stripping operation at 500 to 550 C to remove surface oxygen, and the use of high-fre-

quency induction heating to raise the temperature to 1200 C for the determination of "body" oxygen. This procedure has been applied to alloy and simple steels, resulting in complete reduction of FeO and MnO and in some instances, of SiO_2 and Al_2O_3. Large amounts or large particles of silicates and alumina are incompletely reduced under these conditions. Difficulty has been encountered in the analysis of material with a high content of FeO (Armco iron, for example), because of inability to separate the surface from the body oxygen in this type of material. On the other hand, the presence of manganese and aluminum should cause less interference in the hydrogen reduction method than in vacuum fusion at higher temperatures. Under optimum conditions, results are reproducible to about 0.002% of oxygen, but according to Stevenson,[2c] accuracy of this order is not always obtainable.

Baker[8] proposed a modified hydrogen reduction procedure, using a small amount of hydrogen at reduced pressure, to keep the blank correction low. The hydrogen was purified by diffusion through palladium.

Aluminum Reduction Method. Gray and Sanders[2a] suggested that the total oxygen content of steel samples might be determined by melting the sample with an excess of aluminum at 1150 C, in a neutral atmosphere or in vacuum, with subsequent solution of the cooled fusion in acid and determination of its Al_2O_3 content. Operating in vacuum is usually preferred to operating in hydrogen or other neutral atmospheres.

British investigators[2c] have reported that the results were in satisfactory agreement with results by vacuum fusion and that complete recovery of oxygen was obtained from samples of SiO_2, $Al_2O_3.2SiO_2$, Fe_2O_3 and MnO. The procedure has been applied to the analysis of plain carbon and simple alloy steels, slags, pig irons and cast irons.

Residue Methods. The chief claim for the residue methods is that they determine oxides as they exist in steel. Results of the residue analyses usually are reported as FeO, MnO, SiO_2 and Al_2O_3; other oxides (for example, Fe_2O_3 or the oxides of alloying elements) may be determined when their presence is indicated. Disadvantages of the residue methods lie in the necessarily complicated procedure of purifying and analyzing the residue, and in the varying degrees of insolubility of the different oxides in the different solvents. Results that were available for these methods previous to the co-operative analysis indicated that most of the methods needed further study. The benefits derived from further study are evident in the improved reproducibility of results and in the agreement of results by different methods in the subsequent work of British investigators.[2]

Iodine Method. When a sample of steel is treated with a suitable solution of iodine, the metallic constituents are dissolved, leaving a residue of unattacked oxides, usually contaminated by carbides and other materials.

An aqueous solution of iodine in ferrous iodide, as recommended by Cunningham and Price, has been used in this country. It is claimed that sulfides and nitrides are completely dissolved and do not interfere with analysis of the insoluble residue. Results of the co-operative analysis[1] indicated that good results for SiO_2 and Al_2O_3 may be obtained by this method, properly operated, but that the values obtained for FeO and MnO are less certain. Some of these difficulties have been overcome by subsequent research in England,[2] particularly in the analysis of pig and cast irons.

The use of a solution of iodine in anhydrous methyl alcohol was proposed by Rooney and Stapleton and this alcoholic iodine method has been studied extensively in England. Rooney[2c] concluded that the method can be used for the determination of oxides in low and medium carbon steels that do not contain appreciable amounts of elements which form stable carbides (for example, chromium, vanadium and titanium) or which form insoluble iodides (for example, titanium and molybdenum). Variable results for MnO are obtained sometimes, special precautions must be observed in the analysis of rimming steel, and difficulties are encountered in the analysis of aluminum-killed or aluminum-containing steels, because of the presence of aluminum carbides and nitrides. According to Pearce,[2c] the alcoholic iodine method is not suitable for the analysis of cast irons because of interference by phosphorus.

Electrolytic Method. In this method, the soluble metallic constituents are separated from the insoluble residue by making the sample anode in a suitable electrolyte. Purification and analysis of the residue are similar to operations in the chemical solution methods.

Solutions recommended for use as electrolytes include ferrous sulfate plus sodium chloride; sodium citrate plus potassium bromide; ferrous chloride; and magnesium iodide. Results obtained in the co-operative analysis[1] indicated that electrolytic methods in general were more reliable for determinations of SiO_2 and Al_2O_3 than for FeO and MnO. Scott's method, using a magnesium iodide electrolyte and a carefully controlled procedure, yielded the best results of any of the electrolytic methods.

Electrolytic methods appear to be even more complicated and difficult to control than the chemical residue methods. Perhaps because of this, electrolytic methods have received less attention recently than other methods. Hare and Soler[9] used Scott's electrolytic method in combination with petrographic examination to study the relation of inclusions to furnace practice for alloy steels.

Chlorine Method. If a sample of steel is heated at moderately elevated temperatures in a stream of purified, dried chlorine, the metallic constituents are converted to soluble or volatile chlorides and the unattacked oxides may be determined in the insoluble residue. If the temperature is too low, the residue is contaminated by particles of metal; if it is too high, some of the oxides are attacked by the chlorine. Alloying elements generally require higher temperatures to react with chlorine, and some alloying elements form insoluble chlorides.

Investigators for the Heterogeneity Committee[2c,2d] used 350 C as the chlorination temperature for a number of simple steels. For killed steels, the results were reproducible and the total oxygen values agreed with those obtained by vacuum fusion. Low recoveries of oxygen were obtained from basic Bessemer rimming steel, and difficulties were encountered with a steel that contained 0.75% Cr.

Mercuric Chloride Method. Separation of oxides from the metallic constituents by solution of the latter in an aqueous solution of mercuric chloride has been described by Maurer, Klinger and Fucke.[10] The procedure is intended particularly for the determination of FeO and MnO, which are the least satisfactory determinations by most of the residue methods. Difficulties of purification and analysis of the residue are comparable to those of other methods, and the available data indicate that satisfactory results may be obtained for MnO but that results for FeO are consistently high.

Hydrochloric and Nitric Acid Methods. These methods depend on the solubility of metallic constituents and relative insolubility of certain oxides in approximately 10% hydrochloric or nitric acid. The hydrochloric acid method,[11] somewhat faster and more convenient, is an integral part of the aluminum-reduction method of Gray and Saunders.

Either method furnishes a relatively simple means for the accurate determination of Al_2O_3. Results for SiO_2 are less reliable and neither method is applicable to the determination of FeO or MnO.

Methods for the Determination of Nitrogen. Nitrogen exists in steel primarily in combination, as nitrides of metallic elements. Other possible forms are nitrogen in solution in the metal, or molecular nitrogen in cracks or blowholes, but the amounts ordinarily present in these forms are insignificant. Of the various methods that have been proposed for the determination of nitrogen in steel, two methods of proven worth are available—the vacuum fusion method and the solution-distillation method. It has been shown repeatedly, in England[2d] as well as in this country, that both methods yield accurate results for nitrogen in a wide variety of plain carbon and alloy steels.

In the vacuum fusion method, nitrides in the sample are decomposed by the action of graphite at high temperatures in a high vacuum, forming molecular nitrogen, which is subsequently determined by appropriate analytical means. Some of the nitrides present, particularly in alloy steels, are decomposed slowly. Consequently, it may be advisable to continue the vacuum extraction beyond the minimum time required for reduction of the oxides, to insure complete decomposition of all the nitrides.

In the solution-distillation method, also known as the Allen method or chemical distillation method, the sample is dissolved in acid to convert the nitride nitrogen to ammonium salts. The acid solution is made alkaline and distilled and the ammonia in the distillate is determined by titration or by colorimetric means. Properly operated, this simple procedure indicates correctly the total of the nitrogen present in the specimen as metallic nitrides for a wide variety of steels. However, it has been shown that modern alloy steels may contain nitrides (for example, nitrides of columbium, vanadium, titanium or zirconium) which are not completely decomposed by the simple treatment. To remedy this, variations of the decomposition treatment have been proposed.[2d] For example, Cunningham and Hamner[12] used a mixture of hydrochloric and hydrofluoric acids to decompose the sample, filtered the insoluble residue and digested it with sulfuric acid plus addition agents. The two solutions may be combined for a single determination of total nitrogen or may be analyzed separately for "soluble" and "insoluble" nitrides. Johnson[13] treated the steel with hydrochloric acid, digesting the residue in a mixture of perchloric and sulfuric acids. With these modified procedures, even the alloy steels yield the same results for nitrogen by solution-distillation as by vacuum fusion.

Suggestions to simplify or to hasten the operation of the solution-distillation procedure have been offered by Morrison and Gill[14] and by Beeghly.[15]

Methods for the Determination of Hydrogen. The amount of hydrogen present in solid ferrous materials is seldom as much as 0.001% and the possible importance of such amounts of any constituent has been recognized only recently. Consequently, the determination of hydrogen in steel has received less attention and is less firmly established than the determinations of oxygen and nitrogen. The Fourth Report of the Oxygen Subcommittee in 1943 showed a satisfactory agreement in results obtained by vacuum fusion and by vacuum extraction, and presented other evidence that both methods recover all the hydrogen present. On the other hand, the symposium conducted in this country in 1944 by the American Institute of Mining and Metallurgical Engineers, indicated that the determination of hydrogen is a highly controversial matter. A major difficulty is the uncertainty that the hydrogen content of the sample at the time the analysis is made is the same as the content when the sample was taken. Hydrogen diffuses readily through steel at elevated temperatures and even at room temperature it can diffuse out slowly. The sampling of molten steel presents additional problems, including how to prevent loss of dissolved hydrogen during solidification of the sample.*

The presence of hydrogen in the gases evolved in analysis of steel by vacuum fusion has been recognized for a long time, but the accurate quantitative determination of these very small amounts of hydrogen is not practical in the ordinary operation of the vacuum fusion method. The blank correction for hydrogen is frequently too large and variable to permit determination of a few ten-thousandths of one per cent of hydrogen, and the difficulty of determining a minute amount of hydrogen is increased by the presence of much larger amounts of oxygen and nitrogen. In addition to the analytical difficulties, it is uncertain that all the hydrogen originally present in the sample is recovered in the analysis.

The availability of the vacuum fusion method for hydrogen may be summarized as follows: Satisfactory results are obtained if the hydrogen content of the specimen is high and stable; that is, if there is a large amount of hydrogen to be determined and this hydrogen all stays in the specimen until the latter is dropped into the melting crucible.

The vacuum extraction procedure depends on the ability of hydrogen to diffuse in solid steel at moderately elevated temperatures. Newell[16] recommended vacuum extraction for 1 hr at 600 C. Holm and Thompson[17] preferred to operate at 800 C for more rapid extraction of the gas. Fifteen minutes at 800 C appeared to be ample for the complete extraction of hydrogen from specimens of plain carbon steel but subsequent experience showed that other types of steel required longer extraction periods. Advantages of the vacuum extraction procedure include rapid operation, analysis of a hydrogen-rich mixture, and a low blank correction. The rate of evolution of hydrogen from the specimen tapers off, sometimes making it difficult to determine when extraction has been completed, but evidence submitted in the papers cited, and in others,[2d] shows agreement with results by vacuum fusion; that is, complete extraction of hydrogen was obtained by vacuum extraction, for the samples examined. However, some evidence presented at the AIME symposium does not confirm this conclusion. Further work is needed to establish the limitation of the method.

Reports have been made of several attempts to determine hydrogen in ferrous materials by combustion in purified oxygen, with subsequent determination of the water formed. Schwartz and Guiler[18] described a procedure for white cast-iron samples, but the application of combustion methods to the determination of the small amounts of hydrogen found in commercial steel has not been satisfactory. However, some recent experiments at the National Bureau of Standards indicate that the high results frequently obtained by combustion may be corrected by the observance of special precautions, with the result that values for hydrogen by combustion are at least of the same order of magnitude as the results by vacuum fusion and vacuum extraction. Further work is needed to determine the applicability of combustion procedure for the determination of hydrogen in steel.

Moreau, Chaudron and Portevin[19] reported that hydrogen could be extracted from metallic specimens by ionic bombardment at low temperatures, but the procedure has not been developed as an analytical operation.

Summary. The present status of the determination of oxygen, nitrogen and hydrogen in ferrous materials is briefly as fcllows:

1 For the determination of total oxygen, the vacuum fusion method yields reliable results for a wide variety of plain and alloy steels. Satisfactory determinations of total oxygen have been obtained by the reduction and residue methods; but, in general, reduction methods are most successful in the determination of easily reducible oxides, whereas residue methods are most reliable for the determination of Al_2O_3 and SiO_2.

2 Accurate results for the nitrogen content of a variety of ferrous materials are obtained by either the vacuum fusion or solution-distillation methods.

3 The determination of hydrogen is still in an early stage of development.

* Editor's Note. A recent paper,[21] published since the proof of this article was read, gives a detailed account and a comparison of five methods of sampling the liquid steel bath.

Physical and Mechanical Testing of Tool Steels

BY THE SUBCOMMITTEE ON TOOL STEEL*

THIS article deals with the physical and mechanical tests applied to tool steels. The practical value of such tests depends on the interpretation of them. The principal objective of this article is to assist in the selection of tests for evaluating tool steel in relation to service conditions.

Fracture Tests. Visual examination of fractured surfaces may provide information concerning (1) internal defects and (2) the effects of previous thermal treatment, especially the grain size.

1 Fracture Tests for the Determination of Internal Defects. Either hardened or annealed steel may be examined in a fracture test for internal defects. However, the conditions to be described can usually be recognized more easily in hardened than in annealed steel.

Hardened test disks of suitable thickness (usually ¼ to ⅜ in., depending on the other dimensions) can be fractured by applying a load at the center of the disk either by pressure or by a blow. Short pieces of bars 1 in. or less in diam are fractured transversely in the same manner. Proper precautions should be taken to avoid danger from flying pieces. Hardened disks or tools may be nicked with a thin cutoff wheel to assist in obtaining satisfactory breaks. The use of macro-etched disks for hardening is not recommended. Segregation and nonmetallic inclusions may be distinguished by heat-tinting the fractured specimens.

The various defects that may be recognized on a fractured surface are discussed below.

Decarburization. Decarburization is determined by the difference in grain size between outer edges and the interior of a specimen. The decarburized zone will exhibit a grain larger in size and brighter in color than the interior of the specimen. All hot rolled bars have a decarburized surface, so acceptance of material is based on whether the amount present may be detrimental (Fig. 1).

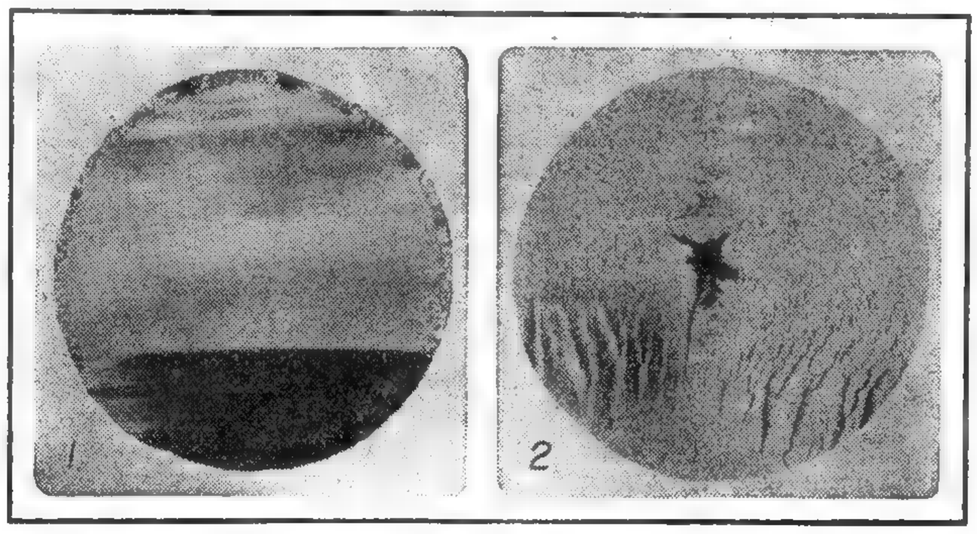

Fig. 1 Decarburized surface
Fig. 2 Pipe

Pipe. Piped steel, caused by shrinkage cavities in the ingot, will be recognized from an actual discontinuity at or near the center of the specimen. When this condition has been largely removed, a coarser or brighter grain may appear in the center (Fig 2).

Bursts. Ruptures produced by forging or rolling resemble pipe somewhat. Distinction may sometimes be made from the shape of the defect or from deep-etch tests.

Flakes. Flakes will appear as short ruptures or bright spots in longitudinal fractures. When fractures are made through, rather than across the flakes, the bright colored spot will appear somewhat conchoidal in form. Care should be taken not to confuse this defect with areas that have been made bright by rubbing during fracturing, or with sections that have been elongated during breakage.

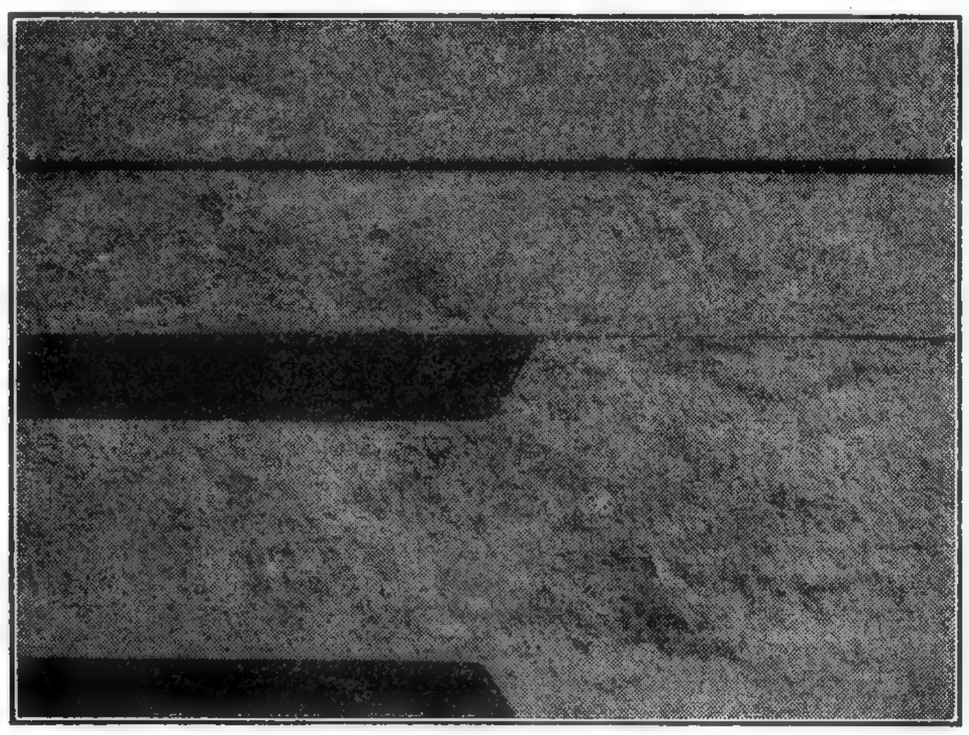

Fig. 3 Woody structure

Woody Structure. Fractures taken in the direction of rolling or forging often have a fibrous appearance. Since all steels are heterogeneous, the fibrous appearance will depend on several factors, such as composition, cleanliness, amount and direction of working. Steels so highly alloyed as to be segregated, such as high speed steel, may reveal a fibrous structure, especially in larger sections where there has been comparatively little reduction from ingot to finished bar. The effect of the fibrous structure can be interpreted only when the general characteristics of the steel are known. Figure 3 shows a woody structure.

Inclusions and Carbide Segregation. Excessive inclusions or carbide streaks may be detected by examination of longitudinal fractures of hardened disks (Fig. 4 and 5).

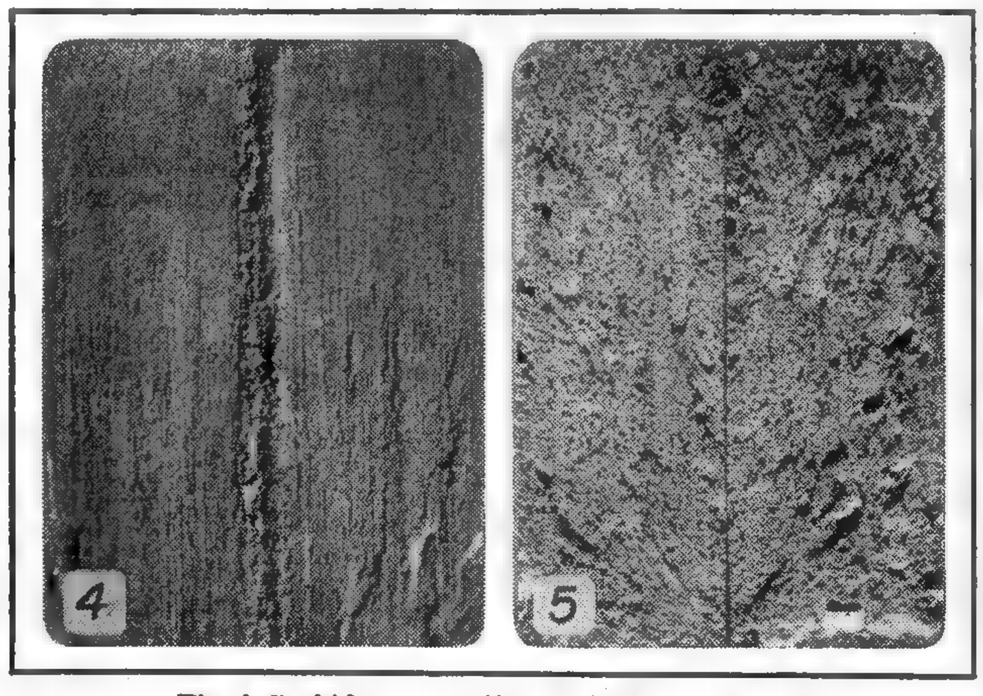

Fig. 4 Carbide segregation in high speed steel
Fig. 5 Inclusions in high speed steel

2 Fracture Test for Grain Size. This test consists of hardening the specimen (machined to ¾ in. in diam by 3 in. long), notching it in the middle and fracturing by impact. The surface of the fracture is then examined for grain size, in comparison with the Shepherd grain size standards illustrated in Fig. 6. (*See also* Grain Size and Hardenability Tests, below.)

* The members of this subcommittee are S. C. Spalding, *Chairman*, (The American Brass Company), W. L. Badger (General Electric Company), A. D. Beeken (Vulcan Crucible Steel Company), J. P. Bindyke (Heppenstall Company), G. E. Brumbach (Carpenter Steel Company), W. R. Frazer (Union Twist Drill Co.), W. H. Macmillan (Remington Arms Company, Inc.), W. E. Mahin (Armour Research Foundation), J. H. McCadie (National Twist Drill and Tool Co.), J. E. McCambridge (U. S. Navy Yard, Philadelphia), H. E. Replogle (Universal-Cyclops Steel Corporation), G. A. Roberts (Vanadium-Alloys Steel Company), R. Schempp (Crucible Steel Company of America), A. G. Spencer (Chevrolet-Flint Division of General Motors Corporation), W. H. Wills (Allegheny Ludlum Steel Corporation), and G. P. Witteman (Bethlehem Steel Company).

Hardness Tests. Descriptions of the several methods of hardness testing and data for hardness conversion are given in the article on page 93 of this Handbook. The so-called "microhardness testers" are used to determine the hardness of small tools or to detect nonuniformity of hardness caused by variation of structural constituents. Machines using the principle of indentation by a spherical ball are preferred for testing tool steels of medium or low hardness. For testing steel of high hardness, the machines employing diamond indenters are generally used. The file test is used on hardened steels only. Hardness tests at elevated temperatures are of interest, especially with high speed and hot work steels.

Macro-Etch Tests. The procedures for macro-etching are presented in the article on page 389. Too strong concentration of the etching solution, too high temperature, or too long immersion of the specimen in the etchant may result in overetching and should therefore be avoided. Macro-etching is ordinarily applied to steels in the annealed condition.

The deep-etch test reveals readily and quickly many of the characteristics of tool steel, but in some instances, further examination by standard testing methods is required to evaluate the characteristics properly. The knowledge that a piece of steel is dendritic or contains metallic and nonmetallic segregates is not sufficient evidence on which to base definite conclusions concerning the properties of the steel. The deep-etch test is of real value in separating materials that are obviously defective from those that are not. The test is easy to perform; however, experience and judgment are required for interpretation of the results.

Cracks From Etching. Before being etched, hardened or otherwise highly stressed steels should be tempered sufficiently to prevent cracking, because they may crack in the etching solution.

Surface Appearance. Steels may etch with a comparatively smooth surface or with a very rough or pitted surface, depending on composition and variables in manufacture. A roughened surface is not necessarily detrimental.

Irregularity in pitting may usually be attributed to one or more of the defects discussed below. Certain manganese, oil-hardening steels are more readily attacked by the acid than are most other tool steels, and are often decidedly roughened without being defective in any way.

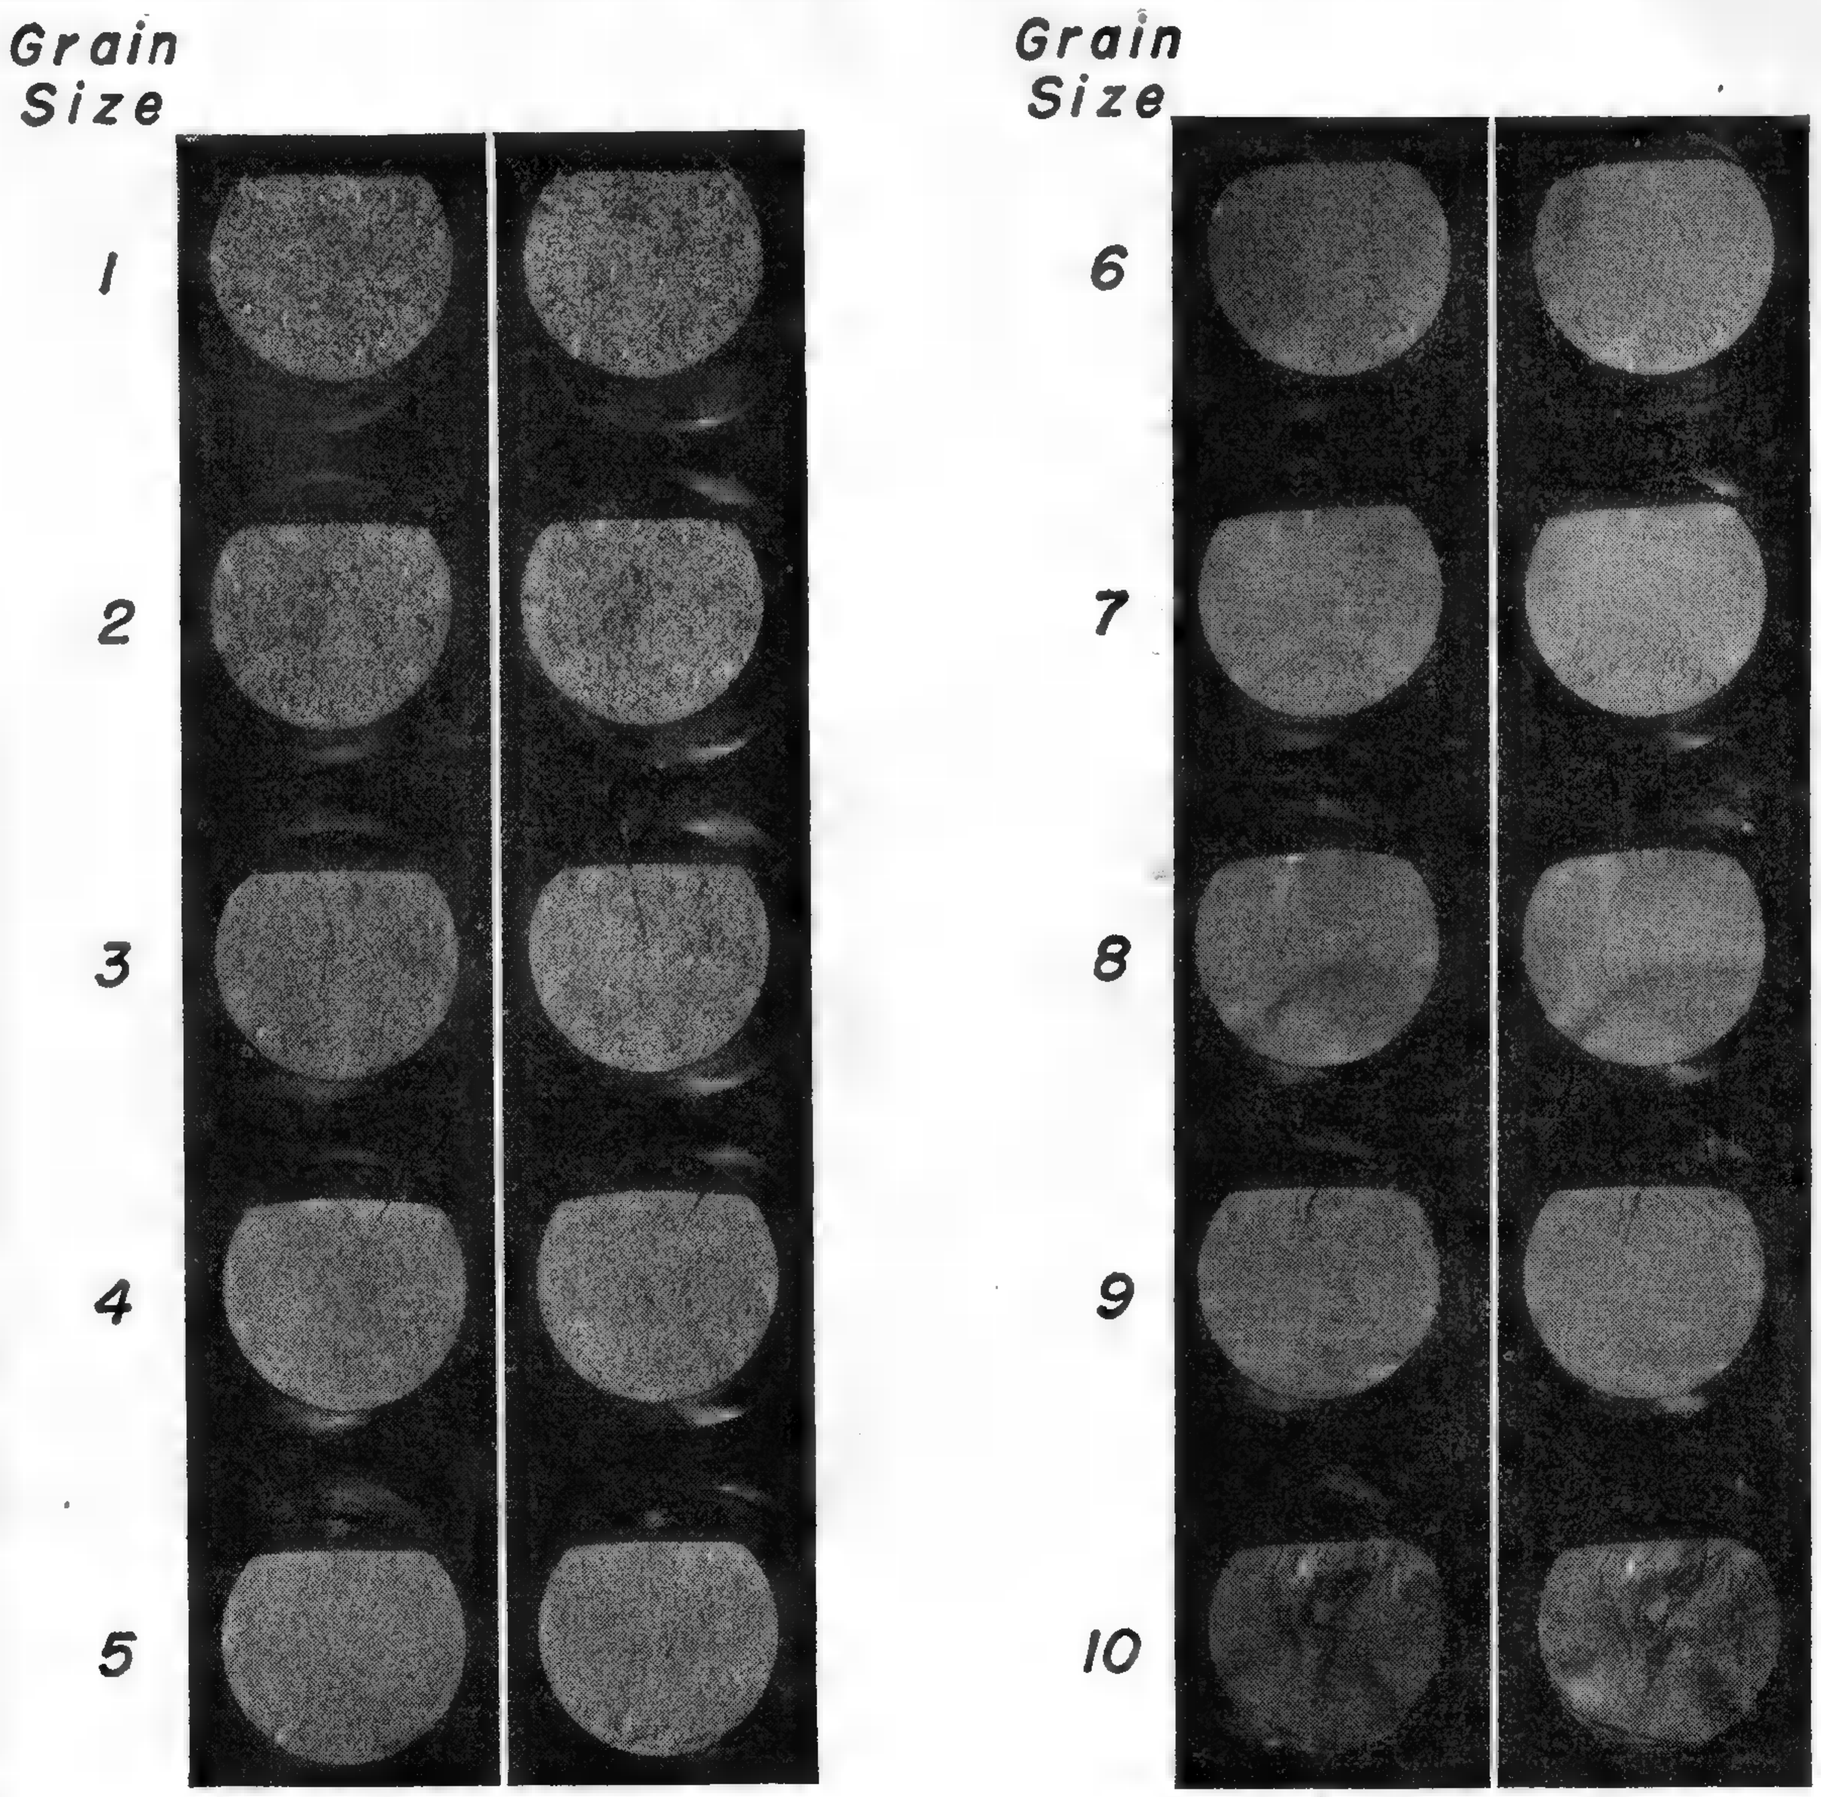

Fig. 6 Shepherd grain size fracture standards

These photographs may be viewed to obtain a three-dimensional or stereoscopic effect by placing a light piece of cardboard, 6 to 10 in. square, so that one edge rests on the center line between the prints and the other edge touches the observer's nose. The eyes should then be adjusted so that there appears to be only one print rather than two. The lighting should be adjusted so that the intensity on each side is approximately the same.

(Metal Progress Data Sheet 78, 1946; stereoscopic photographs by George K. Manning)

Center Porosity. When porosity results from an actual discontinuity within the metal, the defect should probably be classified as "pipe". Usually, however, the porosity is of such a nature that it is not visible until the specimen has been etched. This condition can be found in widely varying degrees, and the question of whether the steel should or should not be used is one for experienced judgment (Fig. 7).

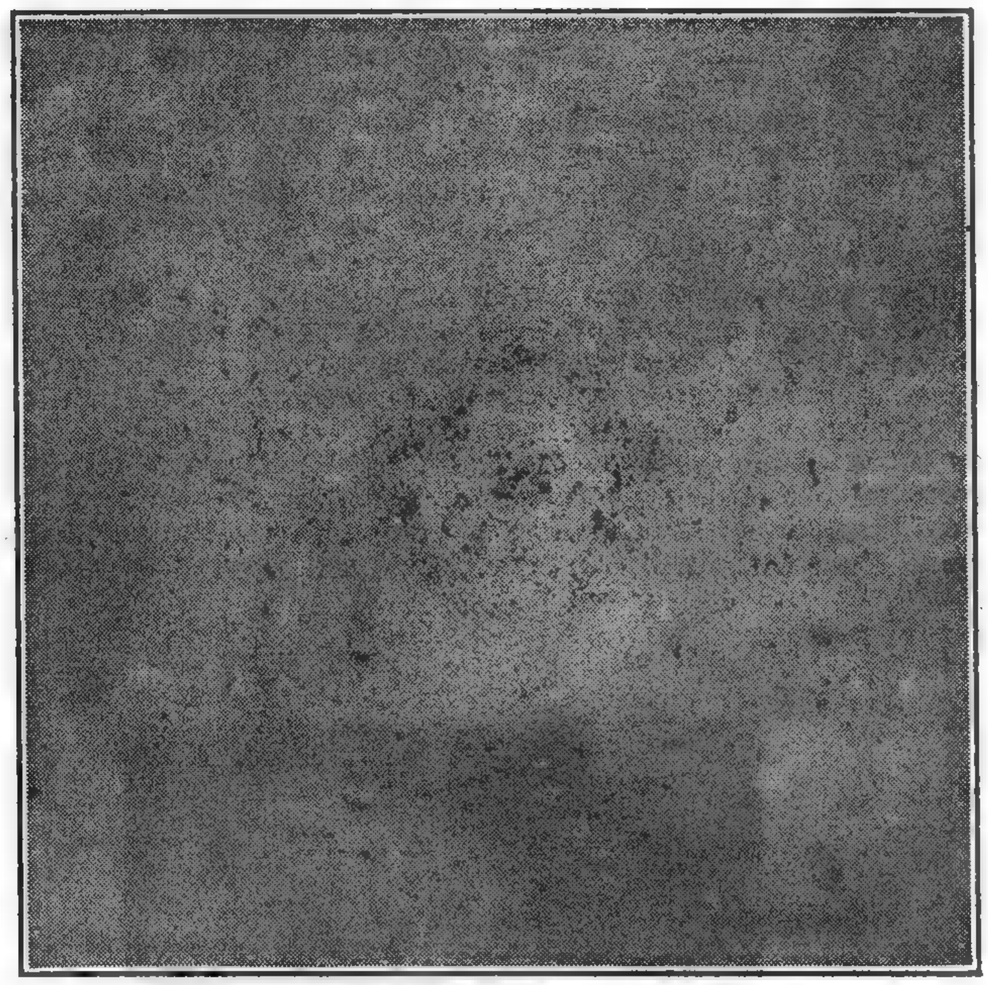

Fig. 7 Porosity

Pipes, Bursts and Center Segregation. Usually such defects are visible before deep etching. After etching, it is often possible to distinguish among the three by the degree of sponginess surrounding the defect. Piped material usually shows considerably more sponginess than burst material (Fig. 8, 9); Fig. 10 illustrates center segregation.

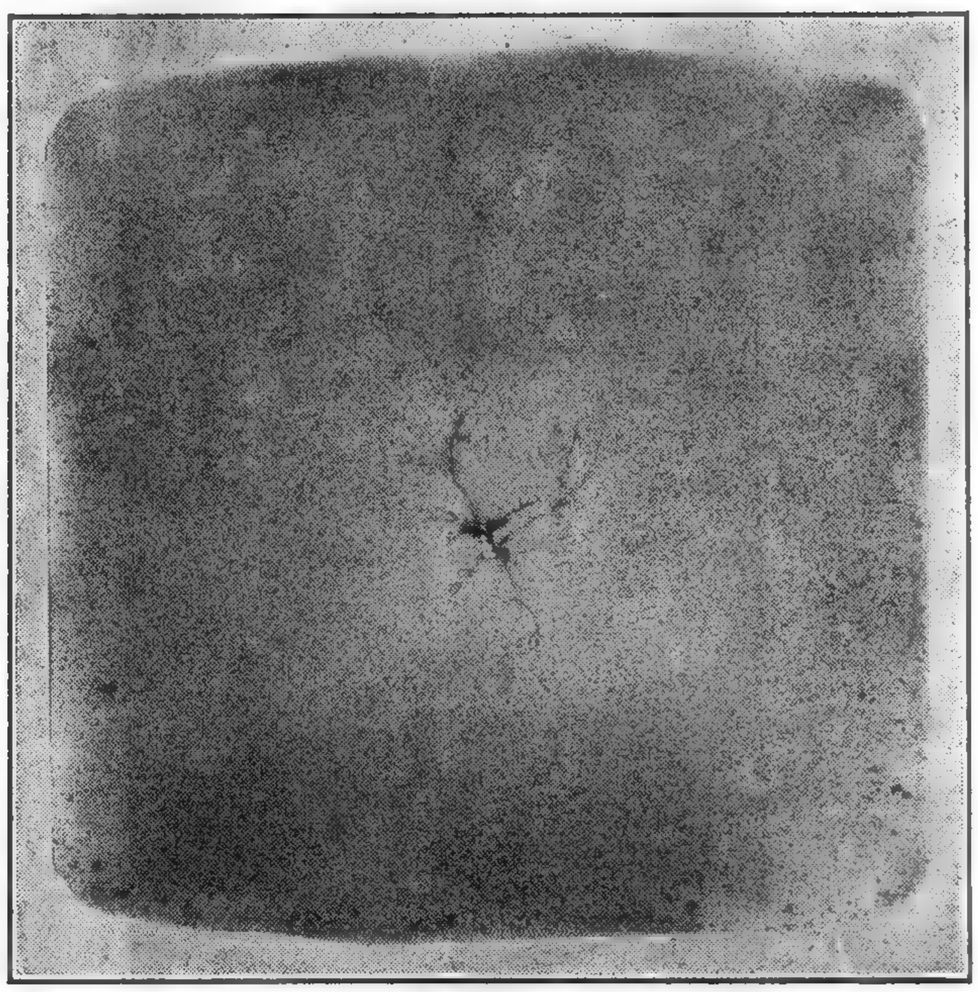

Fig. 8 Pipe

Unsound Steel. When numerous blowholes and nonmetallic inclusions are visible as a result of the deep etch, they usually indicate that both gases and oxides were distributed throughout the steel at the time of casting.

*Nonmetallic Inclusions and Metallic Segregates.** In killed steels, nonmetallic inclusions usually appear as pits, which should not be confused with pits that occur from the etching out of metallic segregates. When the presence of nonmetallic inclusions is suspected in highly alloyed steels that may contain metallic segregates, a comparison should be made of an annealed specimen and a hardened specimen etched alike. If the etching pits are the result of nonmetallic inclusions, the appearance of them will be similar in both the annealed and the hardened specimens; if they are the result of a metallic segregate, they will differ. Microscopic examination is preferable for determining the true character of the segregates.

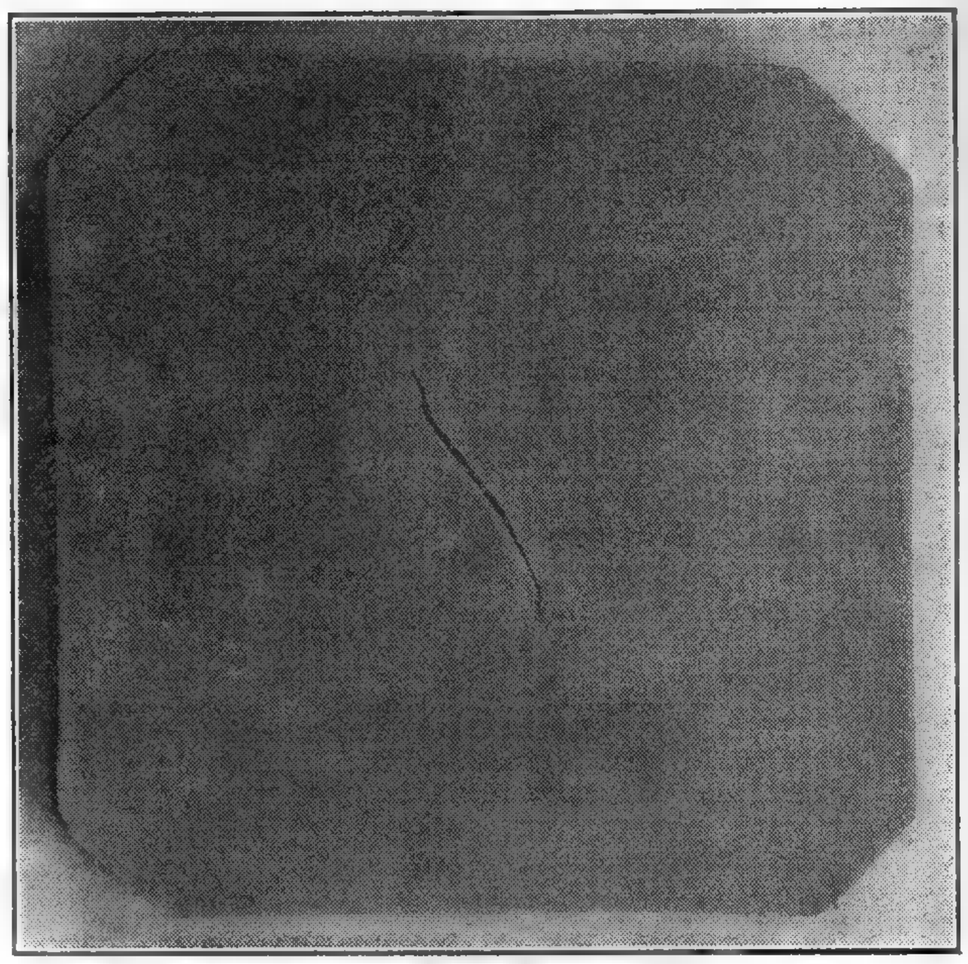

Fig. 9 Hammer burst in high speed steel

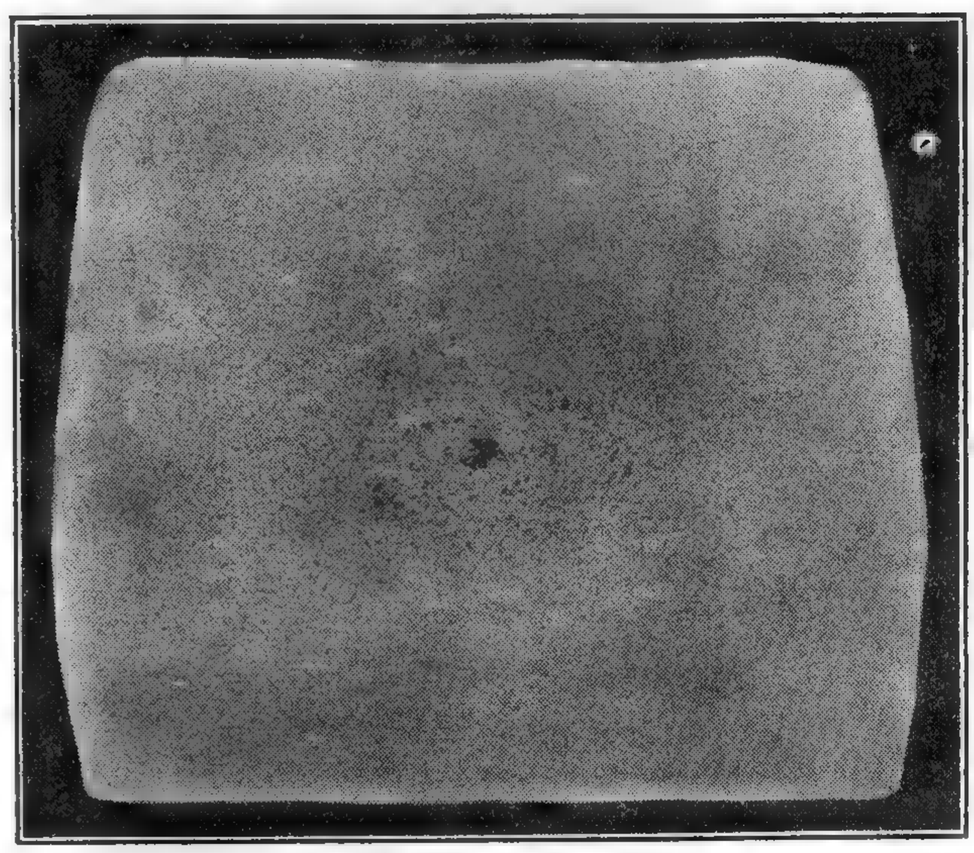

Fig. 10 Center segregation

Internal Cracks. Internal cracks, sometimes called "flakes" or "cooling cracks", can often be observed as the result of the deep-etch test. These cracks are an actual

* *See also* the article "Nonmetallic Inclusions in Steel", page 445.

discontinuity in the metal and, depending on their nature and distribution, may make the steel unfit for use (Fig. 11).

Dendritic Structure. Etching often reveals a dendritic structure, which is the result of the manner of crystallization of the ingot. A dendritic structure is not detrimental

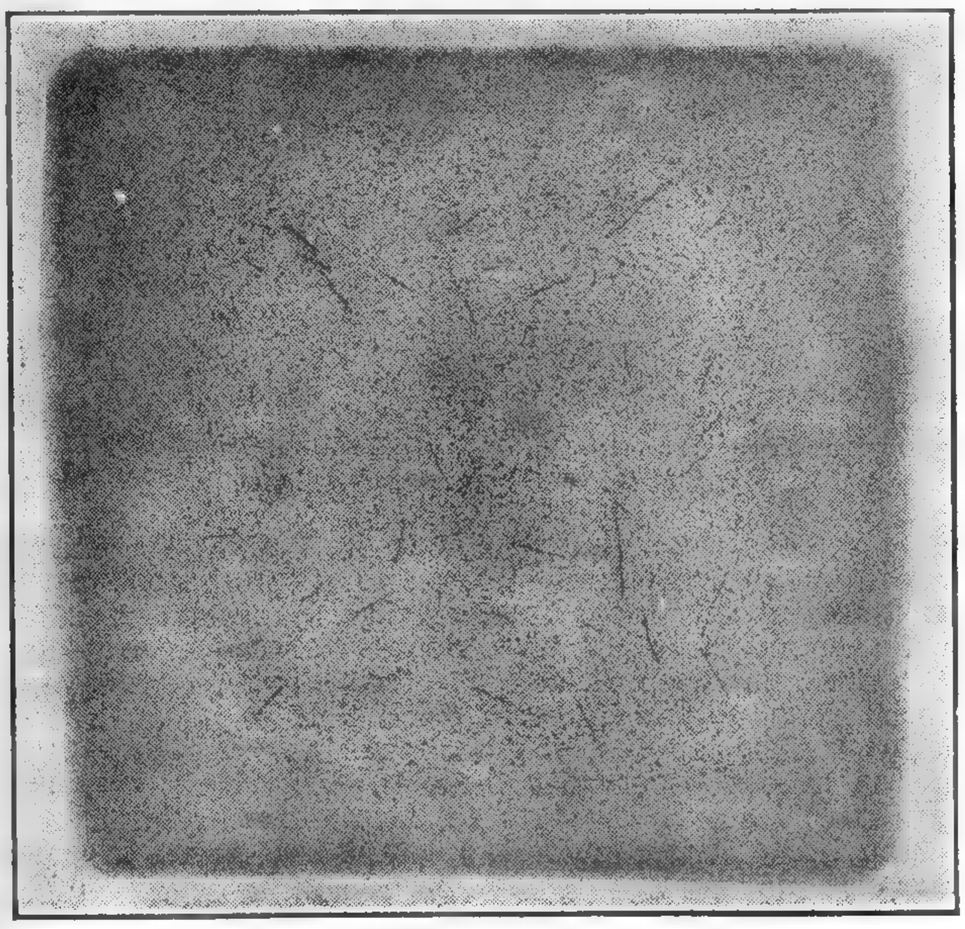

Fig. 11 Cooling cracks

in most instances. The permissible degree depends on the application (Fig. 12).

Pattern Effect. Pattern effect is caused almost entirely by the crystallization of the ingot and generally results when the part of the bar that was the columnar structure of the ingot etches differently from the part that was the granular structure of the ingot. If the steel contains

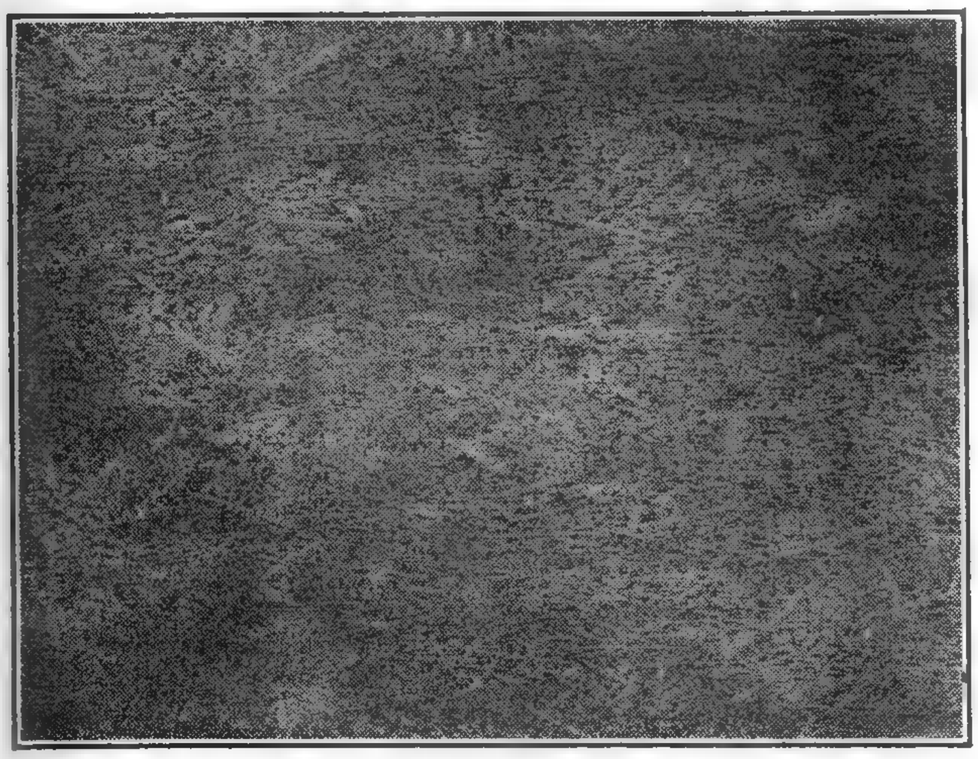

Fig. 12 Dendritic structure

numerous sulfide and silicate inclusions, then the area of contact between the columnar structure and the granular structure may be particularly noticeable. In the absence of large amounts of sulfides and silicates, the pattern effect probably has no serious consequence (Fig. 13).

Grain Size. Although the etch test is of no definite value in determining grain size, nevertheless the manner in which many specimens etch may indicate something of the grain size. Generally, the larger the grain, the coarser is the appearance of the etched surface.

Decarburization and Carburization. Ordinarily the areas that have been either decarburized or carburized, etch differently from the remainder of the specimen; the chief difference is usually in color. Decarburized parts appear lighter in color and carburized parts appear darker (Fig. 14).

Hardened Case. In shallow-hardening steels, a contrast

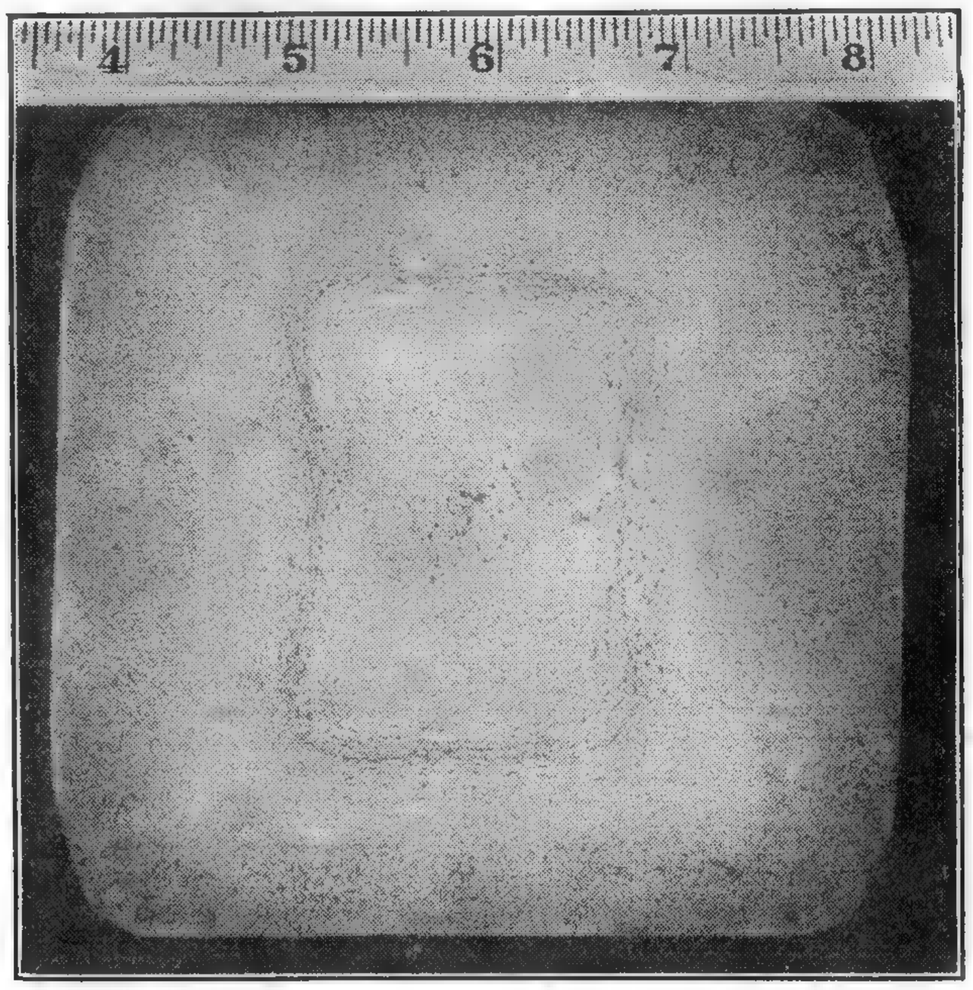

Fig. 13 Ingot pattern

in color between the case and the core appears as a result of mild etching (Fig. 15).

Flow Lines From Forging or Rolling. When subjected to macro-etching, often a longitudinal section shows flow lines because of the elongating of structural constituents. Such flow lines, always more or less visible, indicate the directions in which the steel was worked and do not signify defective material (Fig. 16).

Surface Defects. Seams, laps, cooling cracks and other

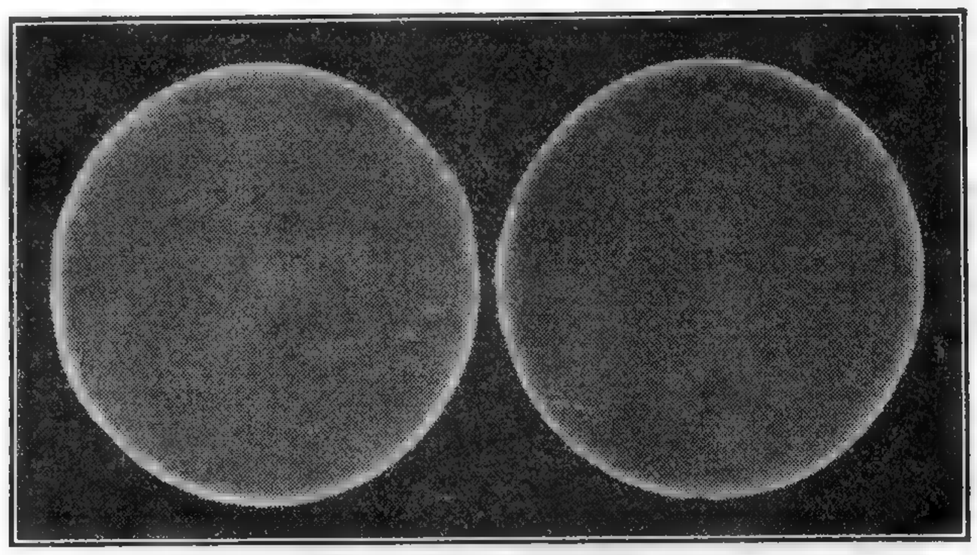

Fig. 14 Decarburization

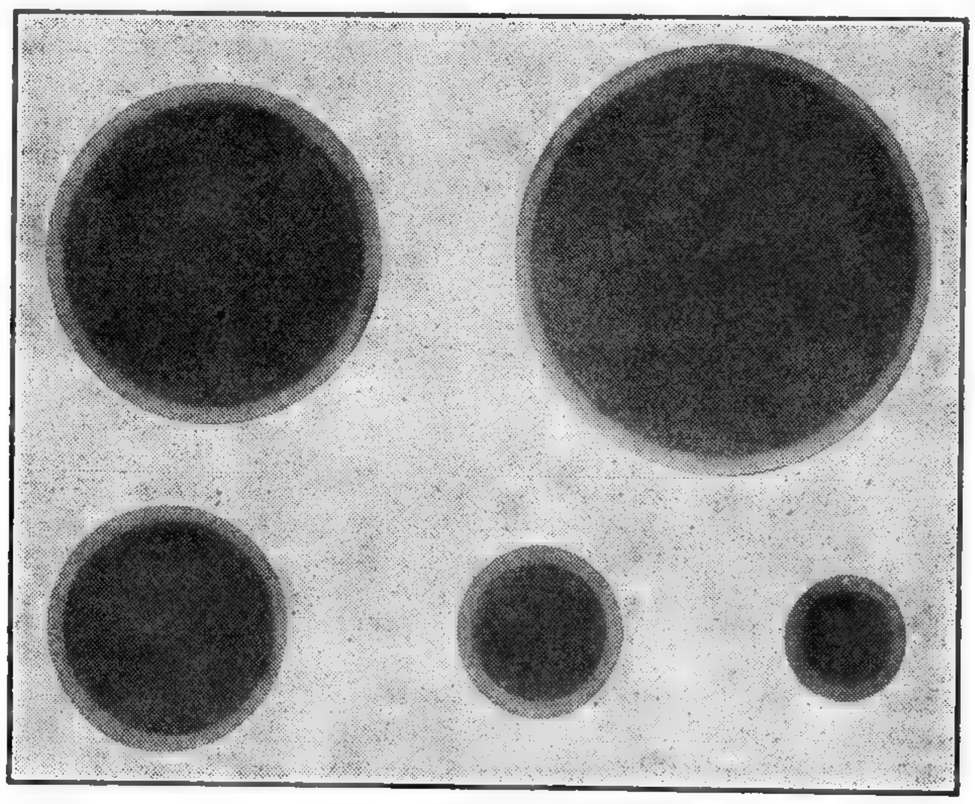
surface defects are revealed and exaggerated in the surface of bars that have been deeply etched (Fig. 17). Therefore, a short-time etch is recommended.

Soft Spots. Soft spots, which often are present after hardening of carbon or low-alloy tool steels, can be distinguished readily by the macro-etch test. The soft spots invariably etch in relief and are not so dark in color as the harder surrounding areas (Fig. 18).

Grinding Cracks. Grinding cracks can be distinguished easily by the standard macro-etch and are usually identified by a pattern of some symmetry (Fig. 19).

Grain Size. The "grain size" of a tool steel usually refers to the size of the austenite grains formed when the steel is heated to the recommended austenitizing temperatures for hardening. A complete discussion of austenitic

grain size, the significance of it and the general methods for measuring it, are presented in separate articles on page 399 and page 407.



Diameter, inches	Chill Penetration, inch	Rockwell C Hardness of Chill	Rockwell C Hardness of Core
2½	10/128	67	35
2	11/128	67	36
1½	12/128	67	37
1	13/128	67	39
¾	14/128	67	41

Fig. 15 Hardness penetration in different sizes of 0.80% C shallow-hardening tool steel

For the determination of grain size in tool steels, the following methods are recommended:

1 The sample is fractured, and the exposed grain structure is compared with the standard (Fig. 6), visually or at a low magnification. The fracture number of the standard that the sample matches most closely is designated as the grain size of the sample. Care must be taken to fracture the sample cleanly, exposing the true grains and not the distorted ones that were pulled apart rather than cleaved. Although particularly well adapted to the carbon tool steels, this test will give a reliable measure of the grain size of any tool steel.

2 The so-called "intercept method" for measuring the austenitic grain size was developed by Snyder and Graff. This method is widely used on high-alloy tool steels such as high speed steels and high-carbon high-chromium steels, because it offers an open scale of measurement in the range of fine grain size. This makes for sensitivity to

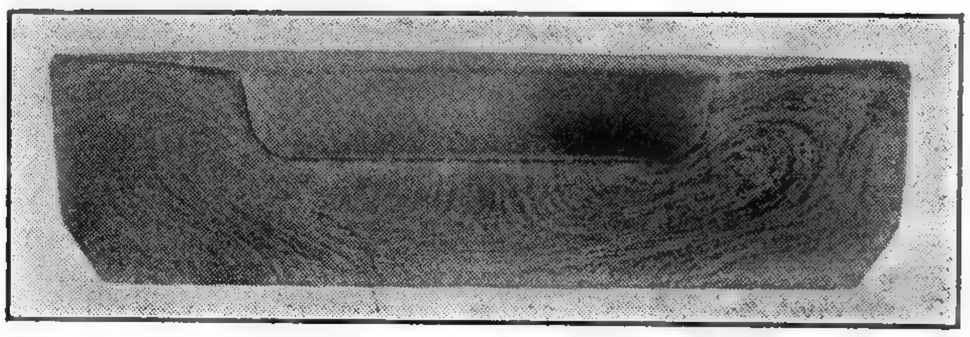


Fig. 16 Flow lines

the slight changes in fine grain size that these steels exhibit and that other tests might not detect. The test may be applied to any steel having prior austenite grains that can be outlined by an etching reagent on a metallographic surface. The sample to be tested is polished as for microexamination, and etched. In the as-quenched state, high speed steel, for example, can be etched in the stronger nital solutions (5 to 10% HNO_3 in alcohol). If the sample has been tempered so that the dark martensite would obscure the grain, hydrochloric acid, added to the nital, will generally attack the grain boundaries sufficiently to leave them defined, after a light repolishing. The sample is then examined through a microscope. The average num-

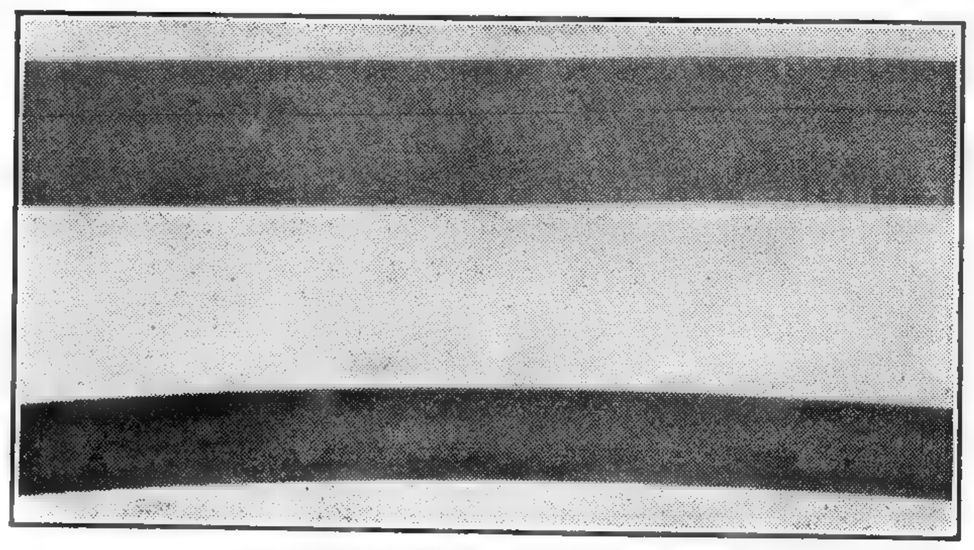

Fig. 17 Surface defects (rolling laps)

ber of grains intercepted by a 0.005-in. line on the sample at ten random points is the grain size of the sample. These counts are usually made by observing the image at ×1000 on the ground-glass screen of the metalloscope, upon which a 5-in. line has been drawn. Illustrations of typical effects of austenitizing temperatures on the intercept grain size of 18-4-1 high speed steel are shown in Fig. 20 to 23. In general, intercept numbers above 15 designate a very fine grain size; from about 12 to 15, a fine grain size; from 9 to 11, a fairly coarse grain size; and 8 and lower, a coarse grain size.

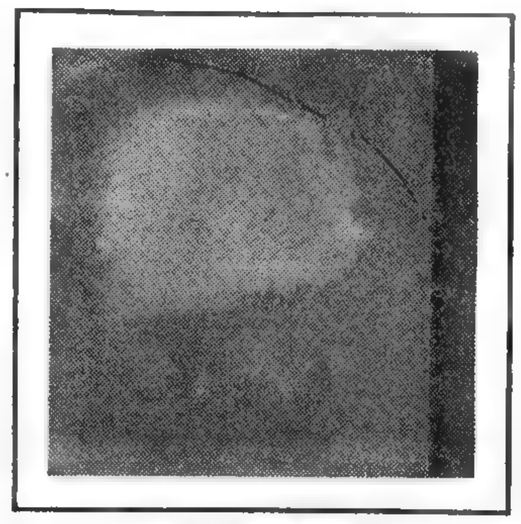

Fig. 18 Soft spot

The knowledge of grain size in tool steels has become increasingly important in recent years, because the actual grain-size number may be used to advantage for the following purposes:

a A guide to determine the correctness of a given heat treatment.
b An indication of toughness (fine grain size is usually associated with improved toughness).
c In conjunction with other tests, such as microexamination, as an aid in establishing the sensitivity of a given steel to heat treatment; that is, a stable grain size over a range of austenitizing temperatures usually indicates a wide range of hardening temperatures.
d An indication of variation in composition or structure, as in a decarburized area, which will have a different fracture grain size and a different luster.

Microscopic Tests. The examination of polished sections of tool steel under the microscope is a common method

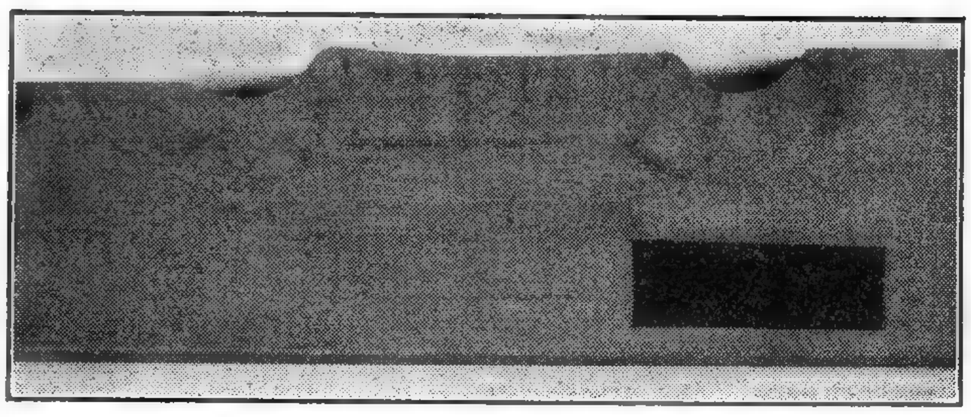

Fig. 19 Grinding cracks on hardened die steel

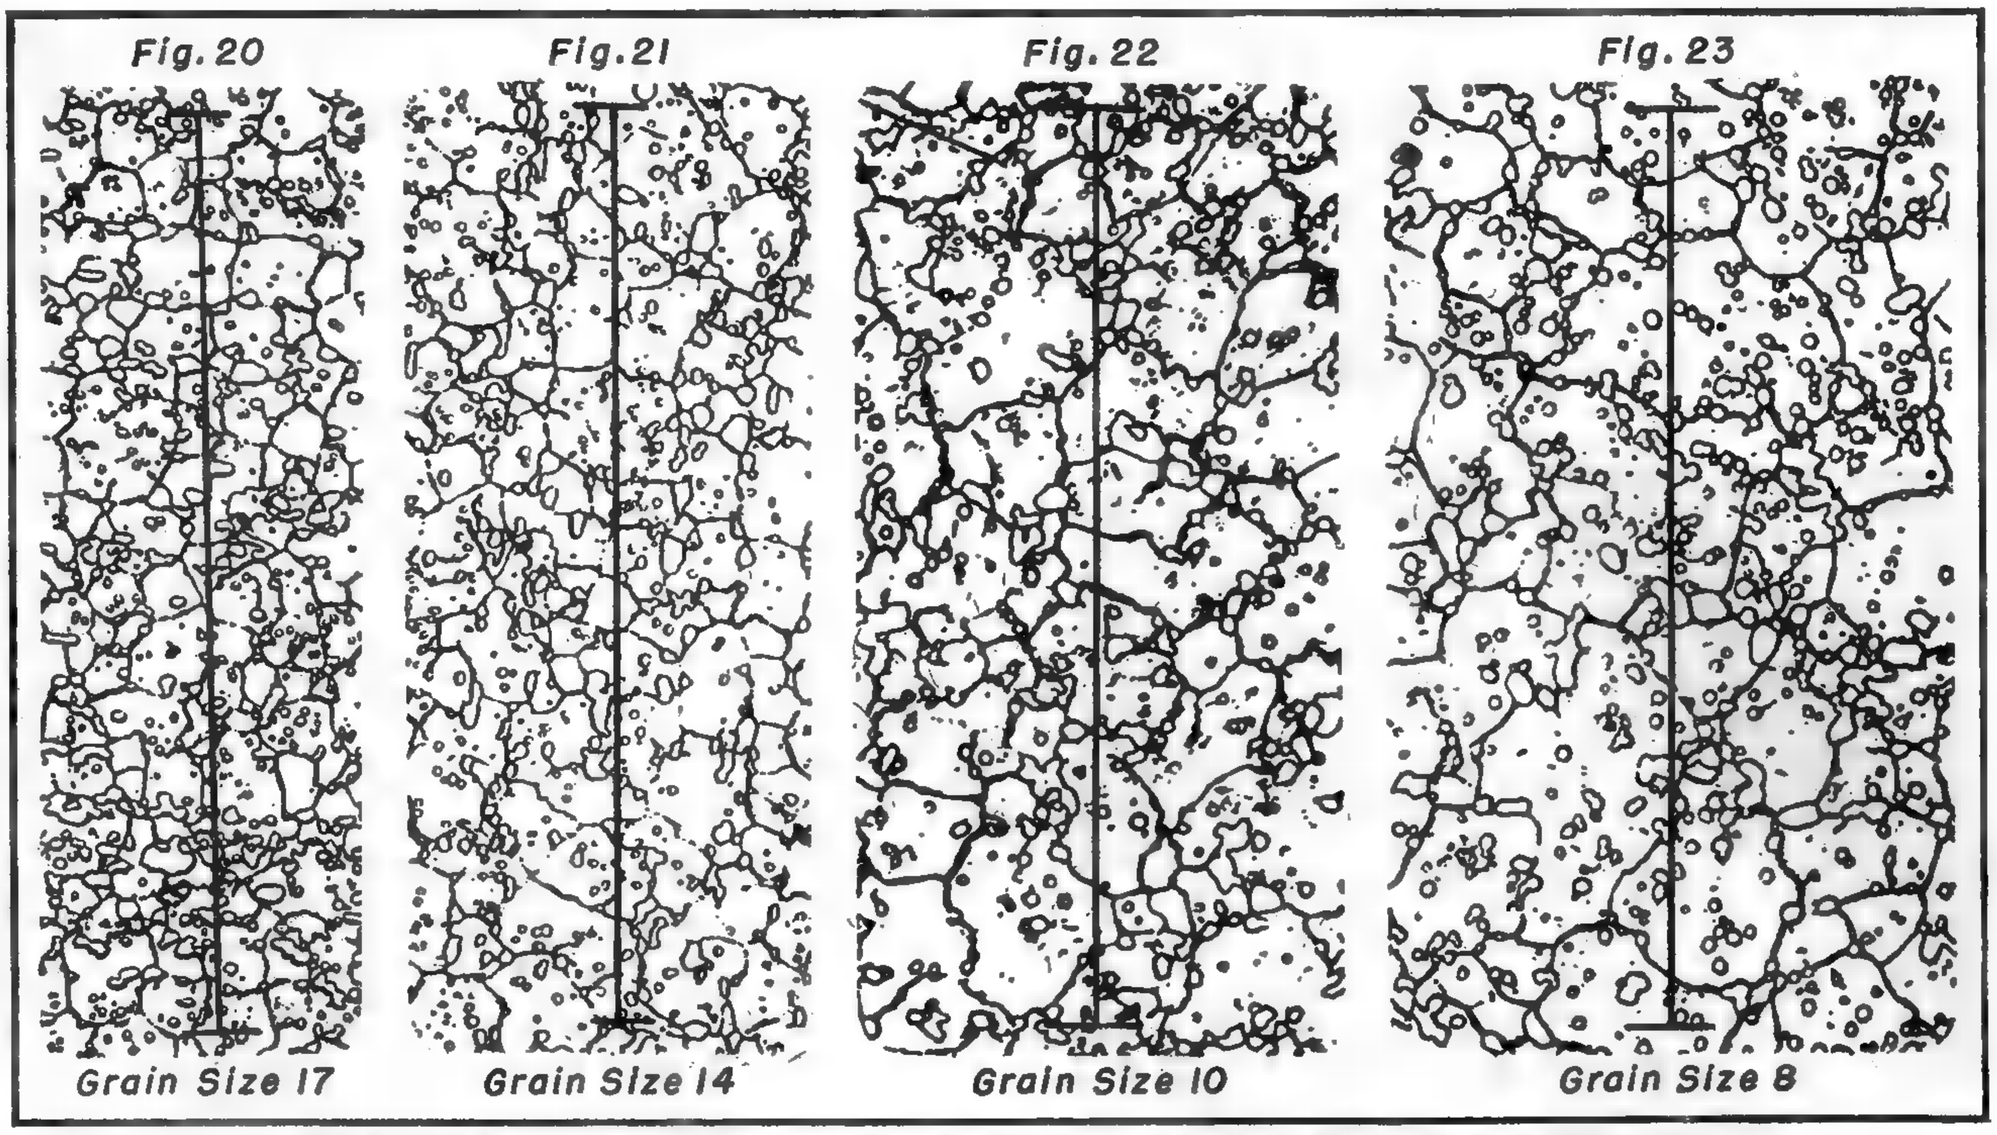

Fig. 20 to 23 Austenitic grain size determined by the intercept method. Specimens were 18-4-1 high speed steel, as quenched. (Original magnification, 750; reduced 20% in reproduction)

used in connection with the inspection of tool steel, the investigation of tool failures, and various research problems.

Cutting, grinding and polishing equipment required for this work is described in the article on page 159. Etching reagents are listed on page 394.

The avoidance of polishing pits and scratches in tool steels is not so difficult as in soft steels. Polishing pits are sometimes mistaken for inclusions and careful polishing is essential for best results. For the etching of tool steel specimens, the use of a solution of 2 to 5% HNO_3 in alcohol is generally applicable. Somewhat stronger solutions may be used for highly alloyed steels.

In the microexamination of tool steel, a microscope with a magnification up to 1000 diam should be satisfactory for all ordinary requirements.

By examination under the microscope, it is possible to determine a number of factors that may affect the quality or performance of tool steel. Among these may be mentioned grain size, effect of heat treatment, structural constituents, size and distribution of carbides, nonmetallic inclusions, and segregations.

Grain Size. (*See* page 415 in this article.)

Effect of Heat Treatment. The most common method of checking the prior heat treatment of tools is by the examination of hardened fractures, but microexamination of hardened structure is more accurate. In instances where steels develop a largely martensitic structure when hardened, the size of the martensitic needles may be considered a measure of the austenitic grain size after a given heat treatment. A structure with enlarged martensitic needles is associated with overheating (*compare* Fig. 24 and 25).

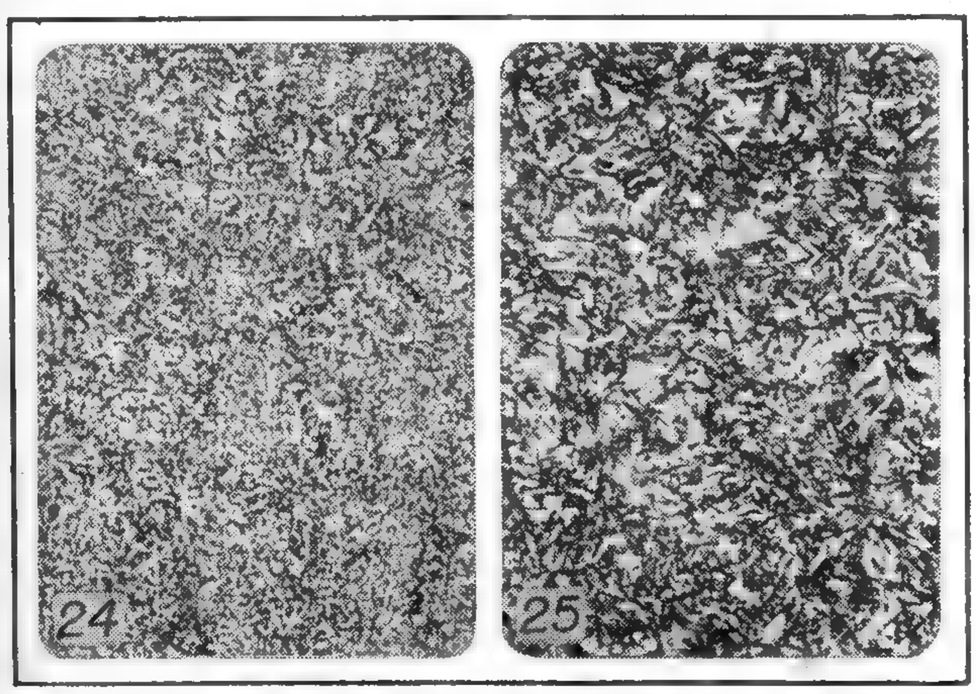

Fig. 24 Manganese oil-hardening steel properly hardened showing a fine martensitic structure. × 500

Fig. 25 Manganese oil-hardening steel, overheated in hardening, showing martensitic structure with enlarged needles. × 500

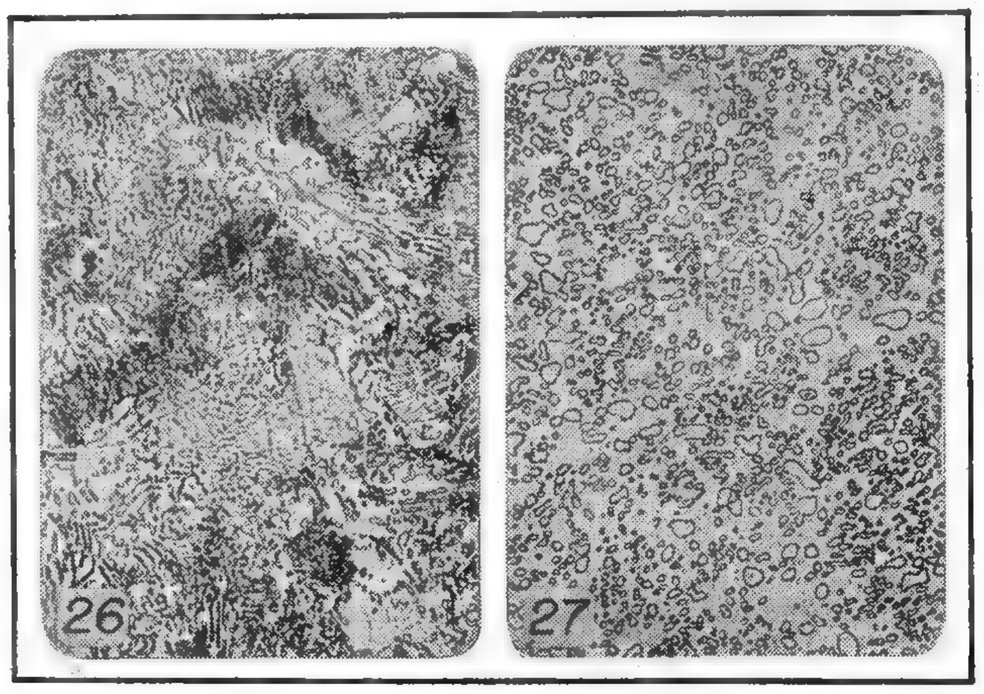

Fig. 26 Carbon tool steel, not fully annealed, with partially lamellar pearlitic structure. × 500

Fig. 27 1.0% carbon tool steel, fully annealed, with carbides spheroidized. × 500

On the other hand, partial or complete absence of martensite, and the presence of numerous small undissolved carbides, may indicate an underheated condition. The relative proportion of austenite, martensite and other constituents sometimes indicates the extent of tempering.

Structural Constituents. A large proportion of tool steels have a comparatively high carbon content and represent eutectoid or hypereutectoid compositions. In such steels, carbide-containing constituents are predominant in the structure. These may be pearlite, cementite, carbide segregate, or other constituents (Fig. 26). Ferrite may exist as a separate constituent in the lower-carbon (hypoeutectoid) tool steels. Also ferrite is the principal constituent of the matrix observed in the examination of the structure of annealed tool steels when the carbides are present in the spheroidal condition (Fig. 27).

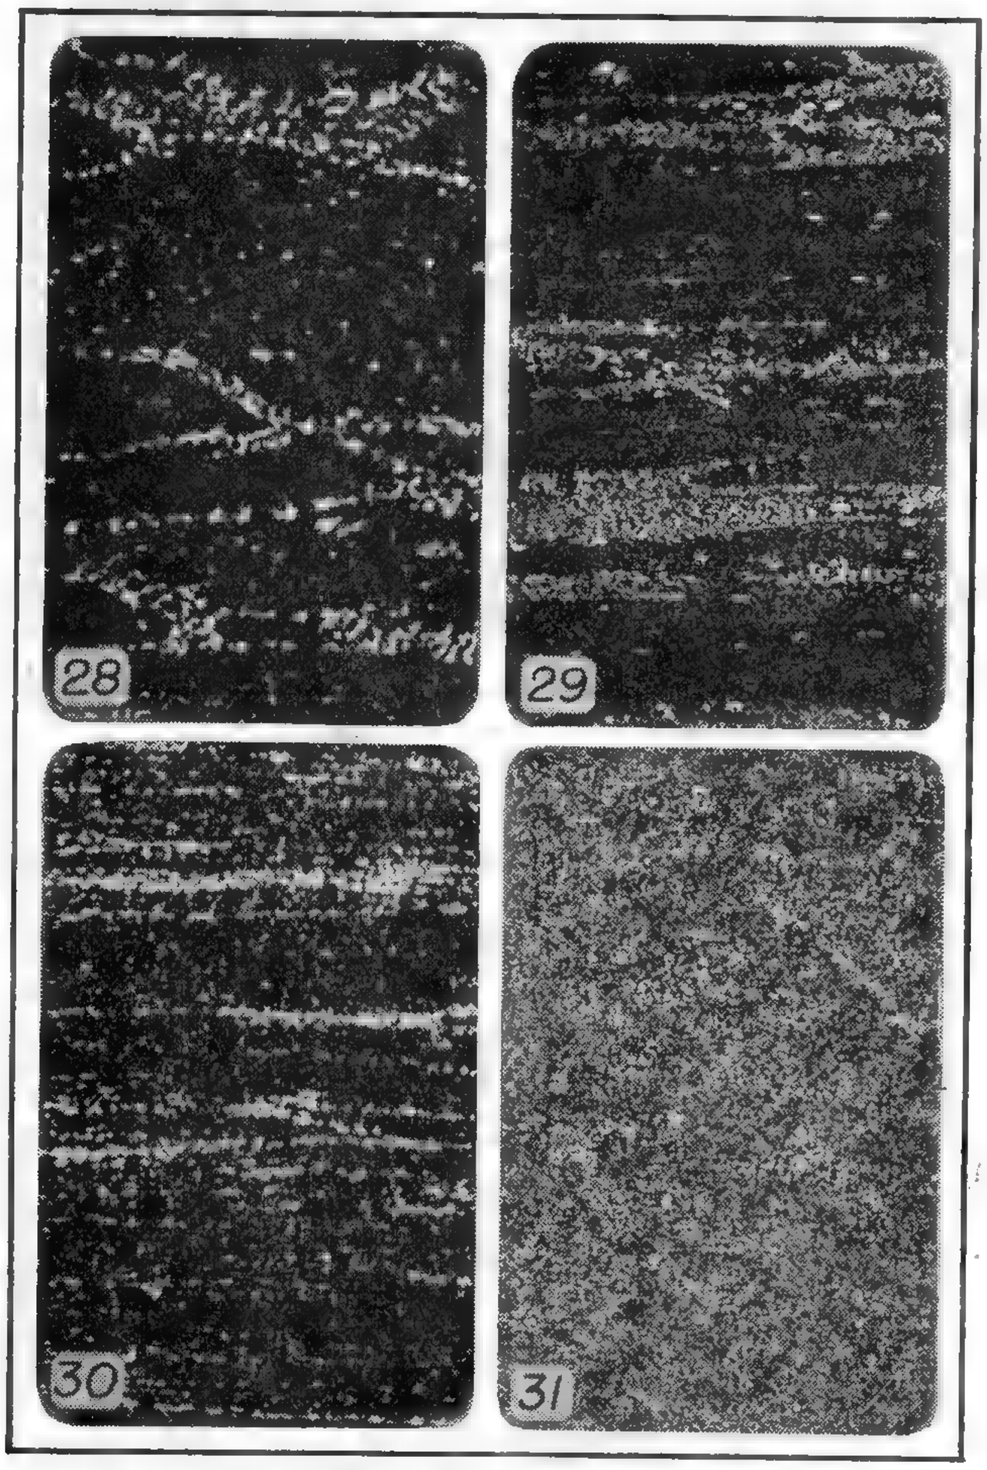

Fig. 28 Section from 6-in. diam bar of 18-4-1 high speed steel showing traces of carbide network. × 100

Fig. 29 Carbide segregation in 3-in. diam bar of 18-4-1 high speed steel. × 100

Fig. 30 Carbide segregation in 1-in. diam bar of 18-4-1 high speed steel. × 100

Fig. 31 18-4-1 high speed steel upset forging, 3-in. diam by 1¾ in. thick, showing uniform carbide distribution. × 125

It may be desired to identify or estimate the proportion of structural constituents of tool steel in the annealed and hardened condition, and sometimes in the hot worked condition. This examination is made on longitudinal or cross sections, usually at 500 diam or more.

Size and Distribution of Carbides. In hypereutectoid carbon tool steels and the more highly alloyed tool steels, such as the high speed and the high-carbon high-chromium types, size and distribution of the carbide segregate affect the quality and may be partly responsible for tool failures. Carbide segregation, the most common kind that may exist in tool steels, is present in varying degrees in the more highly alloyed types, such as high speed and high-carbon high-chromium steels, and less extensively in low-alloy and carbon tool steel. Excessive carbide segregation is objectionable, since it may cause tool failure or difficulty in machining.

The observer must have considerable experience to know what to expect as to uniformity and what is objectionable as to carbide network and segregation in sections of various sizes. Inspection for distribution of carbide is made preferably on longitudinal sections at about 100 diam (Fig. 28 to 31). Size of carbides in low-alloy or carbon tool steels is observed to best advantage at 500 diam or more.

*Nonmetallic Inclusions.** Among the nonmetallic inclusions that may exist in tool steels, are slag or refractory, deoxidation products and various silicates.

Unetched longitudinal sections may be polished and examined for nonmetallic inclusions at 100 diam or more. Steel that tends to pit readily while being polished, should be polished in the hardened condition and examined after the specimens have been etched lightly in nital so that inclusions will show more distinctly (Fig. 32).

Decarburization. The use of the microscope in determining decarburization of tool steels is not recommended because the results obtained are only approximate. More accurate determinations can be made by using a "step-down" test in which successive layers are machined off the surface and are analyzed for carbon content.

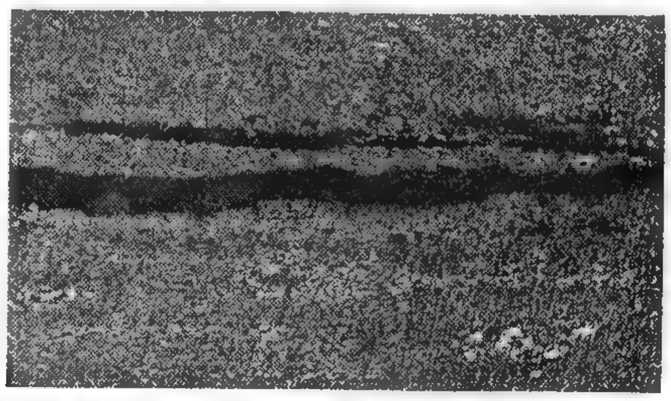

Fig. 32 Large nonmetallic inclusion in high speed steel. × 125

Hardenability Tests. In devising and interpreting tests for the hardening characteristics of tool steel, it is important to consider the type of steel, its application and the method of hardening employed.

Shallow-Hardening and Medium-Hardening Steels. Hardenability is determined by measuring the depth to which a steel will harden during quenching. The carbon and carbon-vanadium steels are typical of shallow-hardening tool steels and the line of demarcation between the hard case and the relatively soft core is quite distinct. Starting with the carbon steel, increasing hardenability can be obtained by the addition of small amounts of such elements as chromium, manganese, silicon and molybdenum. As the hardenability is thus increased, the line of demarcation between the case and the core grows less sharp and, in the extremely deep-hardening steel, is replaced by only a slight decrease in hardness toward the center.

Tests for hardenability are of most value in connection with the shallow-hardening and medium-deep-hardening steels. Because of the wide difference in behavior of these steels, no single test can be adapted to all. Consequently, two types of test—one for shallow-hardening and one for deeper-hardening steels—are suggested here.

For the shallow-hardening steels, a very convenient test is the P-F test (Penetration-Fracture). This consists of hardening in brine four specimens machined to ¾ in. in diam by 3 in. long—one each from 1450, 1500, 1550, and 1600 F—notching each in the middle and fracturing by impact. Then one half of each specimen is examined for the grain size of the case, in comparison with the standard described below. Penetration tests are made on the other half of each sample by grinding the fracture and smoothing it on abrasive No. 0 or finer, etching for 3 min in 1 to 1 HCl at 180 F and measuring the penetration of hardness in sixty-fourths of an inch.

* *See also* the article "Nonmetallic Inclusions in Steel", page 445.

The P-F characteristic is then recorded as numerals. The first four numbers represent the penetration in sixty-fourths, and the last four numbers, the fracture grain size. The first number of each group represents the P-F results for a temperature of 1450 F; the second number of each group represents the P-F for a temperature of 1500 F, and so on. Figure 33 illustrates a typical test; the numbers designate the penetration and fracture values determined for each specimen. This test is especially valuable for measuring the hardening characteristics of a plain carbon steel over a wide range of austenitizing temperatures.

Various precautions must be taken in conducting the P-F test, where results are to be strictly comparable. In the test pieces, the original structure resulting from annealing or pretreatments is important. For general comparisons, since most tools are made and hardened from an annealed bar, it is desirable to make the test on annealed specimens, just as cut from the bar stock. If, however, it is the practice to normalize or in some way to pretreat the tools before final hardening, the P-F tests should be made on specimens that have received these preliminary treatments in order to give an indication of the behavior to be expected from the finished tool.

For accurate results, the time cycle must be controlled carefully, and also the temperature during hardening. Usually the specimens are heated in such a way that the total time in the furnace is 25 min for each temperature. These conditions can be obtained with considerable uniformity by using a relatively large furnace, heating it to the desired final temperature, introducing the specimens, and bringing them up to temperature without allowing the furnace temperature to decrease.

For uniform results, specimens should be placed on a suitable vertical jig and quenched in a flush that contains 10% brine.

Other methods applicable for measuring the hardenability of shallow-hardening and medium-hardening tool steels include (1) the cone tests, described in Trans ASM, **30**, 1202 (1942); (2) the wedge tests, described in Trans ASM, **35**, 584 (1945); (3) the Jominy L-test; and (4) the Shepherd P-V test, described in Trans ASM **38**, 354 (1947). (*See* also "Hardenability Tests", page 489.)

Deep-Hardening Steels. For the determination of hardenability on the deeper-hardening steels, the ¾-in. diam specimen employed in the P-F test cannot be used, since this section would harden all the way through. For such deep-hardening steels, the Jominy end-quench test (*see* article on page 489) has been found much more satisfactory and is generally used. The end-quench test is not applicable to air-hardening steels.

Other Tests Relating to Hardening. *Uniformity of Hardening.* Soft spots are peculiar to tool steels of the shallow-hardening type, because of improper quenching conditions. Misleading information will be developed if standardized methods of quenching are not employed in making a test to determine the uniformity of hardness in these steels.

A hardened sample, tool, or part, may be tested by etching the polished surface with hot 1 to 1 HCl or 10% HNO_3 in alcohol at room temperature. Areas of variable hardness will etch light or dark and may be explored by standard hardness testing methods. Another method is to grit-blast the hardened pieces. This treatment will make the soft spots show up as dark, rough areas.

Susceptibility to Hardening Cracks. A number of tool steels are susceptible to hardening cracks, which result from composition, prior treatment or variables of manufacture. In determining this characteristic in steels of similar composition, it is important that a standardized temperature, time of heating, and quenching cycle be employed. To locate hardening cracks, a properly hardened specimen, tool, or part may be examined magnetically as described under "Magnetic Particle Inspection" on page 145. An alternative method requires the etching of the piece in hot 1 to 1 HCl, 10% HNO_3 in alcohol, or a 10% solution of ammonium persulfate in water, at room temperature.

Sensitivity to Grain Growth. Difference in sensitivity to grain growth may be observed in tool steels when they are heated to different temperatures above the transformation range. This characteristic depends on composition, variables of manufacture, and heat treatment.

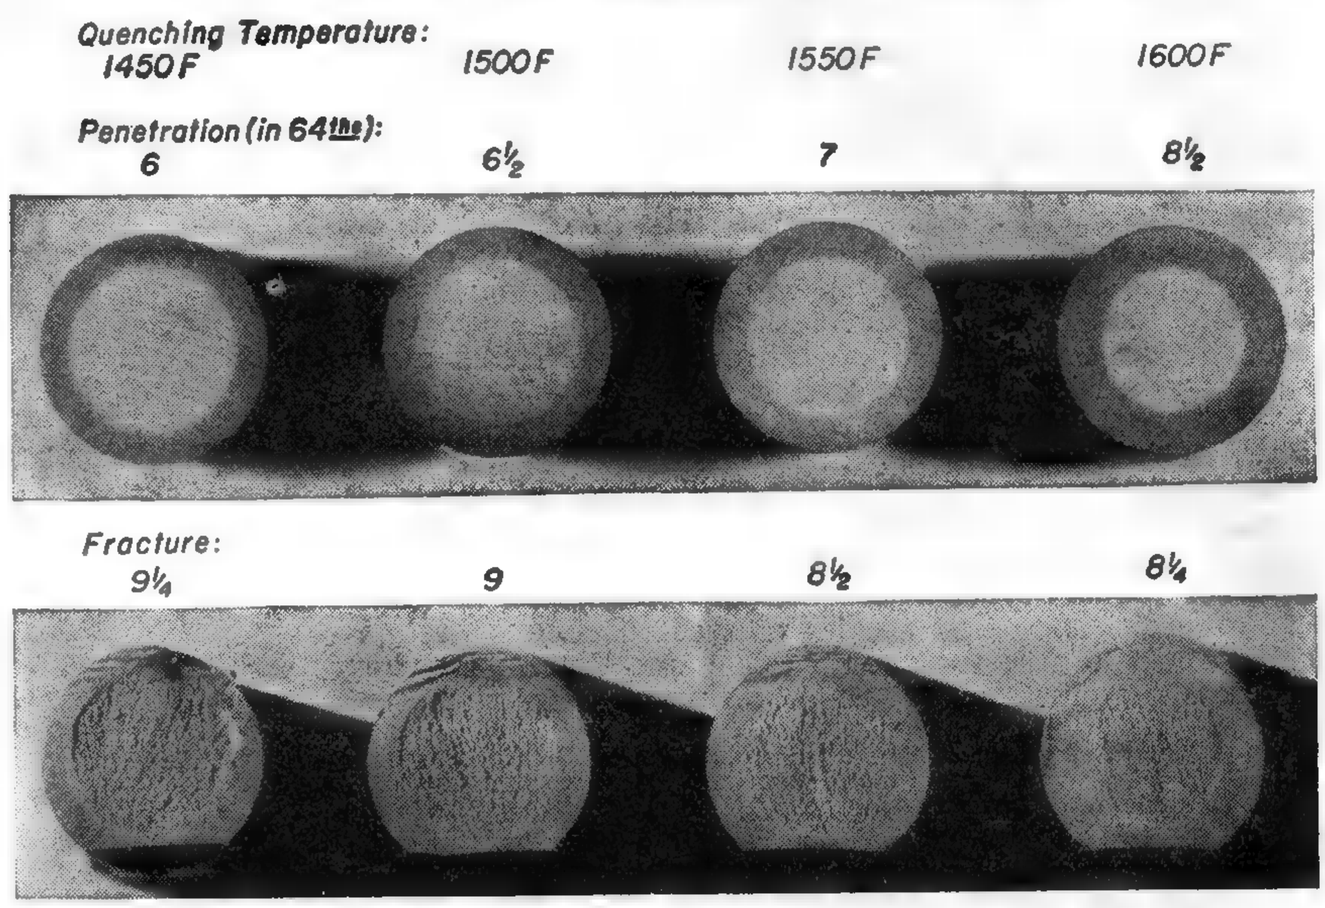

Fig. 33 Etched sections and fractures in P-F test on carbon tool steel

A simple test involves the hardening of test pieces (as described under Hardenability) from various temperatures at and above the customary hardening temperature for a given lot of steel. The pieces are fractured and then compared with a standard or examined microscopically.

Susceptibility to Soft Surface. Several types of tool steel are susceptible to soft surface. Differences between types may be determined by hardening samples of the respective lots from their normal quenching temperatures, after which accurate hardness tests may be made. In testing steels of similar composition, it is important to employ a standardized temperature, correct furnace atmosphere, correct time of heating and suitable quenching procedure. The depth of the soft surface may be measured by a repeated cycle of uniform grinding and hardness testing.

Cutting Tests. The reader may refer to the paper by F. W. Taylor, "On the Art of Cutting Metals", Trans ASME, **28**, 31-279 (1907) and to the recent ASA Standard B 5.19-1946, Life Tests of Single-Point Tools Made of Materials Other than Sintered Carbide.

Machinability. The only practical test for machinability is one based on actual machining operations.

Machinability is not a definable property of tool steel because "machining" may involve a dozen or more different operations, such as turning, tapping, reaming, drilling, broaching, threading, or backing off. Each of these different operations is further complicated by the requirements of the job. For example, milling of the flutes in a tap might require that no burr be thrown up on the teeth, but no such requirement would be imposed for milling the flutes on a reamer. Drilling large holes does not involve the same problem as drilling small holes, and the drilling of gun barrels introduces still other problems. A delicate backing-off operation may dominate all other machining requirements in making certain tools.

Each user must therefore determine which condition in the tool steel produces best machinability for his own particular purpose. Certain tests can be decided on, including chemical analysis, hardness and microstructure, which can reasonably be expected to reproduce the desired machinability. For any given type of tool steel, incoming material can be inspected for machinability by testing the hardness and microstructure and comparing them with standards that have been approved for satisfactory machinability.

Testing of Dimensional Stability. All tool steels change in specific volume during heat treatment. This distortion is affected by the rate of heating, time at the quenching temperature, rate of cooling, tempering time and temperature, design of the part, and characteristics of the steel. Obviously, in any attempt to compare steels for "nondeforming" qualities, all other variables must be controlled.

There should be no difficulty in maintaining uniform rates of heating for test specimens. The holding times and rates of cooling will naturally vary with the type of steel, since some steels must be hardened by quenching in water or brine, others in oil, air blast or still air. The rate of cooling, however, should be uniform when steels of the same type are to be compared.

The hardness resulting from treatment is also important, since a steel hardened to a low hardness will distort less than the same steel hardened to a high hardness. Although uniform rates of heating and cooling should control distortion to some extent, a standard range of hardness for various types of steel should be used.

Numerous sizes and shapes of test specimens are possible, and the observer should select one that most nearly meets his requirements. The following four are suggested:

1 A section of annealed steel may be machined to ¾ in. in diam by 3 to 5 in. long. After machining, the specimen should be stress relieved by heating to a temperature just below the transformation range, and cooling slowly. The specimen should then be ground and measured accurately for length and diameter. A standard uniform heat treatment should be used, with care to avoid scale. The dimensions may be rechecked before and after tempering if desired.
2 A ring 2½ in. OD by 1¼ in. ID by ¾ in. thick may be prepared and handled in the manner of Test 1.
3 Flat specimens at least 6 in. sq by 1½ in. thick are especially valuable as an indication of the distortion that may occur in steels used for large dies. In this test, the specimen may be prepared as described above, but the measurement involves checking the face of the specimen for flatness to determine the extent to which the surface has become convex or concave.
4 Figure 34 illustrates a specimen of nonuniform section sometimes used for tests of distortion. Preparation of this specimen should be similar to that suggested for Test 1. The accuracy of this test is doubtful because slight changes in rates of heating and cooling have a greater effect on the distortion.

Fig. 35 and 36 Compression-test specimens for tool steel. With both specimens, trim *D* to about 0.020 in. oversize. After hardening, grind *D* to 0.505 ± 0.0005 in. Grind both ends square and parallel with no centers. Use special care in finishing radii of specimen in Fig. 36.

Compression Testing.* Generally the object of compression testing is to determine stress and deformation under load, and the load necessary to produce failure. For tool steel, determination of the load necessary to produce failure is all that is usually required. The test is used mostly in solving problems of tool design, or in comparing one type of steel with another, or one heat treatment with another. The material is tested in the hardened condition.

Figures 35 and 36 show types of specimens that have been used. The form in Fig. 36 is usually preferred. The method of carrying out the test is illustrated by Fig. 37. The following precautions are essential:

1 One bearing block must be provided with a spherical seat.
2 The specimen and bearing blocks must be centered accurately on the table of the machine so that the line of pressure will pass through the axis of the specimen, bearing blocks, and testing machine.
3 The load must be applied at a uniform rate, generally less than 0.02 in. per min.
4 Full protection from flying pieces must be provided.

The drop of the beam or dial pointer is usually taken to indicate ultimate failure. It is recommended that the test be stopped at this point. The load at rupture may be somewhat higher, but is considered to be without significance because of the radical change in shape and dimensions of the test specimen. For more complete particulars the reader may consult references 1, 2 and 3, and the article on page 109 in this Handbook.

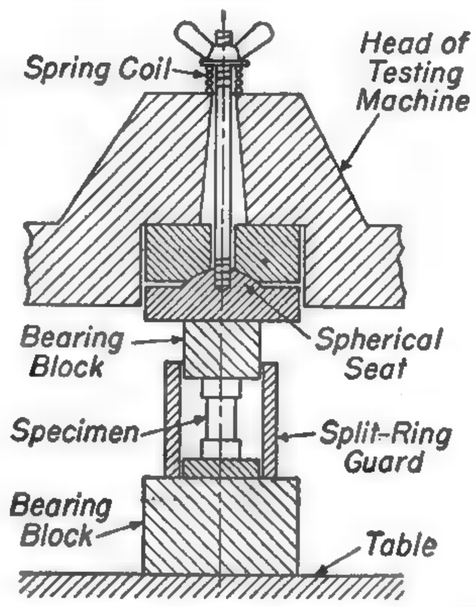

Fig. 37 Method of making compression test

For measuring the resistance of a superficially hardened object to local crushing or sinking under load, two methods have been used. In the first, a plain cylindrical hob is pressed into the object to be tested. After each increase of load is applied, the hob is removed and the piece is examined. The load at which the first signs of permanent sinking occur, is taken as an indication of the local carrying capacity of the surface. In the second method, described by McMullan,[4] special Brinell balls, preferably of the hard carbide variety, are pressed into the surface to be tested under increments of load, and the impressions are measured in the usual manner.

Notched-Bar Impact Tests. The standard impact tests, as described on page 112, are not commercial tests for tool steel except for the shock-resisting types; the values obtained mean little for steel in the annealed condition and when tool steels are tested in the hardened condition, the values are too erratic.

When this type of test is used, the design of the test specimen may be varied according to the characteristics of the steel.

Since the specimens are highly stressed, care is necessary to prevent injury from flying fragments.

With impact test specimens of hardened tool steel, provision should be made for grinding at least 0.005 in. from the surface after heat treating. This grinding will remove surface irregularities that might cause low impact values.

The torsion-impact test is used to measure the torsion-impact strength of tool steels hardened to Rockwell C 60 or higher.

Torsion Tests.* Some of the fundamental properties of hardened tool steel are difficult to determine accurately because exceptionally high strength and low toughness are encountered, as compared with the engineering steels. The tension, transverse bending, and impact tests are limited in usefulness when applied to hardened tool steels, since results are likely to vary and the average is only approximate. The static torsion test has these advantages: the applied stress is less concentrated and it is possible to measure both strength and toughness much more accurately, even when the toughness is very low. With this

* *See also* "Compression Tests", page 109 in this Handbook.

* *See also* "The Torsion Test", page 111.

method of testing, simultaneous observations of both stress and strain are made, and from these results curves can be plotted to illustrate both the elastic and plastic deformation and the approximate location of the yield point.

Method of Making the Torsion Test. Because of the high strength and low toughness of hardened tool steels, a test specimen with a comparatively high ratio of L to D is necessary for best results. (L = length of gage section, D = outside diameter of gage section.) A ratio of 5.78 is used for relatively soft materials, but a ratio of 16 is recommended for hardened tool steels, so that sufficiently high values of strain can be obtained for a given stress. A drawing of the torsion-test specimen for tool steels, a picture of the torsion-testing apparatus, and details regarding the method are given in Proc ASTM, 31, Part 2, 47, 49 (1931). The reader may also consult references 5 and 6.

The principle of the torsion test is that by means of a manually operated turning head, a twisting torque is applied to the torsion specimen, which in turn transmits the torque through a lever system and hydraulic gage to a piston. The gage-reading indicates the applied twisting force or torque in in.-lb, and deformation or angle of twist is measured directly on the twisting head of the machine. The angle through which the specimen twists is recorded for each increment of 25 in.-lb torque until rupture occurs. From these data a stress-strain curve can be plotted that gives information concerning the elasticity, plasticity and ultimate torsional strength of the material being tested.

Tension Tests.* The tensile properties of annealed tool steel are of little commercial value. Tension tests are sometimes used on small sizes of drill rod (for example, less than ⅛ in. in diam) rather than hardness tests because, on such small sizes, the standard methods of testing hardness are rather inaccurate. In heat treated steel, accurate determinations present considerable difficulty and inaccuracy is likely at high hardnesses, such as Rockwell C 55 or more, when the ductility is quite low. A knowledge of tensile properties is useful, chiefly in connection with shock-resisting steels, which are often used when considerably softer than their maximum hardness.

For determining the tensile properties of tool steel, a specially designed test specimen is recommended (Fig. 38).

The specimens are ordinarily heat treated in test-bar size, but about 0.020 in. is left on the diameter to permit removal of decarburized surface and to correct for warpage.

Tension Tests at Elevated Temperature. A joint committee of the ASTM and the ASME has prepared recommended practices* for tension tests of steels at elevated temperatures. These methods are satisfactory for medium-strength or low-strength steels, but it is difficult to obtain accurate results for high-strength steels unless the methods are modified.

The Specimen for Tension Tests at Elevated Temperature. Figure 39 shows a satisfactory form of test specimen. The best practice is to rough turn in the annealed condition, heat treat, and grind as indicated. From high-strength steels with low elongations, best results will be obtained if the ends are tempered for a short time in a liquid bath before grinding.

The diameter of the specimen in the gage-length section may be varied from the dimension shown in Fig. 39 to as small as 0.200 in. with satisfactory results. When a smaller specimen is used, the gage length should equal 4 diam so that the elongation values will be directly comparable with those of the standard specimen. The dimensions of a small specimen are shown in Fig. 40.

Gage marks can be put on the hardened specimens conveniently with the diamond-point hardness tester. The surface is washed with a copper sulfate solution where the gage marks are to be placed; then the 2-in. gage length is scribed with sharp dividers and prick punched or marked with the diamond point. If an extensometer is to be attached to the specimen, it is necessary to put gage marks on opposite sides. This procedure is greatly facilitated by rotating the specimen on centers and using the dividers against a rest while laying off the gage length.

The Testing Equipment. Various forms of shackles may be used to grip the ends of the specimens. A satisfactory

* *See also* "The Tension Test", page 105.

Fig. 38

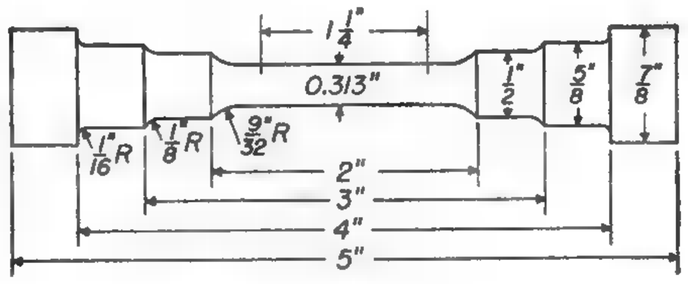

Fig. 39

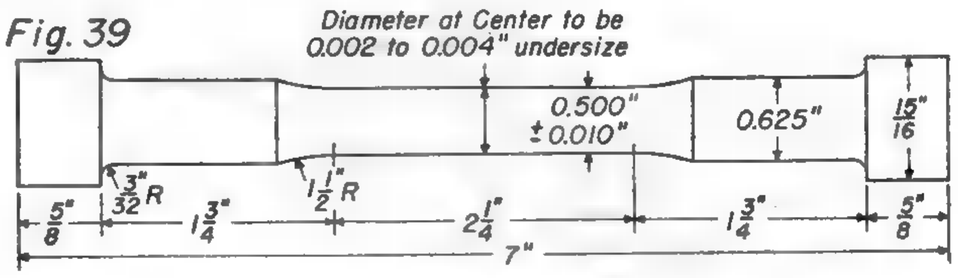

Fig. 40

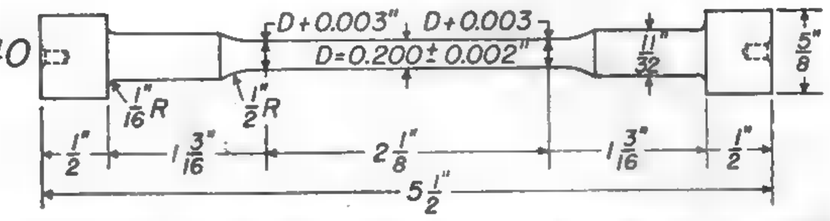

Fig. 38 Special tension-test specimen for tool steel. The ends may be square or ball-shaped.
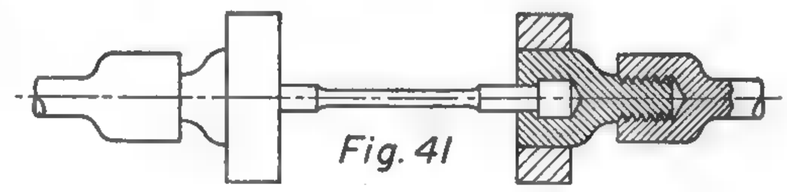
Fig. 39 Tension-test specimen for tool steel at elevated temperature
Fig. 40 Same as Fig. 39, except smaller

form is shown in Fig. 41. This type is readily adapted to both the threaded-end and the shouldered-end types of specimens. The split adapters that fit the ends of the shouldered-end specimens are strengthened by the solid rings, which have a tapered bore so that they can be wedged on the adapters after the specimen is inserted. Another satisfactory form for shouldered-end specimens is shown in Fig. 42.

The best furnace for making high-temperature tension tests is a differentially wound or gap-wound resistance type of electric furnace. Particular attention should be given to baffling, insulation, and tightness, in order to prevent temperature gradients either in the specimen or in the adjoining shackles. For short-time tension tests at



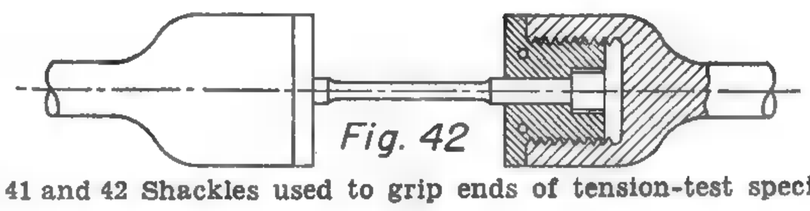


Fig. 41 and 42 Shackles used to grip ends of tension-test specimen

elevated temperature, manual control of the temperature is generally adequate; but for the long-time or creep tests, automatic control is necessary. Under any circumstances, it is essential to know the actual temperature of the specimen and to hold this temperature constant over the part of the specimen that is strained.

The use of the extensometer in high-temperature work makes the maintenance of uniform temperature so difficult that the best results are often obtained by compromises between equipment for heating and apparatus for measuring deformation. When the smaller sizes of specimens are used, uniform temperature can be obtained more easily throughout a specimen.

Self-aligning shackles are essential. The usual method is to provide ball-and-socket joints at the ends of the shackles where they are attached to the heads of the testing machine, as indicated in Fig. 41.

Testing Procedure. It is particularly important, in short-time, high-temperature tension tests, to heat slowly for consistent results. Many of the reported discrepancies are caused by an excessively rapid rate of heating. The elastic properties of tool steels as usually determined—elastic limit, proportional limit, and frequently Young's modulus—are of questionable value because of creep at the

higher temperatures and because of consequent difficulties hindering the accurate determination of such properties. Better results will be obtained by the use of values of yield strength based on some arbitrary value of permanent set or perhaps on two different values of permanent set, such as 0.1% and 0.2%, following the methods given in the Standard Methods of the ASTM (E 8–46). Such values for yield strength need be used only in the absence of a well-defined yield point in the steel, but most tool steels have no well-defined yield point.

Temperatures are best obtained by clamping thermocouples directly on the shoulders adjacent to the gage length of the specimen. To shield the hot junctions from the heat of the furnace walls, asbestos paper should be placed over the junctions before the clamps are applied. Additional thermocouples in the furnace atmosphere may assist in obtaining and controlling the desired temperature, but ordinarily they are not reliable for measuring the temperature of specimens.

In a report of results, the details of the specimen, apparatus and procedure should be given, in addition to the composition and history of the specimen material.

Bend Tests. (*See* the article on page 125.)

Fatigue Tests. The ordinary fatigue tests (*see* page 118) used on soft or medium-hard materials may be applied to annealed tool steels, but seldom are, since tool steels are used largely in the hardened condition. Fatigue tests are not generally used on hardened tool steels, because notches, scratches and residual stresses cause much greater variations in results than are caused by differences in the quality of the steel. The best application of fatigue tests for tool steels would be on specimens that have been hardened and tempered to a hardness of Rockwell C 40 to 50. However, such treatments are seldom used for tools. Information from these tests is most likely to be required in connection with shock-resisting steels.

Fatigue tests on tool steel indicate an endurance limit from ⅓ to ⅔ the static tensile strength, and demonstrate that the resistance to fatigue is increased substantially by changing the direction of final polish of the specimen from circumferential to longitudinal.

In problems of fatigue in tool steels, the main emphasis should be on the design and treatment.

Some manufacturers and users of hollow mining-drill steel have long employed a practical fatigue test to check the quality of various lots of this material. With modifications, this test may be applied to other types of pneumatic tools. It consists of using a representative number of specimens of definite size and length in a jack hammer until failure occurs from fatigue. The time required is compared with standards set up jointly by manufacturer and user.

Nondestructive Testing and Inspection. Magnetic particle inspection, fluorescent penetrant inspection, magnetic testing and radiography are discussed on pages 141 to 158.

A special application of magnetic testing for tool steels has been the use of measurements of magnetic saturation value as a means of following the transformation of austenite during tempering.

Spark Tests. (*See* the article on page 397.)

Determination of Transformation Temperatures. There are three methods of determining the transformation temperatures of tool steels: (1) by plotting the heating and cooling curves on time-temperature co-ordinates (Fig. 43); (2) by dilatometric measurements involving the charting of interruption of progressive expansion or contraction on linear expansion-temperature co-ordinates; and (3) by plotting the change in loss of magnetic intensity during heating.

Thermal Method. In most steels, transformation points are ranges of temperature, since a small temperature range is required to complete the phase transformation.

Inserting a thermocouple into the drilled test specimen and observing and recording on a time-temperature diagram the rate of increase or decrease in temperature, is probably the oldest and simplest method for obtaining transformation points.

A heating and cooling rate from 1 to 2 °F per min is used to determine the transformation points with fair accuracy. Accuracy, of course, depends largely on the quality of the furnace equipment. To eliminate this factor, a neutral or nontransforming metal, such as platinum or an austenitic alloy steel, is heated along with the sample and temperature differences of the two are observed. The "inverse rate" curves, indicated in Fig. 43, give sharp peaks on the curves corresponding to the amount of heat absorbed during heating or evolved during cooling. The inverse rate curves are in general use. Autographic recorders are desirable; in fact, they are almost indispensable where frequent determinations are required.

Dilatometric Method. The dilatometer is a mechanism for determining the expansion or contraction of a sample during heating or cooling. *See* page 168.

Magnetic Method. The magnetic determination of transformation points depends on the loss of ferromagnetism

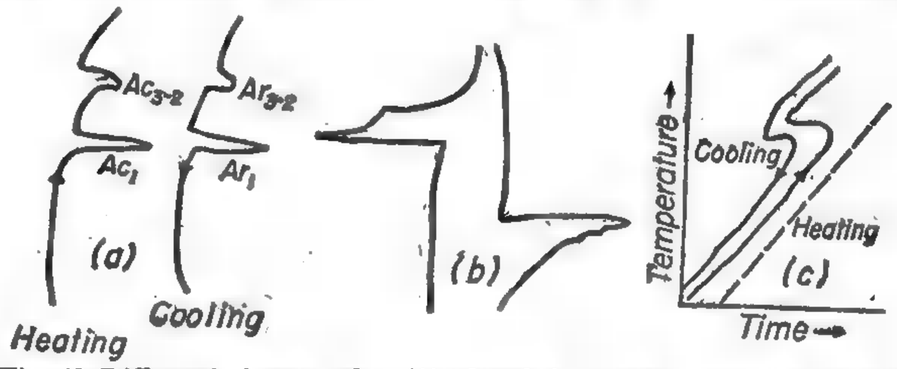

Fig. 43 Different types of critical-point curves. (*a*) Inverse-rate heating and cooling curves for a 0.45% C steel, (*b*) the same for a 1.0% C steel, (c) dilatometric expansion curve for a 0.45% C steel

during heating. These points are established by observing the magnetic transformation and the corresponding temperature. The specimen of tool steel is inserted as an armature in a magnetic circuit, and when the temperature is reached at which magnetic flux ceases to pass through the specimen or when the circuit is disrupted, the loss of ferromagnetism indicates the transformation temperature. A galvanometer in the circuit will then register no deflection and will thus record the transformation temperature.

Abrasion Tests.* Abrasion testing consists in measuring the weight lost from a unit surface area of a tool steel specimen that has been moved over and in contact with a standard hardened and finished machined surface, under a definite pressure, representing service conditions as far as practicable. There is no standard method of testing for resistance to abrasion.

The loss per unit area from the tool steel specimen, compared with the loss per unit area from specimens of different chemical composition, but of identical surface dimensions and tested in this same manner, gives the abrasion value expressed as loss in weight per unit area.

The surfaces may be cylindrical, spherical, or flat, but whether they are curved or straight, maximum and uniform contact and surface finishes are essential.

For an illustration of a wear-testing machine for cylindrical surfaces, the reader may refer to French and Herschman, Wear of Steel, with Particular Reference to Plug Gages, Trans ASST, 10, 692 (1926).

Physical and Mechanical Properties of Iron

By Reid L. Kenyon*

IN SPITE of the difficulties encountered in preparing iron of high purity and in making an accurate chemical analysis of the small amounts of impurities present, the need for accurate information is probably greater today than ever before, because of the demands for greater reliability and for improved or new properties in ferrous metals and alloys.

Determinations of the properties of so-called "pure iron" appear throughout the literature, but the more recent values should be the most reliable since in general they were obtained by using improved methods of preparation, chemical analysis and testing.

The purpose of this article is to give a condensed statement of the physical and mechanical properties of iron, as reported in technical publications.

The data are usually from tests on material prepared by special methods in the laboratory, so in many instances considerable variation in the values of properties must result. An attempt has been made, as far as the data were available, to include the results of tests on commercially available materials such as carbonyl iron, electrolytic iron and ingot iron.*

Because of the variability in composition and treatment of the many different samples of iron used by various investigators, the values given should be considered the best approximations now available for the different properties and should not be used for specification purposes.

Composition. Table I gives the typical composition of several common forms of iron available commercially. Elsewhere in this article are the chemical compositions of a number of individual samples used by various investigators in determining various property values.

Atomic Structure. *Isotopes.* Iron has four isotopes: 54 (6.04%), 56 (91.57%), 57 (2.11%) and 58 (0.28%).

Atomic Number. The atomic number is 26.

Atomic Weight. The atomic weight is 55.85.

Nuclear Structure. The iron nucleus consists of 26 protons and 28, 30, 31 or 32 neutrons (corresponding to the four isotopes). The iron nucleus has considerable stability.

Arrangement of Electrons. In accordance with present concepts of nuclear structure, the 26 outer electrons are distributed on different "shells". Iron is believed to have 2 electrons in the inner K-shell, 8 in the L-shell, 14 in the M-shell, and 2 in the outer N-shell.

Atomic Radius. As reported by Morse, the atomic radius for alpha iron is 1.236×10^{-8} cm, and for gamma iron is 1.284×10^{-8} cm.

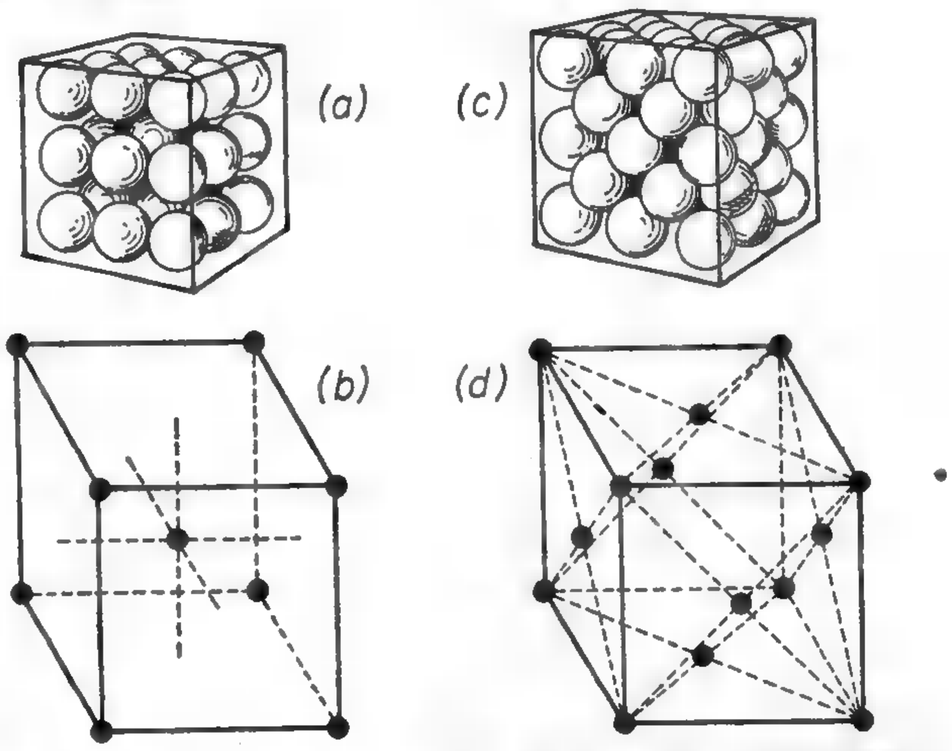

Fig. 1 Crystalline forms of iron: (*a*) body-centered cubic packing, alpha and delta iron; (*b*) alpha and delta iron, body-centered cubic; (*c*) face-centered cubic packing, gamma iron; and (*d*) gamma iron, face-centered cubic

Atomic Volume. This term ordinarily refers to the volume of a gram-molecular weight, and for iron at room temperature this is 7.1 cu cm. The volume of an individual atom can be derived from this by dividing by Avagadro's number which gives 11.7×10^{-24} cu cm for alpha iron at 16 C.

Crystallographic Properties. Iron has two crystallographic forms: body-centered cubic for alpha iron and delta iron, and face-centered cubic for gamma iron (Fig. 1). The dimensions of the unit cube (lattice parameter) vary with temperature, as shown in Fig. 2. The body-

The data and information for this article have been selected from a number of sources; the preceding edition of this article was taken mainly from the book "The Metal—Iron" by H. E. Cleaves and J. G. Thompson. The author acknowledges the assistance of J. B. Austin (Director of Research, United States Steel Corporation); W. E. Ruder (Metallurgical Engineer, Research Laboratory, General Electric Company); J. G. Thompson (Chief, Division of Metallurgy, National Bureau of Standards); H. E. Cleaves (Metallurgist, National Bureau of Standards); T. D. Yensen (Manager, Magnetic Dept., Research Laboratory, Westinghouse Electric Corporation) in appraising the preceding article critically and making suggestions for its revision.

* In this article "ingot iron" refers to Armco ingot iron.

Table I. Typical Composition of Commercial Irons

Description	C	Mn	P	S	Si	Cu	Ni	O_2	N_2

(b) Unable to identify, also Cr, Co, Mo, and Zn
(c) Unable to identify, also Ag, As, Au, B, Ba, Bi, Ca, Cb, Cd, Ce, Co, Cr, Ga, Ge, Hf, Hg, In, Ir, K, Li, Mg, Mn, Mo, Na, Ni, Os, Pb, Pd, Pt, Rh, Ru, Sb, Sc, Sn, Sr, Ta, Th, Ti, Tl, U, V, W, Y, Zn, Zr, total impurities <0.010%

centered cubic lattice may be considered as two interpenetrating simple cubic lattices of which the co-ordinates are (0, 0, 0) and (½, ½, ½). The face-centered lattice may be considered as four interpenetrating simple cubic lattices and there are, consequently, four atoms in the elementary cell, having the following co-ordinates: (0, 0, 0), (½, 0, ½), (½, ½, 0) and (0, ½, ½).

Density. Determinations of the density of individual specimens may be made with great precision, but the results apply only to the specific small pieces used in the test; therefore, results carried out to several significant figures are of questionable value, at least as a measure of the density of the material as a whole. Three common methods for determining the density of iron are (1) direct measurement, (2) calculation from the lattice constant, as determined by X-ray examination, and (3) extrapolation to

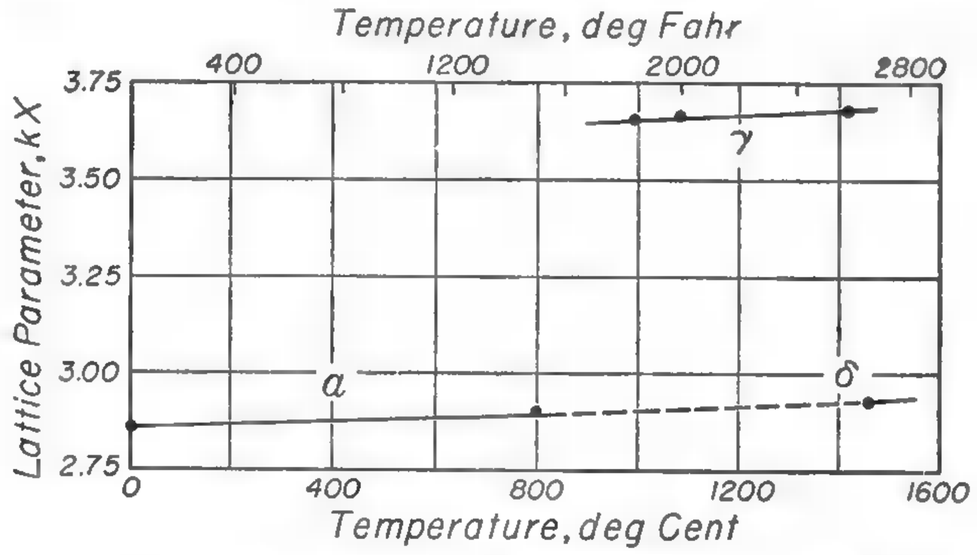

Fig. 2 Effect of temperature on lattice parameter of iron (Sato)

zero content of alloying element of a series of iron alloys. Table II gives average values computed by Cleaves and Thompson from the work of a number of investigators, as well as the value of 7.874 ± 0.001 g per cu cm at 20 C, obtained by Cleaves and Hiegel on iron of high purity prepared at the Bureau of Standards.

Avg of 4 investigators	....	....	7.868
Nat Bur Standards Iron	7.874 ±0.001	....	....

Variation of Density With Temperature. At temperatures above room temperature the density is generally determined by calculation from either the coefficient of thermal expansion or the lattice constants. Lack of accurate data on volume changes at the transformation points results in the values for density above the A_3 point being unsatisfactory.

Variation of Density With Cold Working. Cold working lowers the density of iron, as shown by the work of various investigators. Maier's results on rods cold drawn from ingot iron are shown in Fig. 3. Beyond about 87% cold reduction the density increases again but does not attain its initial value corresponding to zero per cent cold work.

Transformation Points. The transformation points are the temperatures at which the various polymorphic changes occur. Because of the wide variation in the methods used for determining these transformation points, considerable

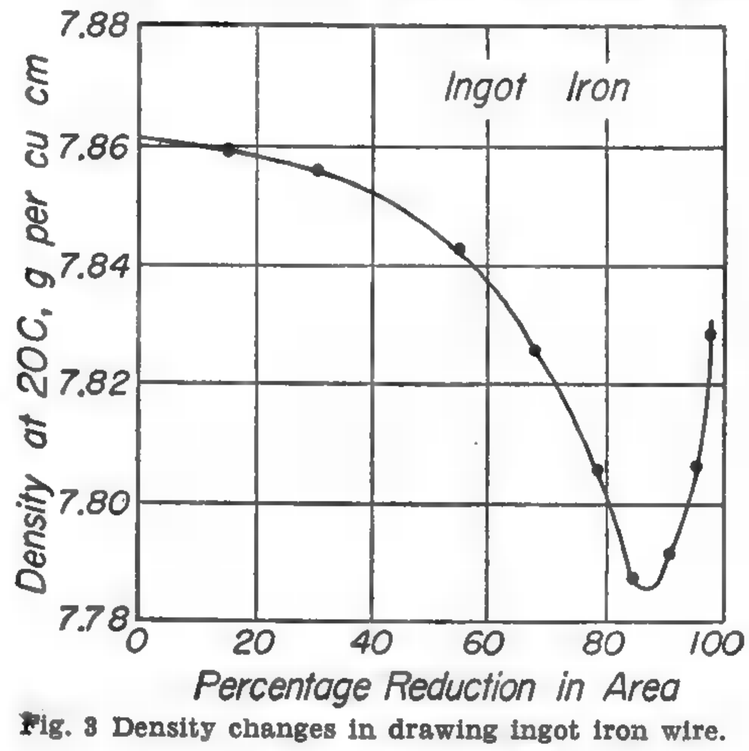

Fig. 3 Density changes in drawing ingot iron wire.

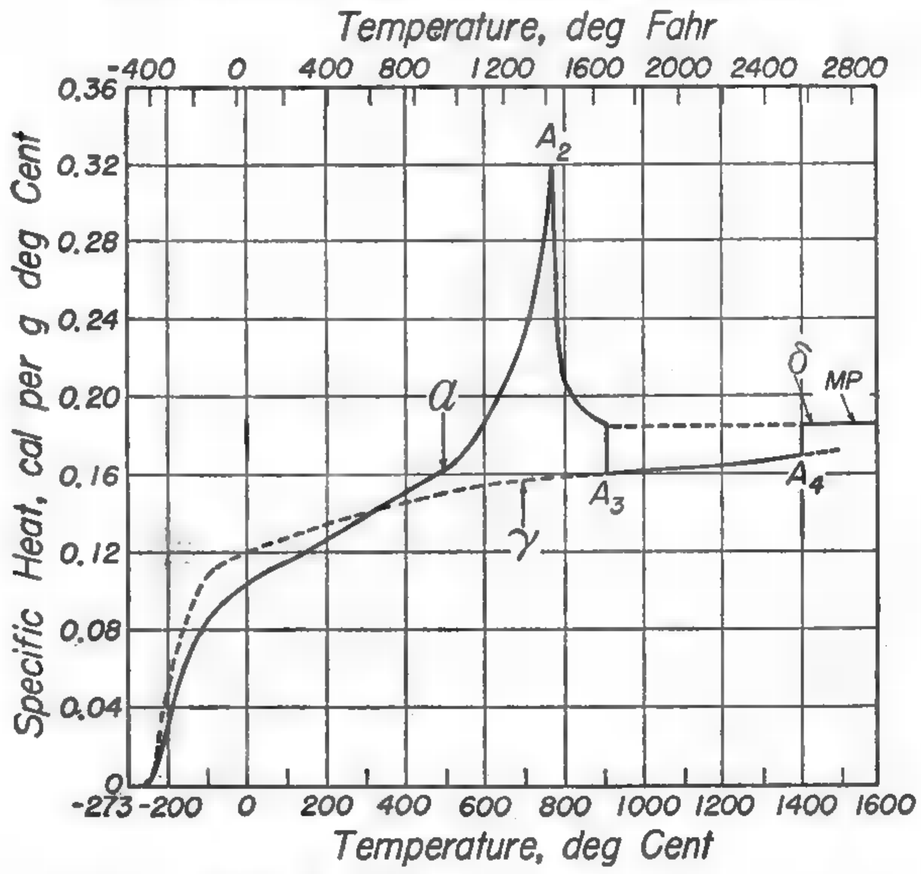

Fig. 4 Specific heat of iron (Austin)

difference in results is to be expected. Some of the methods that have been used are the following: heating and cooling curves and variations of this method, including differential curves; calorimetric measurements; magnetic tests; thermoelectric phenomena; electrical resistance measurements; and dilatation.

A_2 Transformation Range. This is the Curie point of pure iron, below which iron is magnetic and above which it is not. X-ray methods have shown paramagnetic α iron

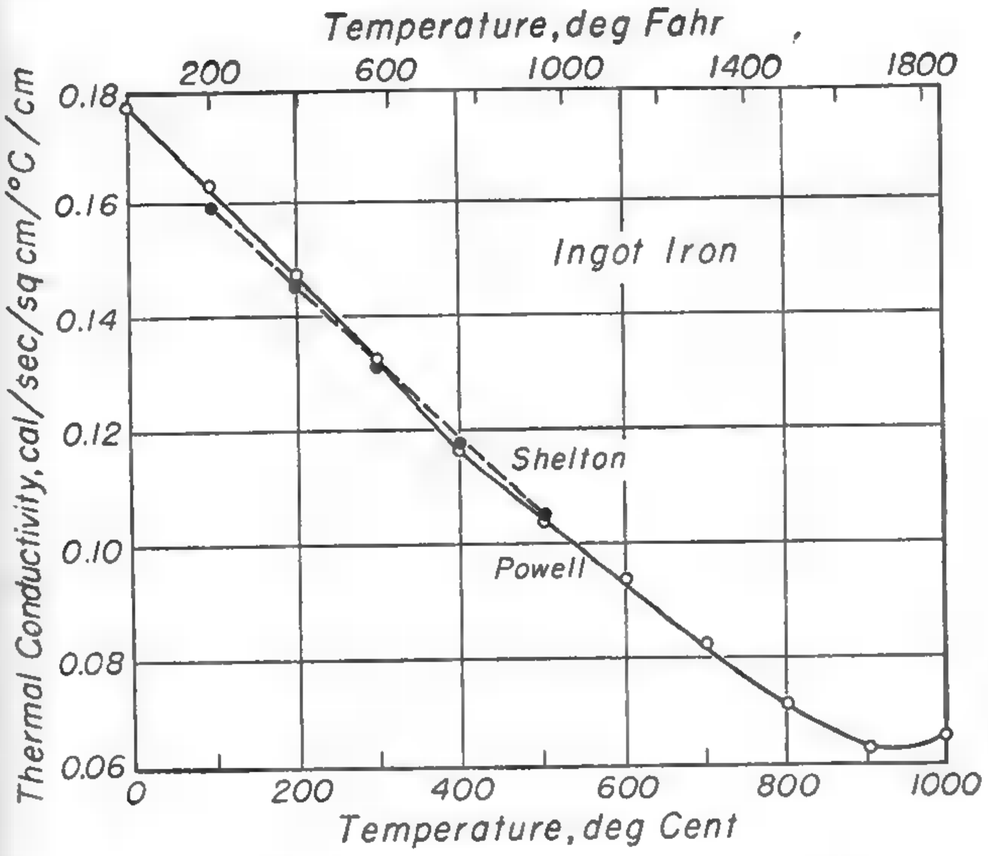

Fig. 5 Effect of temperature on the thermal conductivity of iron

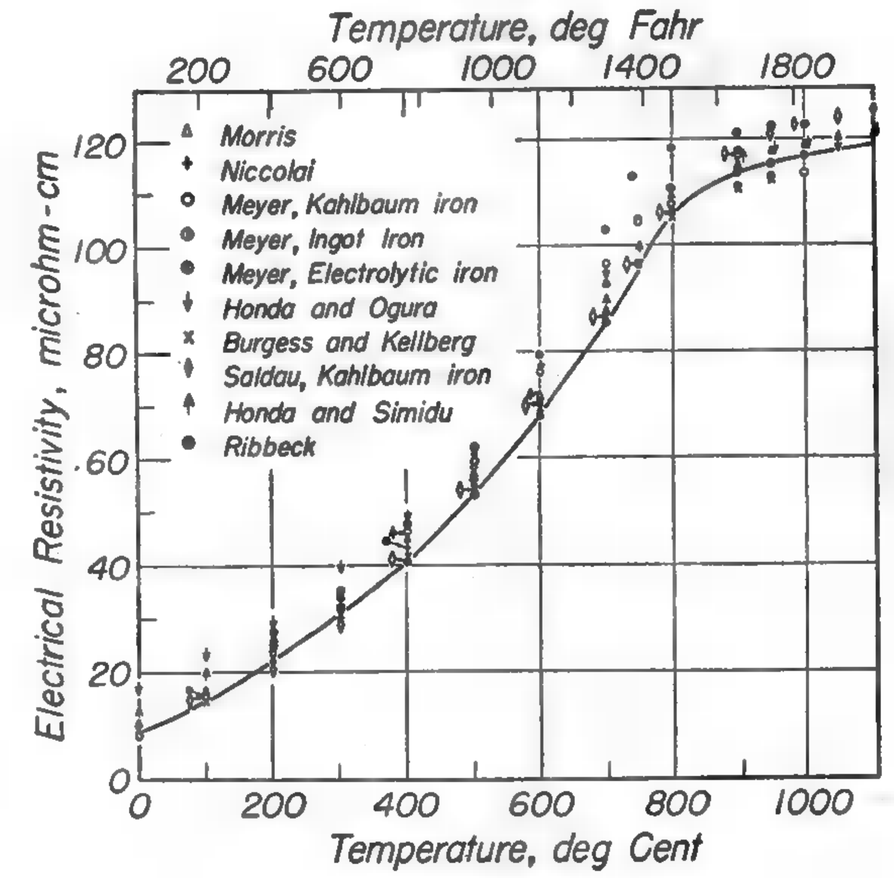
(formerly called β) to be of the same crystal structure as magnetic α iron. The magnetization is not all lost at one point. Most of it is gone after the iron is heated to 768 C, but remaining traces are detectable at temperatures as high as 791 C. This upper temperature depends on the sensitiveness of the instruments used, and on the different conditions of various parts of the specimen. Calorimetric results, which seem to be most consistent, indicate the value 768 C.

Methods that involve heating and cooling curves have yielded fairly consistent results, and several investigators have shown that the greatest thermal effect of the A_2 transition occurs at 768 C. Sauveur found that previous heat treatment has some effect on the determination; successive heatings tend to raise the value gradually to a constant temperature.

A_3 Transformation Temperature. This is the temperature at which pure iron undergoes a crystallographic change from a body-centered cubic to a face-centered cubic lattice. The change is not instantaneous and consequently there is some difference between the transition temperature on heating and that on cooling; also differences accompany variation in heating and cooling rate. Values are given for Ac_3 (heating) and Ar_3 (cooling).

Cleaves and Hiegel[1] report for the iron of high purity prepared at the National Bureau of Standards: "The results obtained by the three (magnetometric, thermal-analysis, and dilatometric) methods are not in perfect agreement—for example, the magnetometric method shows that Ac_3 is completed at constant temperature, whereas the transformation extends over a few degrees in the thermal-analysis experiments and over a greater range in the dilatometric observations. All three methods are in agreement, however, that the Ac_3 transformation in this high-purity iron occurs at 910 to 910.5 C and that the Ar_3 transformation is about ▮ C lower than Ac_3 even with very slow cooling."

A_4 Transformation Temperature. The δ-γ transformation of an iron prepared from ferrous chloride by a chemical



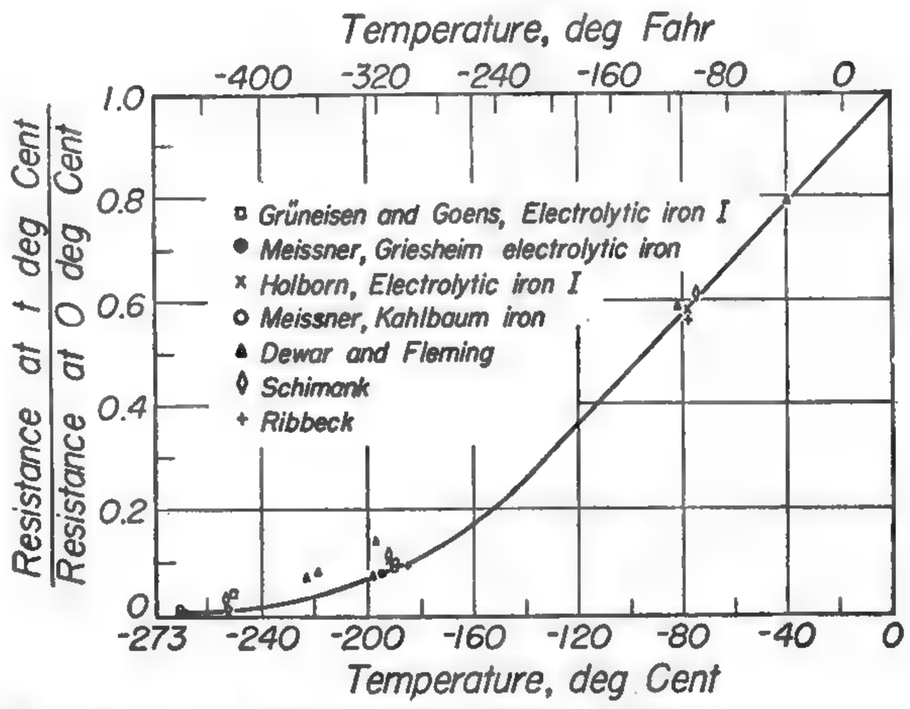


Fig. 7 Electrical resistance of iron at low and elevated temperatures

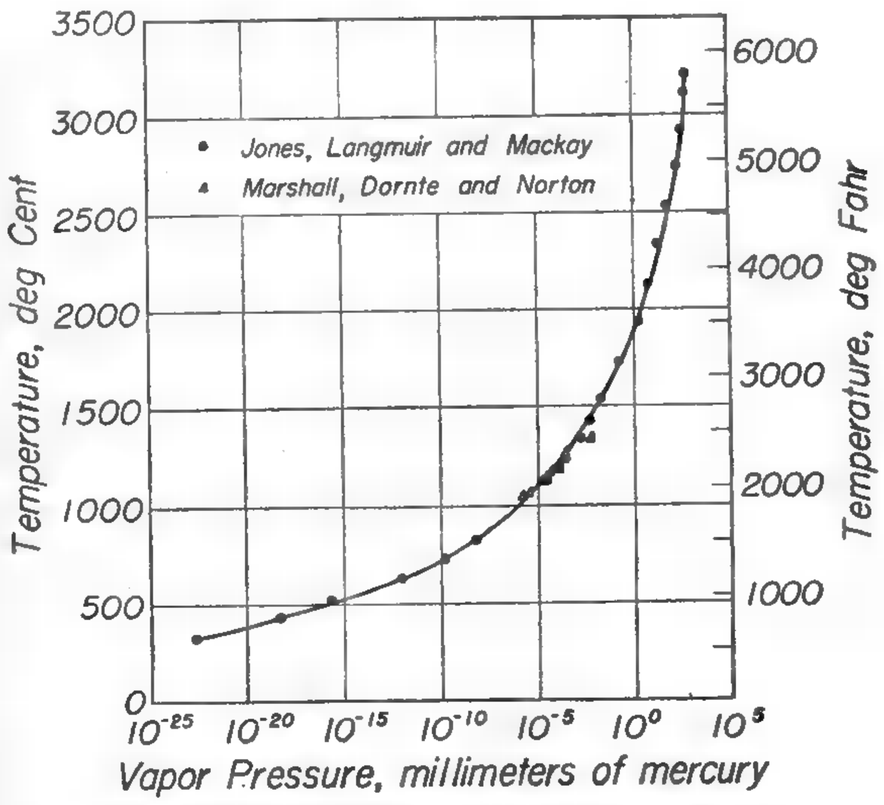

Fig. 6 Effect of temperature on the vapor pressure of iron

process (0.0016% Cu, 0.0006% Si, 0.0024% Ni, 0.0018% Al, 0.0027% S, traces of Mn and Ca) was determined by Adcock,[2] using the thermal-analysis method with Pt-PtRh thermocouples. He found this transformation occurring at 1388 ± 5 C, which is well below the previously accepted value of 1401 to 1403 C.

Heat Capacity, Specific Heat, Entropy. Although considerable data have been published concerning these properties, numerous discrepancies among the data make concise presentation difficult. Both Ralston and Austin have made critical surveys of the available results. Cleaves and Thompson prefer Austin's review, because it is more recent than Ralston's and includes data obtained by improved methods. Thompson considers Austin's results good in spite of recent values given by Jaeger, Rosenbohm and Zuithoff, and by Esser and Baerlecken.

The variation in specific heat with temperature is shown in Fig. 4. In this discussion "specific heat" refers to the rate of change of heat content at a given temperature (sometimes called "true specific heat" in technical literature) and "mean specific heat" refers to the average rate of change through a given temperature range.

Tables III and IV, adapted from Cleaves and Thompson, give values selected by Austin for entropy, heat content, free energy, and specific heat of both alpha and gamma iron throughout the range from absolute zero to the melting point. The specific heat of liquid iron has been reported by various investigators (Wüst, Meuthen, and Dürrer; Umino; Oberhoffer and Grosse) at values varying from 0.142 to 0.222 cal per g. The average of four reported data is 0.177 cal per g.

Heats of Transition. There is no discontinuity in the total heat curve at the A_2 point. Ralston interprets this as indicating only a change in specific heat and not a real heat of transition. Numerous values of heat of transformation are given in the literature for the A_2 point, but these may be the magnetic component of the specific heat integrated over a range of temperature. Ralston states: "The true heat of transition of A_2 is therefore zero, unless we look on the heat accompanying the magnetic changes as a distributed (over a temperature range) latent heat. This latter idea is quite permissible, although not in common acceptance."

Most values for heat of transition at the A_3 point have been determined by measuring the heat content above and below the transition temperature; and since the results are small differences between large numbers, the variations recorded in the literature are not surprising. Since Ralston calculated his value of 4.9 cal per g from an average heat content curve, Klinkhardt and Esser and Bunghardt have made direct determinations of the heat absorbed during the transformation. The average of their results gives 3.63 cal per g or 203 cal per g-atom.

From Umino's data for heat content, Yap computed the heat effect during the alpha-gamma change, when this occurred at various temperatures (Table V).

Although Ralston's value of 1.7 cal per ■ or 94.9 cal per g-atom for the heat effect at the A_4 point, is somewhat lower than Umino's subsequently reported determination of 1.86 cal per g, Cleaves and Thompson state that Austin considered Ralston's value as the most probable one for the heat effect at the A_4 point.

Heat of Fusion. Ralston and Austin agree in their selection of 64.9 cal per ■ as the best value for heat of fusion, and Cleaves and Thompson suggest that this be rounded to 65 cal per g (3630 cal per g-atom) because the reported

data indicate that even the unit figure may be in doubt.

Thermal Conductivity. Most of the published determinations of this property are for impure specimens—a fact which undoubtedly accounts for much of the disagreement among the results of different workers. Grüneisen and Goens found that impurities had a much greater effect at low temperatures than at room temperature. The results of Powell and of Shelton are shown in Fig. 5; Powell's results contain an extension of previous investigations, including determinations at 900 and 1000 C. It is indicated that the thermal conductivity of γ iron increases with an increase in temperature.

Coefficient of Thermal Expansion. The coefficient of linear thermal expansion is the increase in length per unit length for an increase of one degree in temperature, and is sometimes referred to as the "true coefficient of expansion". The average expansion through a range of temperature is the "mean coefficient of expansion" through that range.

The thermal expansion data of Hidnert (on National Bureau of Standards high-purity iron) are given in Table VI. Both Austin and Pierce, and Cleaves and Hiegel report difficulties in determining the coefficient of thermal expansion above 600 C. Cleaves and Hiegel state: "The expansivity of the iron at high temperature is not satisfactorily established by the data available."

Table V. Temperature Variation of Heat Effect at A_3 Point

400	16.6	15.9
500	16.8	16.2
600	16.0	16.0

Melting Point. Many determinations of the melting point of iron are recorded in technical literature, but it is generally conceded that the latest and best value is that reported by Cleaves and Hiegel[3] for the value of 1539 ± 1 C determined by Roeser and Wensel for the National Bureau of Standards high-purity iron.

Boiling Point and Vapor Pressure. Table VII gives the results of determinations of vapor pressure reported by Jones, Langmuir and Mackay and by Marshall, Dornte and Norton. Cleaves and Thompson suggested that a rounded value of 3000 C be used for the boiling point. The data of Table VII are plotted in Fig. 6.

Electrical Properties. The electrical resistance of iron is greatly influenced by impurities and by the previous thermal and mechanical treatment, so reported values are often discordant. Cleaves and Hiegel report the electrical resistivity of the National Bureau of Standards high-purity iron, as determined by Thomas and Cooter, to be 9.71 microhm-cm at 20 C. They also give the fundamental temperature coefficient (through the range from 0 to 100 C) as 0.00651 ohm per °C per ohm at 0 C. These are believed to be the best available values for pure iron.

(a) This vapor pressure corresponds to the boiling point under "standard conditions".

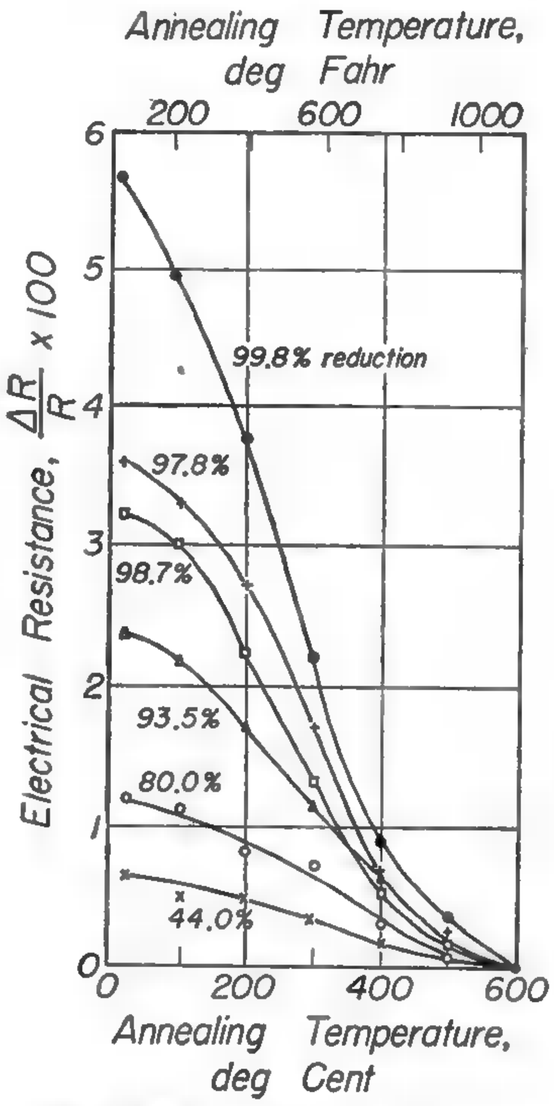

Fig. 8 Effect of annealing on the electrical resistance of cold worked iron. Reduction in area of 97.8% obtained by rolling; other reductions obtained by cold drawing.

The variation in resistivity with temperature shown in Fig. 7, is probably only relative since the resistivity seems to be affected by the prior thermal history of the specimens, and grain growth above 600 C may influence the results from some specimens.

Effect of Mechanical and Thermal Treatment. Cold working increases the resistivity, but reannealing of cold worked iron lowers the resistivity to its initial value. Bardenheuer and Schmidt found virtually no change in resistivity of electrolytic iron cold drawn various amounts as high as 95% reduction in area, but Tammann and Moritz obtained a maximum increase in resistivity of about 5.7% by cold working 99.8%. Annealing at 600 C (1110 F) restored the iron to its original resistivity. Figure 8 is taken from the work of Tammann and Moritz.

Effect of Hydrostatic Pressure. Beckman found the pressure coefficient of electrical resistivity for Swedish iron of low purity (fundamental coefficient of 0.0048) to be 27.4×10^{-7} per atmosphere between 425 and 2097 atmospheres at 0 C ($a = 1/R \times dR/dP$). Bridgman measured

the pressure coefficient on basic open hearth iron (fundamental coefficient = 0.0062) and obtained 24.9×10^{-7} per atmosphere at 0 C and zero pressure, and 21.9×10^{-7} per atmosphere at 0 C and 12,400 atmospheres.

Thermoelectrical Properties. Table VIII gives the thermal electromotive force produced by bimetallic couples of iron and other metals. The values are in millivolts and are considered positive if the current flows from the iron to the other metal at the junction which is at 0 C. The data were obtained in some instances on samples of unknown purity and would not be duplicated exactly on other specimens, but are given as an indication of the magnitude of the thermoelectromotive forces produced.

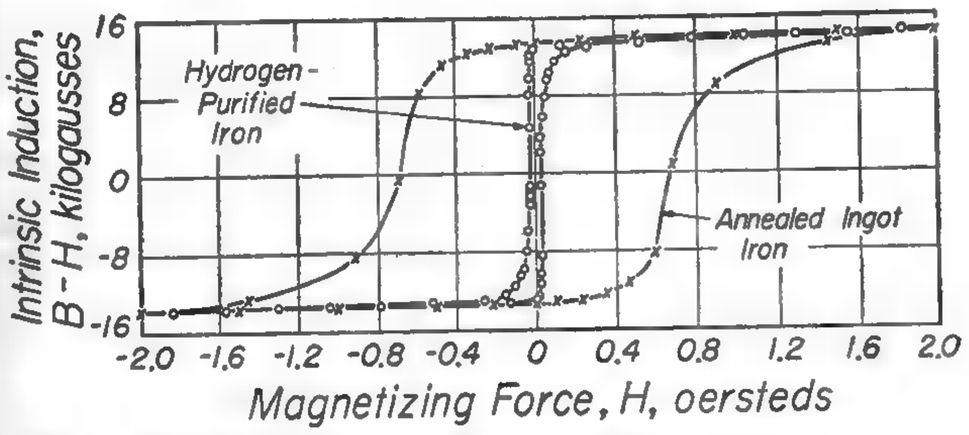

Fig. 9. Hysteresis loops for ingot iron and hydrogen-purified iron.

Electrochemical Equivalent. This constant is computed from the atomic weight and the valence; consequently there are two values for iron: 0.1929×10^{-3} g sec^{-1} amp^{-1} for trivalent iron, and 0.2893×10^{-3} g sec^{-1} amp^{-1} for bivalent iron.

Magnetic Properties.* The magnetic properties, like the electrical, are quite sensitive to small changes in treatment and amount of impurities. Samples of high-purity iron prepared by long-time hydrogen annealing just below the melting point, have furnished new and interesting values for the magnetic properties of iron, but the

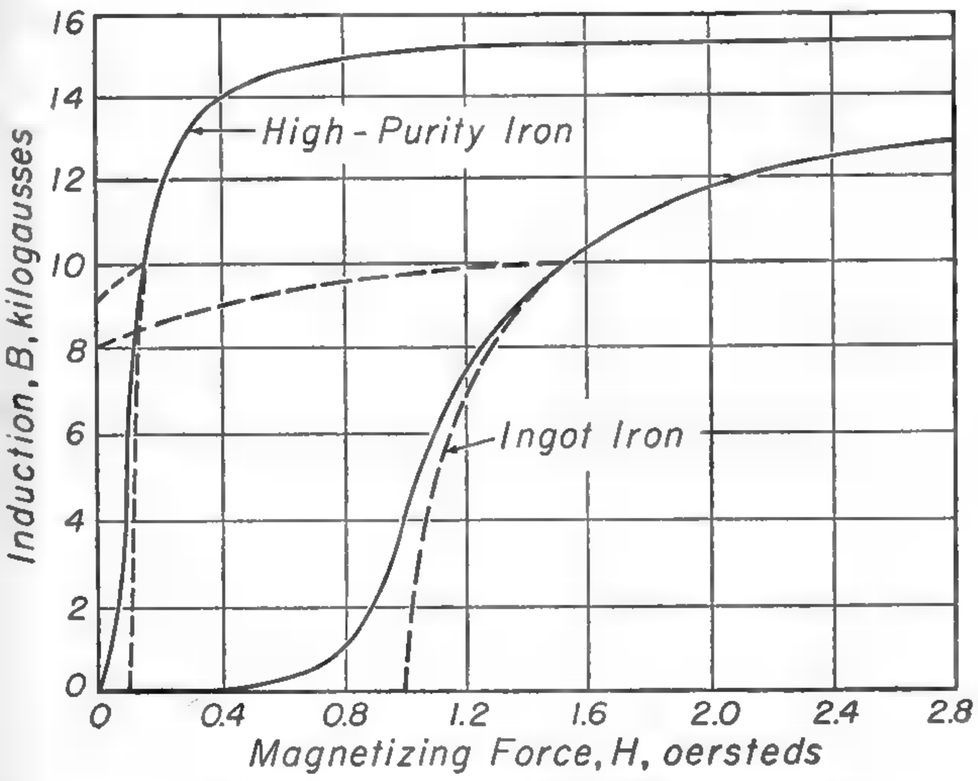

Fig. 10 Magnetization curves for ingot iron and iron of high purity (Yensen)

concomitant effect of large grain size is undoubtedly present also, and the results are included here with the reminder that grain size may have increasing influence on the magnetic properties as the purity increases.

Figure 9 shows hysteresis loops of ingot iron and hydrogen-purified iron as determined by Cioffi. Figure 10 shows hysteresis loops and magnetization curves for ingot iron in comparison with those for iron of high purity prepared at Westinghouse Research Laboratories, where high-vacuum melting was used for eliminating carbon and oxygen. The iron was subsequently annealed in a vacuum to produce large grains. The permeability of the hydrogen-purified iron (0.005% C, 0.028% Mn, 0.004% P, 0.003% S, 0.0012% Si, 0.003% O_2, 0.0001% N_2) is far greater at low inductions than the permeability of irons of commercial purity; but the difference fades out at higher inductions, as shown in Fig. 10 and 11.

A typical hysteresis curve for commercially annealed "magnetic ingot iron"* is shown in Fig. 12. For other magnetic characteristics of this iron, see Fig. 13, 14 and 15.

The magnetic saturation induction for this material is 21.6 kilogausses, which checks the value of 21.578 reported by Cleaves and Hiegel for the high-purity iron prepared at the National Bureau of Standards.

Effect of Temperature. In studying the effect of temperature on permeability of Burgess' electrolytic iron, Terry found that this effect depends on the field strength as

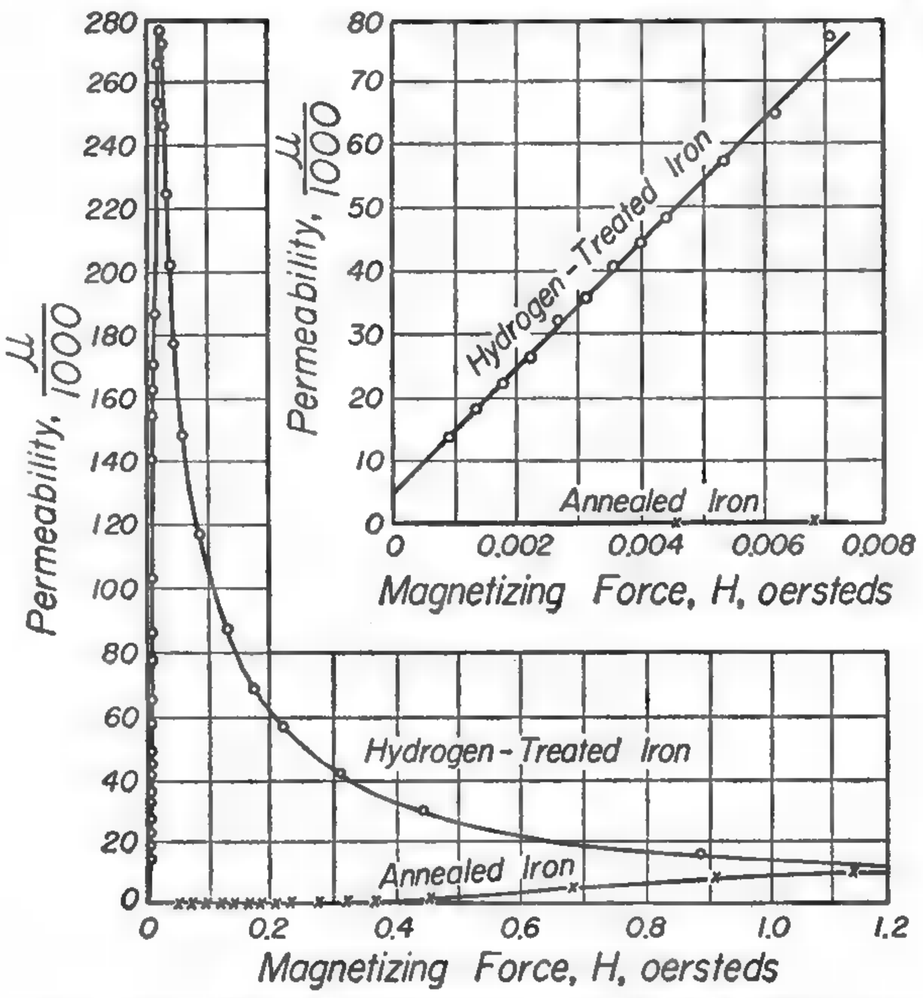

Fig. 11 The effect of hydrogen treatment on the permeability of annealed iron (Cioffi, according to Ellis and Schumacher)

shown in Fig. 16. His results concerning the effect of temperature on the hysteresis constants are given in Fig. 17.

Effect of Grain Size. The work of Sizoo on electrolytic iron (0.024% C, 0.012% S, 0.014% Si) is shown in Fig. 18, while that of Yensen and Ziegler is given in the following equations:

Coercive force = H_c, oersteds
Hysteresis loss = W, ergs per cu cm per cycle
Minimum reluctivity = $\rho_{min} = \frac{1}{\mu_{max}}$

For less than 0.002% C	$\rho_{min} = 0.34 \times 10^{-5} N$; $H_c = 0.0018 N$; $W = 56 N$
For 0.002 to 0.004% C	$\rho_{min} = 0.21 \times 10^{-5} N$; $H_c = 0.00114 N$; $W = 34.4 N$
For 0.004 to 0.008% C	$\rho_{min} = 0.46 \times 10^{-5} N$; $H_c = 0.0025 N$; $W = 75 N$

where N is the number of grains per square millimeter.

The effect of orientation is present, no doubt, in specimens that have larger grain size, but this effect seems not to have been considered by the investigators quoted.

Effect of Cold Work. Cold working has a deleterious effect on the magnetic properties of iron. The effect of various amounts of cold reduction on the hysteresis loop of electrolytic iron (polycrystalline), as determined by

* "Magnetic ingot iron" refers to a commercial product known as "Armco Magnetic Ingot Iron", which is a special grade of ingot iron made particularly for electrical and magnetic applications. This material is selected to have the best composition, and is given the best processing—especially heat treatment—to produce desirable magnetic properties.

* *See also* "Magnetically Soft Materials", page 587.

Gries and Esser, is shown in Fig. 19. Cleaves and Thompson state that cold working decreases permeability and increases residual induction, coercive force and hysteresis loss, leaving only the saturation intensity unaffected.

Optical Properties. *Emissivity.* Determinations of emissivity are rarely made on high-purity iron, and even when

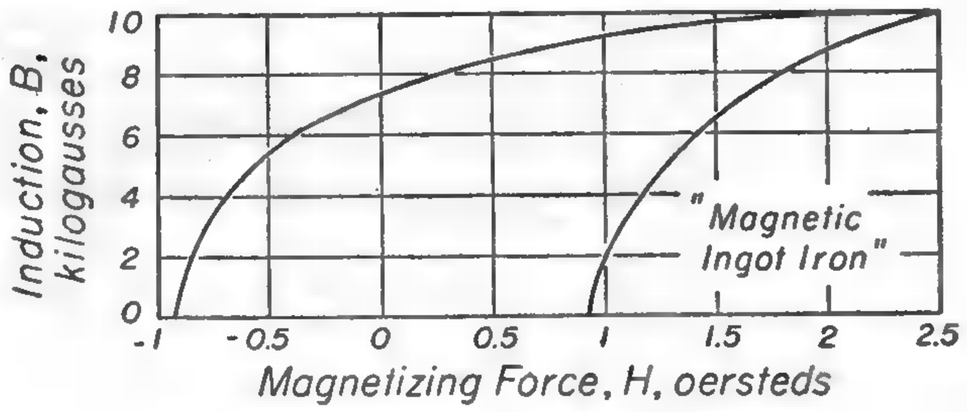

Fig. 12 Typical hysteresis curve for commercially annealed ring sample of "magnetic ingot iron"

specimens of such material have been used, the experimental procedure has often affected the purity; for example, when the source of heat was an arc between carbon electrodes. The best accepted values are those of Burgess

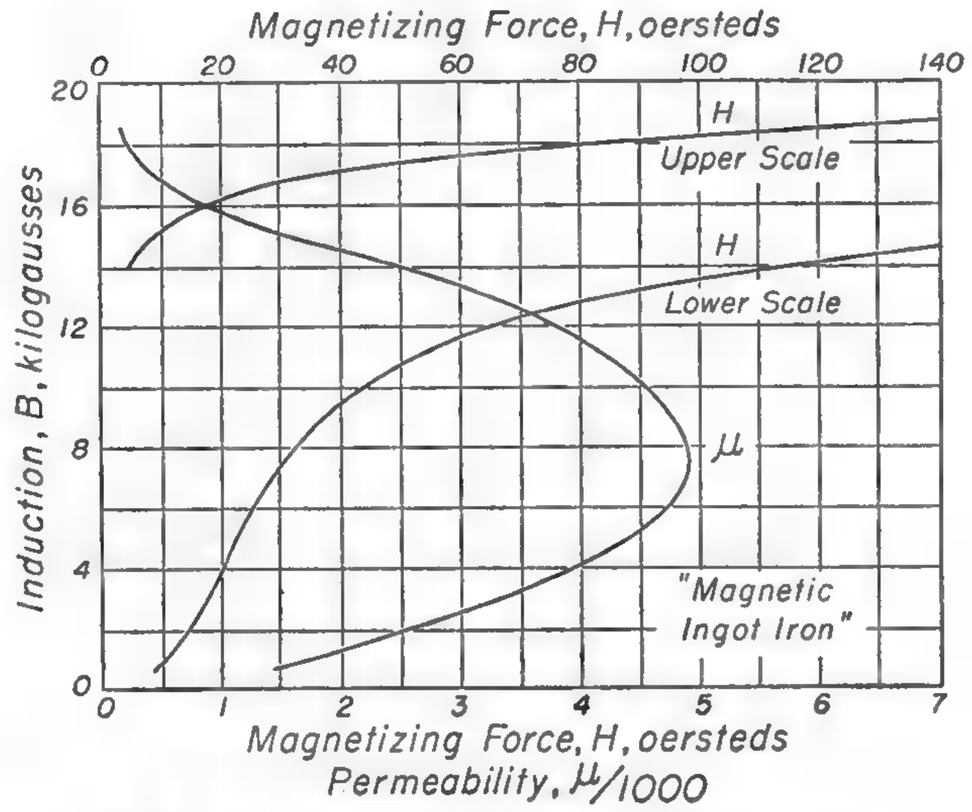

Fig. 13 Typical medium and low induction values for annealed "magnetic ingot iron" tested in ring form

and Waltenberg in Table IX, determined with a micropyrometer.

The above values are all for $\lambda = 0.65\ \mu$ and the average should probably be rounded to 37%.

Emissivity values for iron and steel, as measured in various industrial operations, may differ from this because of oxide on heated surfaces of solid metal, and floating slag on liquid metal. Cleaves and Thompson state that

Table IX. Emissivity of Iron at Various Temperatures

State	Temp, °C	Emissivity, %
Liquid	1050	37.9
	1350	37.2
	1450	36.3
	1530	36.0
Solid	1535	36.5
	Average	36.8

values have been reported between 40 and 45% for liquid metal or for solid metal with a bright surface, and as high as 90% for solid metal with an oxidized surface. In the International Critical Tables, volume 5, page 244, the total emissivity for oxidized surfaces of steel is quoted as 79% at 200 C, 78.8% at 400 C, and 78.7% at 600 C.

The *reflectivity* determinations in technical literature are chiefly for iron of unknown composition. Moreover, the effect of impurities on reflectivity seems not to have been the subject of investigation. Figure 20 presents the combined results of several workers.

Mechanical Properties. *Elastic Constants.* Abram found that ingot iron and mild steel have a slightly higher

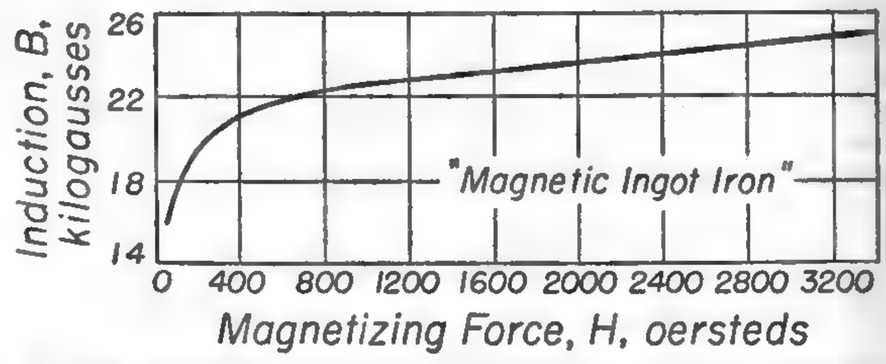

Fig. 14 High induction values for "magnetic ingot iron" annealed bar

Young's modulus than medium-carbon and high-carbon steel. They reported 30.1×10^6 psi for ingot iron and considered that for pure iron in the annealed condition, the value would be about 30.2×10^6 psi. Goens and Schmid determined Young's modulus for different directions in a single crystal of ingot iron and found that it was more than twice as great in the [111] direction as in the [100] direction.

E [100] = 19,000,000 psi (13,500 kg per sq mm)
E [111] = 41,000,000 psi (29,000 kg per sq mm)

Kimura and Ohno have reported the values in Table X for the elastic constants for single crystals of iron.

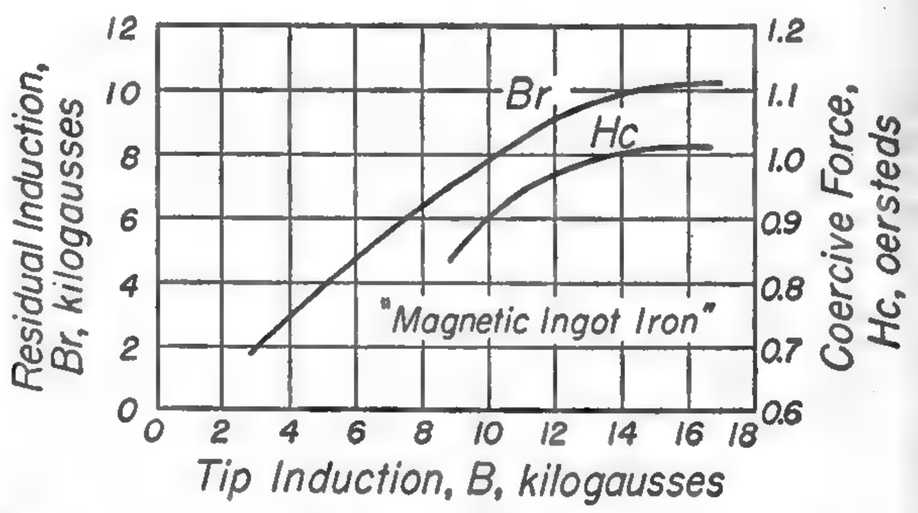

Fig. 15 Residual induction and coercive force versus tip induction for annealed "magnetic ingot iron" ring sample

Other values reported for polycrystalline irons are 29,300,000 psi for ingot iron as determined by Kenyon; 29,600,000 and 30,600,000 psi for electrolytic iron as reported in the International Critical Tables and by Grüneisen, respectively; 29,400,000 psi for carbonyl iron as given by Duftschmid, Schlecht and Schubardt; and 27,200,000 to

Table X. Elastic Constants for Iron (Single Crystals)

	[100]	[110]	[111]
Young's modulus, psi	18.9×10^6	31.3×10^6	40×10^6
Modulus of torsion, psi	16.1×10^6	9.6×10^6	8.5×10^6
Bulk or Voight's modulus, psi	$S_{11} = 10.9 \times 10^6$	$S_{12} = -4.7 \times 10^6$	$S_{44} = 14.7 \times 10^6$
Elastic constants, psi	$C_{11} = 39.4 \times 10^6$	$C_{12} = 24 \times 10^6$	$C_{44} = 18.2 \times 10^6$

30,000,000 psi as found by Cleaves and Hiegel for the National Bureau of Standards high-purity iron.

Values for the modulus in torsion or the shear modulus of polycrystalline irons are as follows:

Ingot iron	11.77×10^6 psi
Ingot iron	11.78×10^6 psi
Electrolytic	11.45×10^6 psi
Electrolytic	11.81×10^6 psi
Electrolytic	11.66×10^6 psi

Poisson's Ratio is generally considered to lie between

0.25 and 0.33 for most metals and is given for iron as 0.28 in various handbooks.

Compressibility. The compressibility of iron has been studied by various investigators, but the outstanding work in this field is that of Bridgman, who determined the compressibility of ingot iron. Cleaves and Thompson have summarized his findings and state that at 30 C the mean

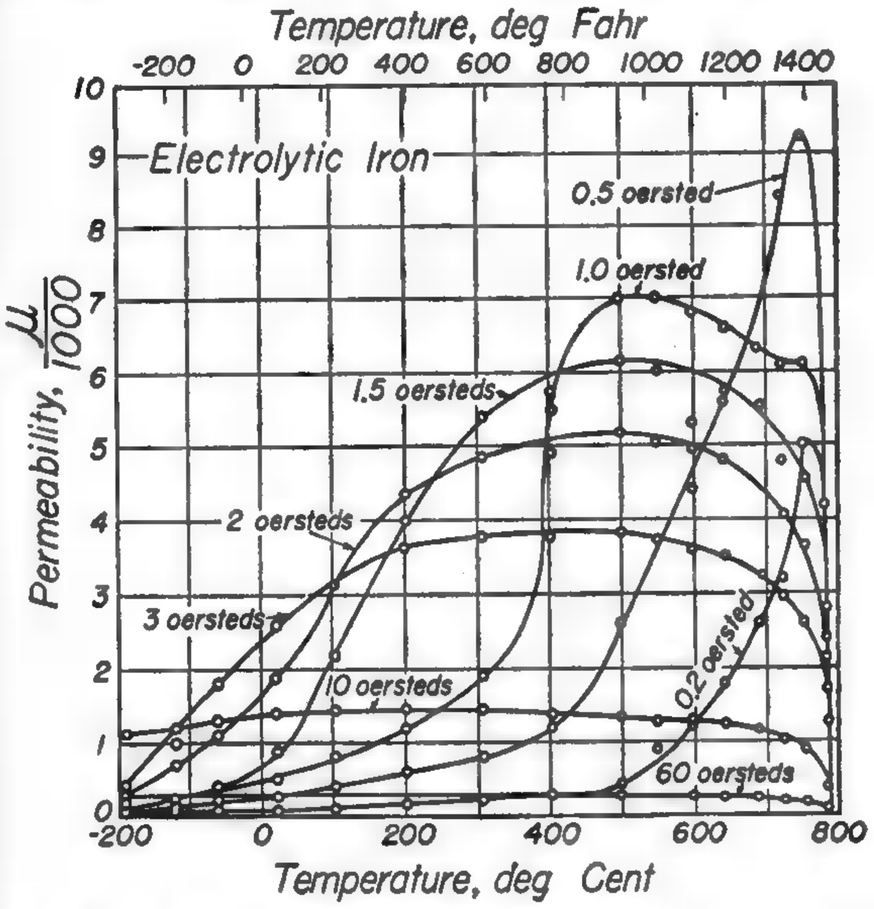

Fig. 16 Variation of the magnetic permeability of annealed electrolytic iron with temperature (Terry)

compressibility between 0 and 10,000 kg per sq cm was 0.566×10^{-6} kg per sq cm, and at 75 C it was 0.572×10^{-6} kg per sq cm over the same range of pressure. The pressure coefficient for this range of pressure was 7.0×10^{-6} per kg per sq cm and the temperature coefficient was 2.3×10^{-4} per degree Centigrade over the range from 30 to 75 C.

Adams found that the compressibility of a specimen of Yensen's high-purity iron agreed with that of Bessemer

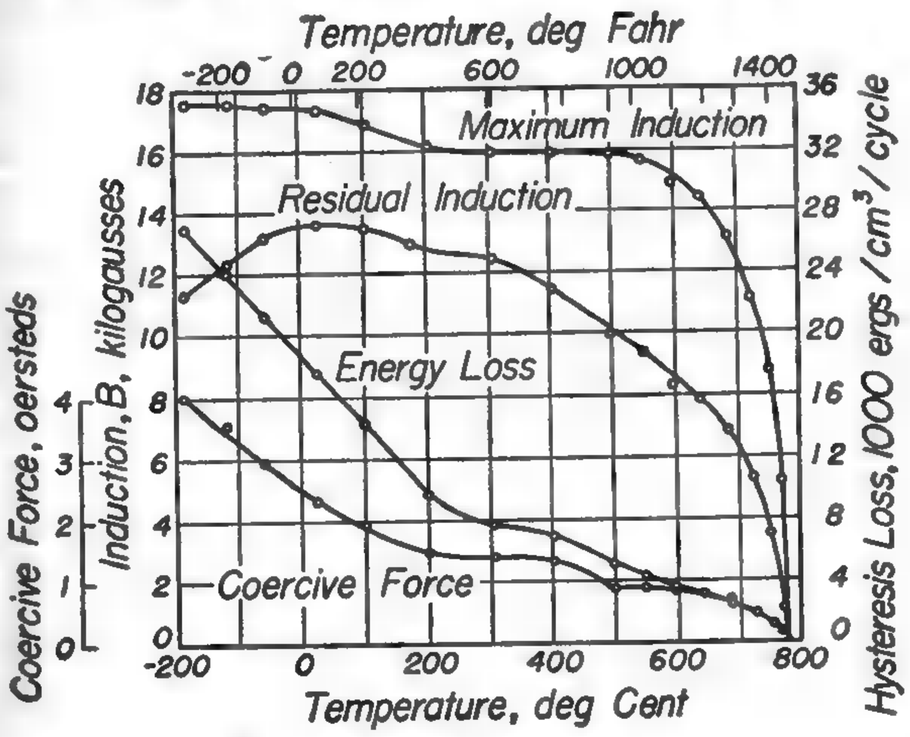

Fig. 17 Variation of the hysteresis constants with temperature in annealed electrolytic iron (Terry)

steel within one part in 500 over a range from 0 to 7000 kg per sq cm pressure.

Compression, Tensile, Torsion, Fatigue, Hardness and Impact Values. These values for polycrystalline irons at room temperature are given in Table XI. The data presented are necessarily only a summary of selected values.

Effect of Temperature on Mechanical Properties. Although variations in testing technique affect the results at room temperature, they have an even greater effect at high and low temperature. Speed of testing, shape of specimen, method of gripping, uniformity of temperature and accuracy of temperature measurement are important factors, which unfortunately are frequently not mentioned in reports of tests found in technical publications.

Results obtained at elevated temperature may be divided into two groups—"short time" and "creep". Tapsell and Clenshaw give the results shown in Table XII for ingot iron when a Martens extensometer was used for determining the modulus at elevated temperatures. The loading

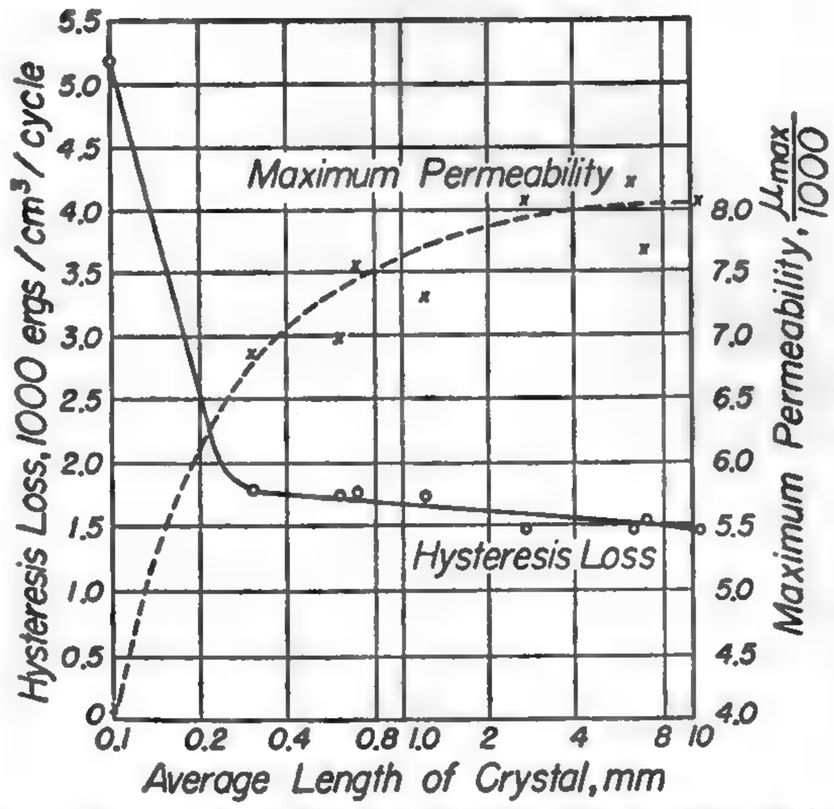

Fig. 18 Effect of grain size of electrolytic iron on hysteresis loss and maximum permeability (Sizoo)

was applied in steps. Total time to proportional limit was about 20 min. Normalized bars 2 in. in gage length and ½ in. in diam were used.

The work of Lea covered the temperature range of minus 40 to 1000 C. In general his tensile values are lower than those of Tapsell and Clenshaw, and above the "blue brittle" range the elongation is greater. These results are shown in Fig. 21.

The maximum in tensile strength at approximately 200

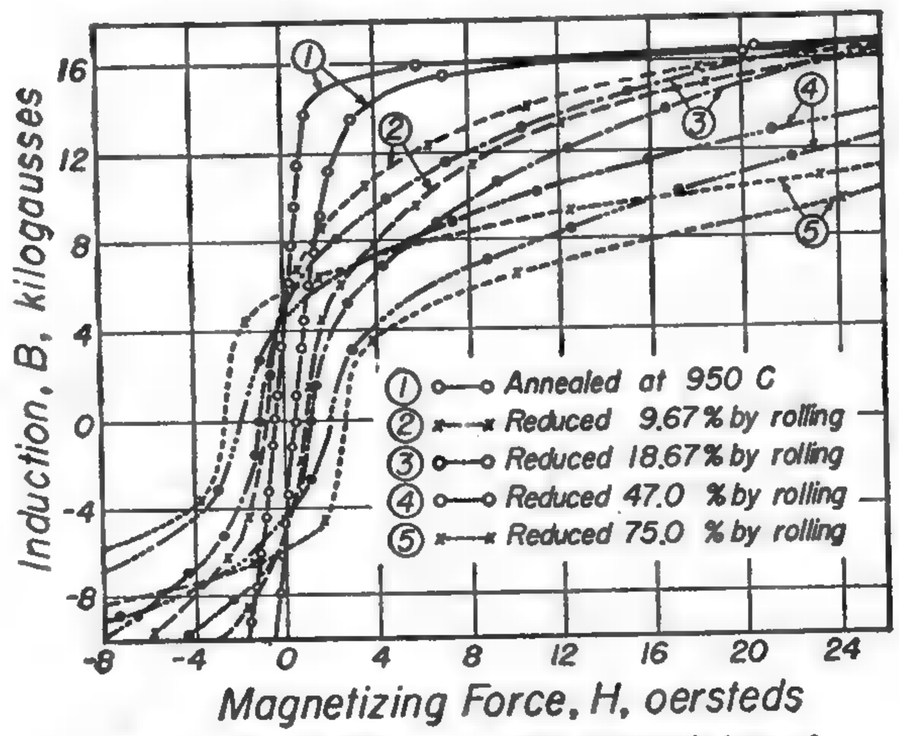

Fig. 19 Effect of cold work on the hysteresis loop of polycrystalline electrolytic iron (Gries and Esser)

C is generally ascribed to the so-called "blue brittle" phenomenon. The temperature at which this maximum tensile strength occurs, depends on testing speed; for slower speeds the maximum is at lower temperatures, and if the test is made slowly enough (two months) at room temperature, a strength is obtained approximately equal to the strength at ordinary rates of testing in the "blue brittle" range.

The "creep" strength is considerably lower than the tensile strength determined in the short-time test. The

value obtained depends on the chosen rate of creep. Tapsell and Clenshaw have determined the strength of ingot iron at various rates of creep, as shown in Fig. 22. The rate of creep used for curve 1 is less than 1×10^{-4} in. per day.

Mechanical Properties of Single Crystals. Osmond and Frémont determined the yield strength in compression to

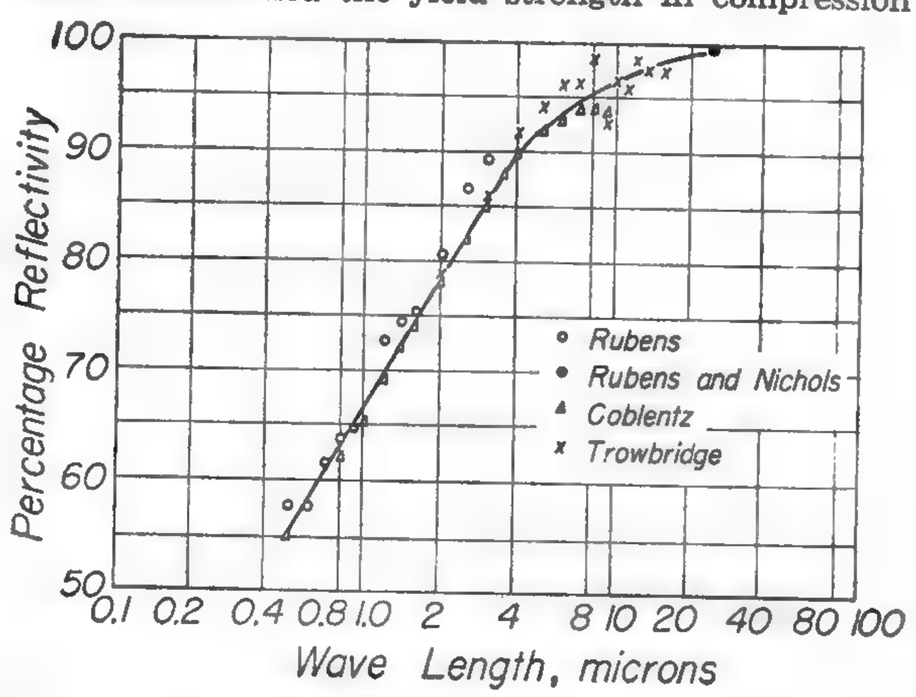

Fig. 20 Reflectivity of iron

be 19,800 psi on cube faces and 24,200 psi on octahedral faces of single crystals prepared from a decarburized steel rail (0.06% C, 0.30% Mn, 0.116% P, 0.02% S, 0.051% Si). This same material had a tensile strength of 39,500 psi and a yield strength of 23,500 psi perpendicular to a cube face, and a reduction of area of 85%.

Edwards and Pfeil prepared single crystals from mild steel and found tensile strength values from 21,000 to 34,500 psi for ten different crystals (orientations not determined); yield strength 4300 to 5600 psi; elongation in 2 in., 30 to 54%; and Young's modulus 22.4 to 29.8 $\times 10^6$ psi.

The results reported by Osmond and Frémont for Brinell hardness of the specimen mentioned above, after annealing at 550 C, were 75 on cube face, 79 on dodecahedral face, and 81 on octahedral face. After the specimen had been annealed at 800 C, the corresponding values were 66, 69 and 76. On his single crystals Pfeil found a Brinell hardness of 80, which was the same in different directions of the crystal, within the limit of accuracy of the test.

Effect of Grain Size on Mechanical Properties. Table XIII gives the variation in tensile properties with grain size as determined by Edwards and Pfeil. Pomp found the

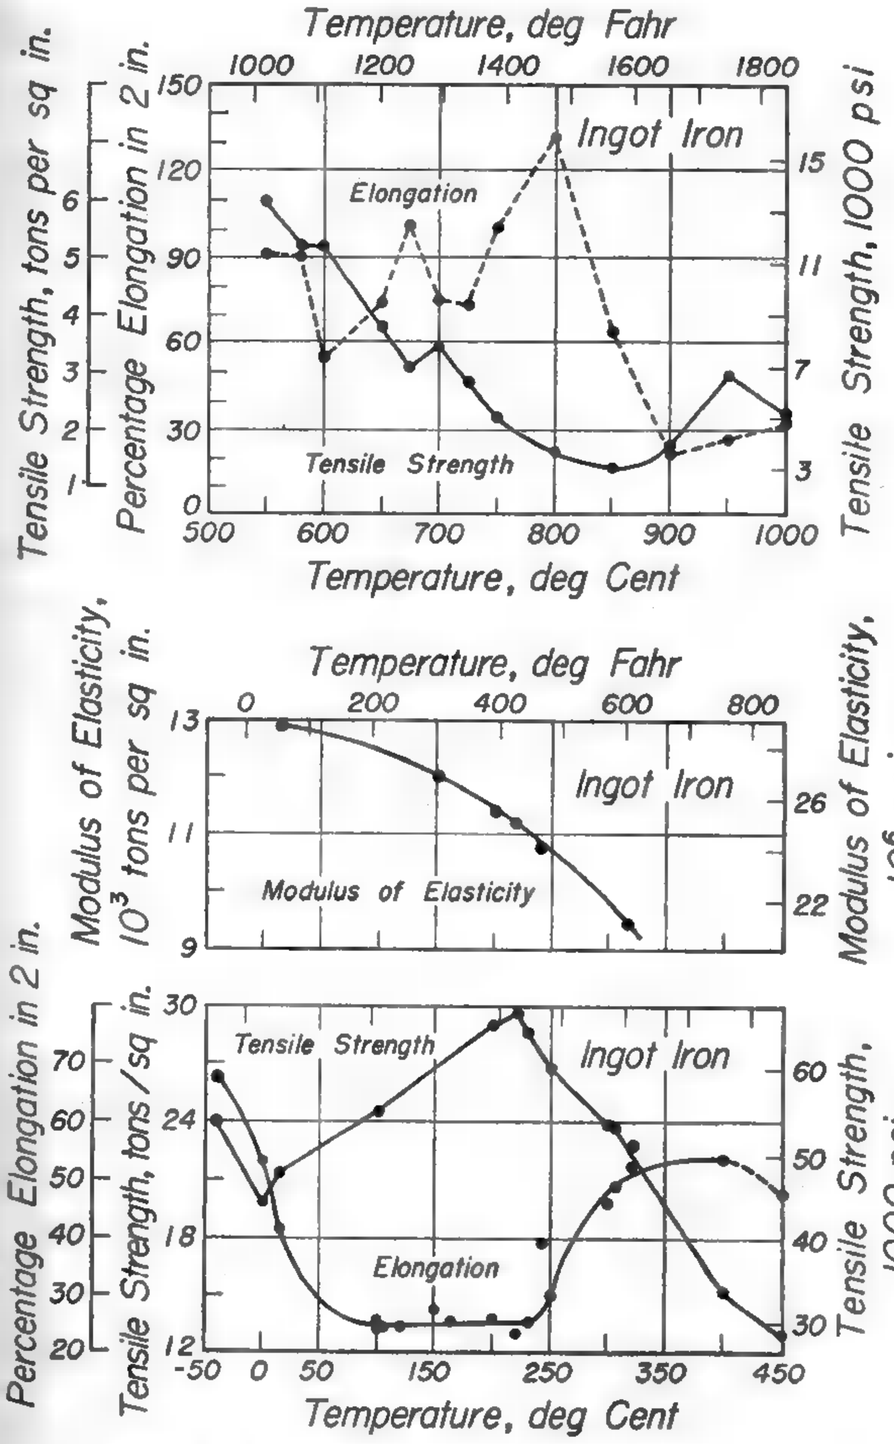

Fig. 21 Tensile properties of ingot iron at various temperatures (Lea)

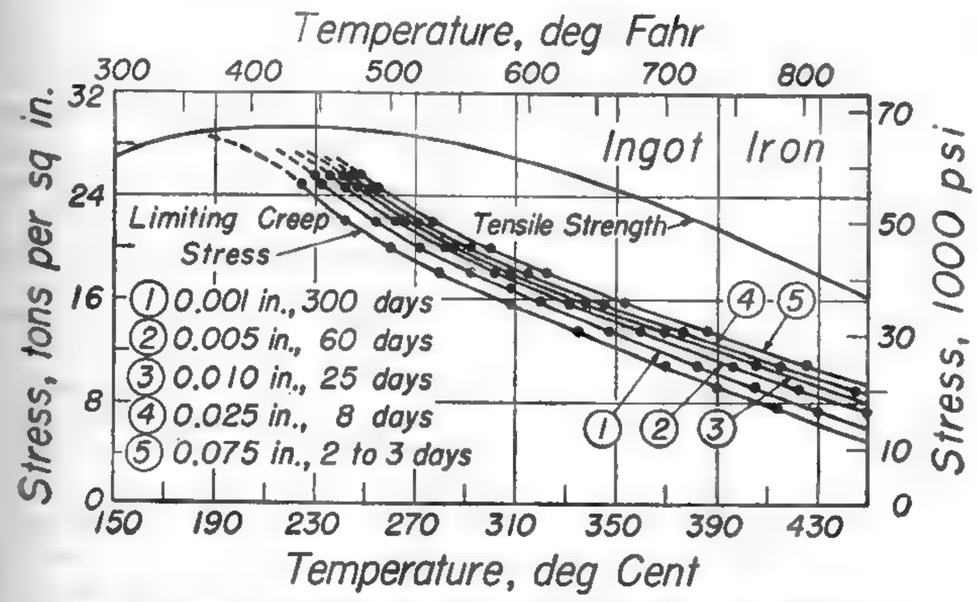

Fig. 22 Creep strength of ingot iron (Tapsell and Clenshaw)

Brinell hardness only slightly affected by grain size and reported the following: Brinell hardness 83 for 68 grains per sq mm; 87 for 827; 89 for 1350; 96 for 2310; and 95 for 3970 grains per sq mm.

Torsion Tests at Elevated Temperatures. Tapsell and Clenshaw determined the torsional strength of ingot iron at elevated temperatures by means of short-time tests of a duration of about 20 min up to the proportional limit and 20 min from the proportional limit to fracture. The results are given in Table XIV.

Hardness at Elevated Temperatures. Both dynamic and static hardness tests have been made on ingot iron by Tapsell and Clenshaw, as shown in Fig. 23. O'Neill determined at various temperatures the scratch hardness of a carbon-free iron made by decarburizing a mild steel in hydrogen. These results are shown in Fig. 24. The hardness values are taken as the resistance to the production of a scratch 0.1 mm wide at various temperatures.

The Plastic Deformation of Iron

By C. H. Mathewson*

IRON as well as other metals accommodates itself to plastic deformation by the gliding of crystal blocks or lamellae on one another. This process ordinarily becomes one of pure translation, in which the orientation of the crystal changes only as the gliding along planes cutting across the axis of stress application sets up a bending moment around an axis in the slip plane at right angles to the direction of slip. It is this bending or twisting of crystals and parts of crystals that produces the preferred orientations or textures found in wrought metal. Such effects are important, because the physical properties of the metal are determined largely by the orientation of its particles. The state of purity has a remarkable effect on the force necessary to start translation or keep it in action, and in general on the dynamics of the process. As a guiding principle, it may be said that translation starts when the shear stress on a competent slip plane in a possible slip direction rises to a critical value, but as the simple slipping process brings about change of orientation, the resolved shear stresses change, and slip on one family of planes may soon be accompanied by slip on another family. In single crystals, the normal outcome of the process may be fairly well predicted; but in ordinary polycrystalline metal the mutual interference among the grains leads to complications, and there is no clearly accepted method of rationalizing the textures formed in such material by the translation process.

X-ray studies have revealed the general characteristics of textures[1,2] formed during the different industrial processes of working iron (and other metals), as indicated in a later paragraph, but it must be realized that data of this character give merely a rough indication of the preferred orientations of the crystals, since considerable deviation from any stated orientation always occurs, and the texture changes from one point to another in the object; for example, from surface to center in a drawn wire. It is this variability that renders the study of textures important as a method of controlling the conditions of plastic deformation in the development of desirable directional properties in wrought metal for any particular purpose.

The gliding process may also become one of mechanical twinning, which requires that each slip plane shall move the exact fraction of the distance between atoms on the adjacent slip (twinning) plane that will set up anew the crystal lattice pattern in a changed or twin orientation. In iron, this process does not appear to be of great importance, since twin lamellae, or so-called Neumann bands are produced only under certain limiting conditions and do not usually represent the major effect of the plastic deformation. A general understanding of the elements and the simple mechanism of block movements defining the processes of translation or twinning may be obtained from the following outline. More detailed information on this general subject may be obtained conveniently by reference to the recent volume "Structure of Metals", by Barrett.[3]

Significant Directions and Planes. At temperatures above 2550 and below 1670 F, crystals of pure iron have their atoms arranged according to the simple body-centered cubic pattern as illustrated in Fig. 1 of the article in this Handbook entitled "Physical and Mechanical Properties of Iron", page 423.

For the purpose of considering displacements of atoms and planes by plastic deformation of the iron crystal, it is best to orient the body-centered cubic unit of structure (Fig. 1) so that one of the body diagonals, *ab*, passing through two corner atoms and the central atom, is in a vertical position. This and the other three body diagonals are lines or directions through the crystal along which the atoms make the closest possible approach to one another. When the crystal is forced to change its shape by the action of an external force, the atoms resist separation in these close-packed strings, and shearing occurs by some form of block movement in one or another of these four significant directions <111>. If other unit cells are grouped around the first in Fig. 1, it is clear that the atom at each corner of the original cell belongs to a close-packed string, including the central atom of a neighboring cell. Similarly, the outlying corner atoms of these new cells belong to close-packed groups derived from more distant cells. Using the central string of atoms as an axis, a vertical plane may be rotated into various positions, such as *a c′ b d′*, which is designated as a plane of form {110}; the other shaded position is designated {112}. Each plane furnishes some characteristic spacing of these close-packed strings of atoms and some characteristic geometrical relationship between the atoms in this plane and those in a parallel plane passing through adjacent strings of atoms. These details can be studied in some form of projection such as the one given in Fig. 2, in which all atoms are projected vertically into a plane of the form {111} at right angles to the close-packed string, *ab* (body diagonal), of Fig. 1.

It is evident in Fig. 1 that the atoms of the three different strings originating at *a*, *c* and *d* do not match one another in horizontal planes, while those originating at *c*, *c′* and *c″* or at *d*, *d′* and *d″* meet this condition perfectly. These differences in level are indicated in the projection

* Professor of Metallurgy, Yale University, New Haven, Conn.

of Fig. 2 by using circles of different sizes, with letters indicating the proper relationship to Fig. 1. A projection of this sort is competent to represent an indefinitely large number of unit cells piled on and around one another according to the plan of orientation selected. Planes of particular significance or interest may be selected for boundaries and in this projection (Fig. 2) dodecahedral planes {110} of Fig. 1 are chosen for right-hand and left-hand boundaries and trapezohedral planes {112} of Fig. 1 for the upper and lower boundaries.

Within the figure it would be possible to draw many sets of parallel lines, bringing the projected strings of atoms into planes of various kinds. Thus a set of lines parallel to the vertical boundaries would represent the closest possible grouping of the strings into dodecahedral planes and inspection of the figure shows that there are two other sets of planes inclined 60 deg to the first set and having these same characteristics.

Slip Planes and Directions. Plastic deformation of a crystal commonly occurs in the direction of a line of closest packing of atoms by block movement along planes of the densest atom-packing on which the stress intensity

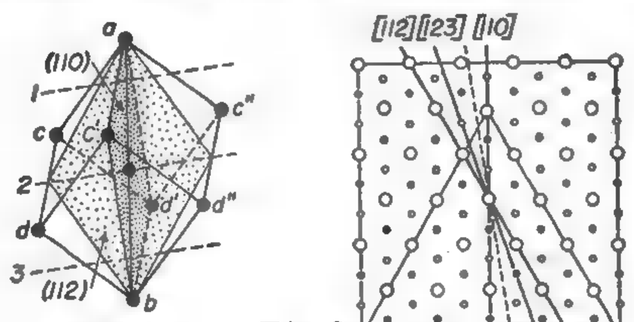

Fig. 1

Fig. 2

Fig. 1 Body-centered arrangement of atoms with a cube diagonal in vertical position. *1, 2, 3.* Body-centered atoms from adjacent cells occur at each of these levels.

Fig. 2 Projection of atoms of body-centered cubic lattice in a plane perpendicular to close-packed strings of atoms (an octahedral plane). Atoms in the plane of the projection and 4th and 7th planes above are shown by large circles; in the 2nd, 5th and 8th planes these atoms are represented by smallest circles; and in the 3rd, 6th and 9th, by circles of intermediate size.

has reached the highest value. In the case of a polished iron crystal, oriented to correspond with Fig. 2, and loaded with maximum stress intensity in the direction of the atom strings (that is, perpendicular to the plane of the projection), this condition would cause one or more sets of slip bands to appear, parallel to the most severely stressed dodecahedral planes. Actually, the slip bands observed in iron are of a more complex character, often irregular, forked or wavy, and apparently unrelated to any principal plane of the crystal. O'Neill[3] and Pfeil[4] have observed bands parallel to planes of the form {112} (horizontal boundaries in Fig. 2). Taylor and Elam[5] emphasize the importance of the close-packed atom strings in guiding the *direction* of slip, but these investigators consider the block movement to occur not along planes of simple indices but in rodlike bundles of atom strings having boundaries that are determined by stress considerations alone. In an elaborate analysis of the deformation of a single crystal of iron stressed in torsion, Gough[6] concludes that slip may occur in the direction of the close-packed atom strings on a variety of planes containing these gliding elements, that is, planes of the form {110}, {112} or {123}. Some of the projections of these planes are shown by the lines drawn in Fig. 2. If the shear stress resolved in the direction of the close-packed atom string is greater on one of the designated crystallographic planes than on any other conceivable plane, slip is likely to occur on the planes of this set without further complication. However, if the maximum shear stress occurs on some intermediate plane corresponding to the dotted line of Fig. 2, slip will occur on particular planes of the above designated forms located on both sides of the plane of maximum resolved shear stress {110} and {123}, in Fig. 2. Under these conditions the slip bands will be of a duplex type with an average slope corresponding to the dotted line of Fig. 2. Fahrenhorst and Schmid,[7] however, considered {123} the most probable planes of slip and Sauerwald and Sossinka[8] found only the traces of these as slip planes after compression at room temperature.

Barrett, Ansel and Mehl[18] have verified Gough's general conclusions, but find that in silicon ferrite, either a low temperature or a high silicon content causes slip to be confined wholly to planes of the form {110}.

Severe Deformation. As the slipping proceeds in any crystal, the process becomes more complicated because of a rotation that accompanies the block movement and consequent increase of stress in other eligible slipping directions. Large amounts of deformation therefore bring many different slip planes into play, and in ordinary polycrystalline material the process is further complicated by inhomogeneity of the force field at the grain boundaries or within the grains themselves. This may result in deformation bands exhibiting characteristic differences of orientation.[19] Hardening accompanies cold deformation, perhaps because of an increased resistance to slip through the minute blocks of crystalline material, which, in moving past one another, have developed slight differences of orientation (nonuniform curvature, lineal nonregistry at boundaries, or other forms of lattice distortion).

Preferred Orientation Under Various Forms of Stress. In spite of the complex mechanism of the slipping process, the crystalline particles of metal, worked into a given form by continued application of stress in some prescribed manner, finally become forced into positions closely approximating a definite and characteristic *preferred orientation*.[2,9] Simple stretching brings a cube-face diagonal <110> into the axis of the rod, with a radial disposition of a corresponding set of cube edges <001> in the different crystals. In cold drawn wires <110> also occurs as the fiber axis. Under compression[5] a body diagonal <111> and to a lesser extent a cube edge occur in the direction of compression, with a cube-face diagonal in the radial position. In torsion, the cube-face diagonal and to some extent the <112> direction become the fiber axis with the body diagonal tangential. Cold rolling brings a face diagonal into the direction of rolling and a cube face into the plane of rolling. For data concerning preferred orientations in iron and other metals, see page 32.

Twinning. Planes of trapezohedral form {112}, parallel to the sides of the triangle outlined in Fig. 2, have the atoms of their close-packed strings at the same level in a given horizontal section. In passing from one to another of these adjacent parallel planes, the strings shift laterally into positions half-way between their former positions and vertically, so as to bring the atoms either one-third or two-thirds of a full atomic distance above the atoms in the first plane, depending on the direction of progression. Beginning with a certain plane (for example, the one projected as the base of the triangle in Fig. 2), if the atoms in the next plane towards the bottom of the figure are brought one-third instead of the normal two-thirds of an atom distance above the atoms in the first plane, and the atoms in the third plane are brought two-thirds instead of the normal one-third above, the altered region is said to be twinned with respect to the rest of the crystal. This change has been effected in the lower rectangular area, which therefore is the projection of a twin band.

Twinning by Pure Shear. The mechanical action of pure shear, in which the distance traversed by any particle in the direction of shear is proportional to its distance from the plane of shear, would produce this result, assuming the first plane (base of the triangle) to be the plane of shear and the shearing movement on the next plane to be exactly one-third of the distance between atoms in the close-packed string. This is believed to be the mechanism of mechanical twinning in iron.[10,11]

Close observation of Fig. 2 will make it clear that this same structural change may be obtained by shearing along any one of the three families of planes of the form {112}, represented by the sides of the triangle, and that no other twin configuration is possible in this projection. However, since there are three additional body diagonals representing close-packed strings of atoms in the iron lattice, three other projections are possible, each competent to illustrate the formation of a new twin configuration by shear, along any one of three additional planes of the form {112}.

Infrequency of Twinning in Iron. So many planes are

available for deformation by the ordinary process of slip that the much more restricted or specialized form of slip necessary for twinning would be expected to occur only exceptionally in pure iron. Stiffening of the lattice by alloying favors the occurrence of twinning. Somewhat brittle coarse-grained ferrite containing silicon or phosphorus twins readily when deformed by impact. Coarse-grained ingot iron also twins readily by impact at room temperature. It is reported[8,12] that pure ferrite twins readily, even by slow deformation at the temperature of liquid air. Barrett, Ansel and Mehl, in their recent investigation[18] of the plastic deformation of iron, have demonstrated that twinning, which could be produced in pure iron by slow deformation (torsion) at minus 200 C, occurs at higher temperatures with increasing silicon content, until, with approximately 5%, it is the favored mechanism of deformation close to room temperature. It is followed in this relatively brittle alloy by cleavage, and then slip on planes of form {110} as the temperature is further increased. Even under the most favorable conditions, only thin sections of a crystal can be stressed in the exact manner necessary to produce the twin structure. Twinning in iron is therefore observed only in the form of thin lamellae usually called *Neumann bands.*

Deformation of Face-Centered Cubic Iron. When ordinary grades of iron are heated above 1670 F but not above 2550 F, or when exceptionally pure iron, containing only minute traces of oxide, nitride or carbide, is heated within the same range, the atoms are arranged according to the face-centered cubic pattern illustrated in Fig. 1*d* of the article "Physical and Mechanical Properties of Iron", on page 423 in this Handbook. Thus far no detailed study appears to have been made of the slip planes and directions brought into play by hot working pure iron in this range of temperature; yet there is little doubt that the mechanics of deformation are analogous to those observed in aluminum,[14] copper,[15] and other face-centered cubic metals.

In wrought and annealed austenitic steels in which iron has been alloyed so as to preserve the face-centered cubic arrangement of atoms, the microstructure is strikingly similar to that of the common face-centered cubic alloy, alpha brass, even exhibiting the familiar twin bands that are seen in both metals after recrystallization following plastic deformation. This resemblance points to a similarity of the deformational process in both metals, and the analogy in all probability may be extended to include the behavior of pure iron at elevated temperatures.

Planes and Directions of Slip in the Face-Centered Cubic Lattice. In the face-centered cubic metals only the planes of closest atom-packing, the octahedral planes {111}, function as slip planes and the slip occurs in the direction of one of the three cube-face diagonals representing close-packed rows of atoms on the given plane. Four families of octahedral planes are available for slip.

In single crystals under tension stress, slip starts on the set of octahedral planes for which the computed shear stress is a maximum, and continues on these planes until rotation of the lamellae brings an equal load on another set of octahedral planes. After a short period of extension by slipping on both sets of planes, the crystal usually breaks with a wedge-shaped fracture.

Pursuing the analogy with face-centered cubic metals still further, hot rolling of iron above 1670 F might be expected to develop preferred orientation of the crystalline particles[9,16] with the normal to a trapezohedral plane {112} approximately parallel to the direction of rolling and a dodecahedral plane {110} parallel to the plane of rolling. Subsequent cooling below the A_3 point would produce some form of reorientation, depending on the relationship between the two sets of crystal axes established during the transformation. No accurate details of this process are yet available.[17]

The Effects of Cold Work on the Properties of Iron

By Reid L. Kenyon* and Robert F. Mehl*

THE physical and mechanical properties of pure iron are given in another article in this Handbook.[1] The present article deals only with the effect of plastic deformation on these properties. Critical examination of the literature reveals that many of the published data on "pure iron" are actually on low-carbon steel, sometimes with as much as 0.10% C and 0.50% Mn, besides other impurities. Because few if any of the properties of *pure* iron can be extrapolated from such data, they are omitted from this article. Although ingot iron and electrolytic iron are not pure iron, they have been taken as pure for the purpose of this tabulation. Since the few published results are from isolated tests, it is impossible to discriminate and select "best values". The data given here should be considered only provisional—an indication of the need for further experimental work on the properties of plastically deformed pure iron.

The Effect of Cold Working. The previous mechanical and thermal history of the material, such as residual strain and grain size, has been found to have a marked effect on the response to cold working. Gries and Esser[2] give the results of Brinell tests on polycrystalline and monocrystalline iron after various degrees of cold rolling. Their values are reproduced in Fig. 1. The method of cold working also affects the results. Wire drawing produces a greater change than rolling for the same amount of reduction. Jeffries and Archer[3] have given tensile strength values for cold drawn ingot iron wire, which are compared in Fig. ■ with cold rolled materials. Greulich[5] also reports the effect of cold rolling on the tensile properties of ingot iron, but shows it to be considerably greater than normal,

probably because of a different previous treatment.

Various attempts have been made to express the properties of cold worked metals as functions of the percentage reduction. Greulich[5] finds these relationships between reduction in thickness and hardness, yield point and tensile strength to be logarithmic up to a limiting amount of reduction, but Templin[6] shows that the tensile strength versus percentage reduction of area is a straight line. He gives the following equation for the tensile strength of ingot iron: Tensile strength $= 37{,}500\ (1 + 1.64\,R)$, where R is the fractional reduction of thickness. Greulich[5] gives the equation: Tensile strength $= 46{,}000 + 7510 \log_e \phi$, where ϕ is the percentage reduction of thickness.

Templin's formula is believed to be in better agreement with most test data, although it should be remembered that all such particular relationships should be expected to apply only to material in the same initial condition. Their general application to pure iron in all conditions is doubtful.

A work hardening coefficient may be derived from Meyer's equation relating load and diameter of impression in the Brinell hardness test.[7] In this equation, $p = a\ d^n$; the exponent n may be taken as a measure of the capacity

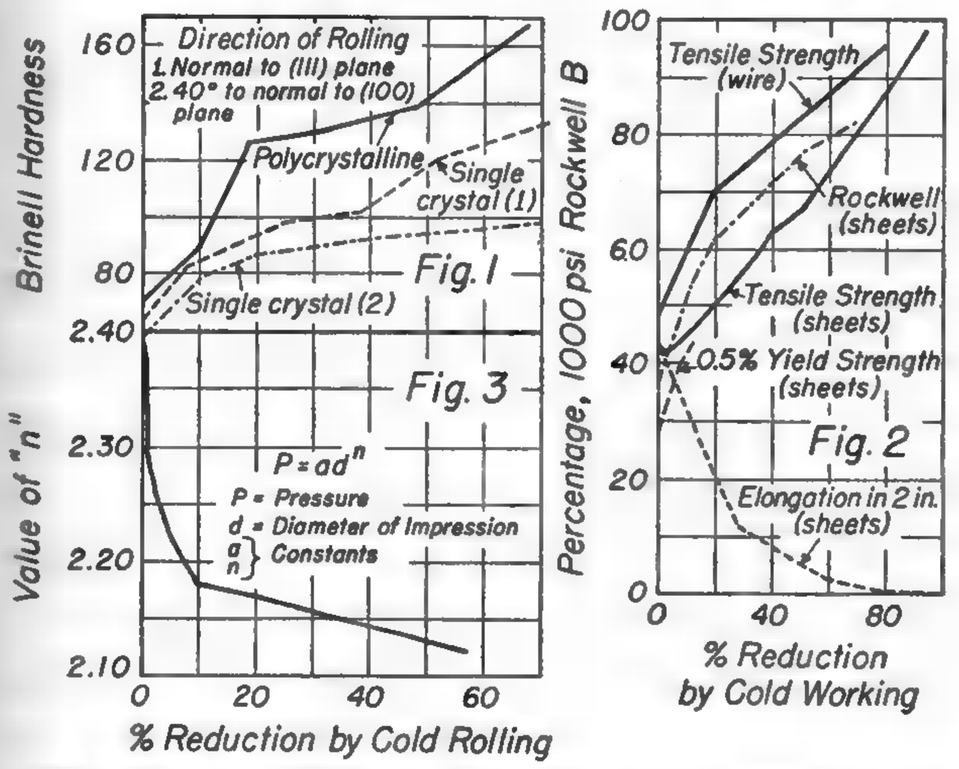

Fig. 1 Effect of grain size and orientation on increase of hardness with cold rolling (Gries and Esser[2]).

Fig. 2 Effect of cold working on the properties of ingot iron (tests on wire by Jeffries and Archer[3] and on sheet by Kenyon and Burns[4]).

Fig. 3 Variation of Meyer's constant n with cold rolling.

of a material to work harden. Figure 3 shows a series of such values of n for ingot iron* cold rolled up to 57% reduction in thickness. It will be seen that n decreases with cold work as expected. The slope of the true stress tensile curve is much used in Germany as a measure of rate of work hardening,[8,9] but doubt has been expressed[4] concerning its usefulness, because this slope is often a constantly changing quantity. (*See* Stead[10] and O'Neill and Greenwood[11] for additional studies on true stress curves.)

The effect of cold working on the shape of the curve of tensile stress versus strain for ingot iron is shown in Fig. 4. The disappearance of the yield point, increase of the tensile strength, and loss of ductility are the most noticeable effects. The curves in Fig. 4 are for specimens tested immediately after cold rolling; aging at room temperature or at slightly elevated temperatures alters these curves profoundly.[15]

The effect of cold work on the density is given elsewhere.[1] The electrical conductivity and magnetic properties are affected adversely, but no data have been found for iron of high purity.

Structure. The first visible effect of cold plastic deformation on the microstructure of iron is the production of slip bands on a polished surface. If the deformation is carried to a sufficient extent, the grains become distorted and elongated, and this appearance, unlike slip bands, is not changed by repolishing and re-etching.

* Unpublished work, Research Laboratories, American Rolling Mill Co.

Sudden or impact deformation produces the so-called "impact twins" or "Neumann bands". These twins differ from twins in face-centered cubic metal in that they frequently exhibit irregular or serrated outlines. Apparently iron forms no strain-anneal twins.

The mechanical properties of plastically deformed iron change with time after cold deformation when the material is held at room temperature, and at a more rapid rate at slightly elevated temperatures. This is called "aging" and is discussed in the next article in this Handbook.

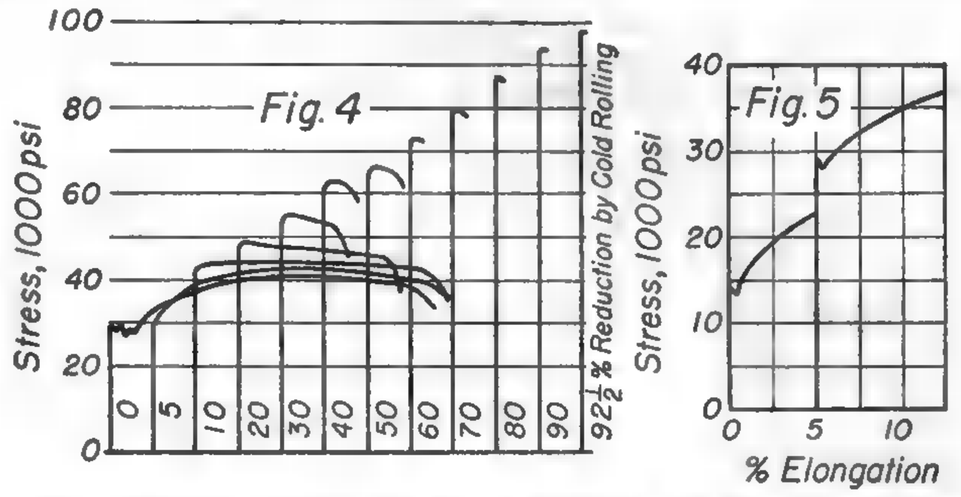

Fig. 4 Effect of cold rolling on the shape of the stress-strain curve of ingot iron (Kenyon and Burns[4]).

Fig. 5 Effect on the yield point of aging electrolytic iron (Ludwik and Scheu[17]).

Sufficient plastic deformation eliminates the sharp yield point from the tension stress-strain curve when the test is performed immediately, but this yield point is made to reappear by allowing the metal to age long enough at the particular temperature. This is shown for electrolytic iron in Fig. 5. Köckritz[15] showed the increase in tensile strength and yield point of ingot iron in comparison with other materials. (Fig. 6)

The behavior of iron plastically deformed at room temperature and aged at temperatures in the blue brittle range, is duplicated in kind, though in somewhat different degree, by simple plastic deformation in the same range. Since at this temperature the rate of aging is very great,

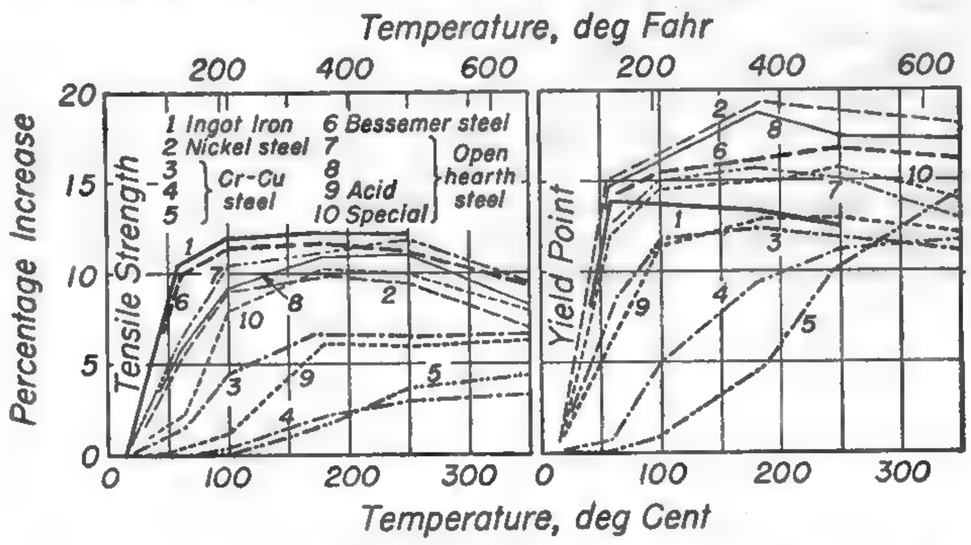

Fig. 6 Increase in yield point and tensile strength of various steels as a result of cold stretching 5% and heating for one hour at the indicated temperature (Köckritz[15]).

the resulting increase in strength and decrease in ductility manifest themselves during a tension test on previously unstrained material. This has been shown by Jeffries and Archer[18] and also by Kenyon[19] for ingot iron. Figure 7 is reproduced from Kenyon's article.[19]

When plastically deformed iron is heated to various temperatures, the properties are altered. The amount of the change depends on the amount of cold deformation, the original condition (such as grain size) and the temperature and duration of heating after cold working. These changes do not all take place at one temperature but are progressively greater as the temperature is raised, although there is a minimum temperature below which the changes are relatively small. The magnitude of these changes is increased if recrystallization occurs.[20] According to Sato[21] the increased energy introduced during cold deformation is released at approximately 570 C. Tammann[22] shows a

gradual decrease in electrical resistivity and thermoelectric force with increasing temperature of annealing, whereas the magnetic susceptibility remains unchanged at temperatures as high as approximately 750 C, at which temperature it suddenly increases.

Annealing of cold worked iron has a pronounced effect on the mechanical properties as determined at room temperature. Published data are almost exclusively for steels; the only results found for pure iron are those for Brinell hardness as reported by Tammann.[22] With suitable conditions of grain size, amount of deformation, and annealing time and temperature, these changes in mechanical properties are accompanied by a profound change in grain size. The metal undergoes *recrystallization*. It is possible, however, to soften cold worked iron without causing recrystallization.[25] The recrystallization of iron is represented conveniently, though inadequately, by a three-dimensional diagram relating to degree of cold work, temperature of heating and resultant grain size. Figure 8, taken from Oberhoffer and Oertel,[23] represents the general relationships, although it is believed that there is a critical temperature range that leads to the extreme grain growth, varying with the amount of deformation. The curve on the basal plane shows the amount of strain required to cause recrystallization at a given temperature and indicates that this may occur as low as 400 C. McAdam[24] showed that ingot iron will recrystallize at 485 C under certain conditions. Factors not represented in Fig. 7 are known to affect recrystallization. Thus, the initial grain size is an important factor; to initiate recrystallization, small grains require less overstrain than large grains as measured by changes in dimensions. The duration of heating is also important, as well as rate of heating if slow.

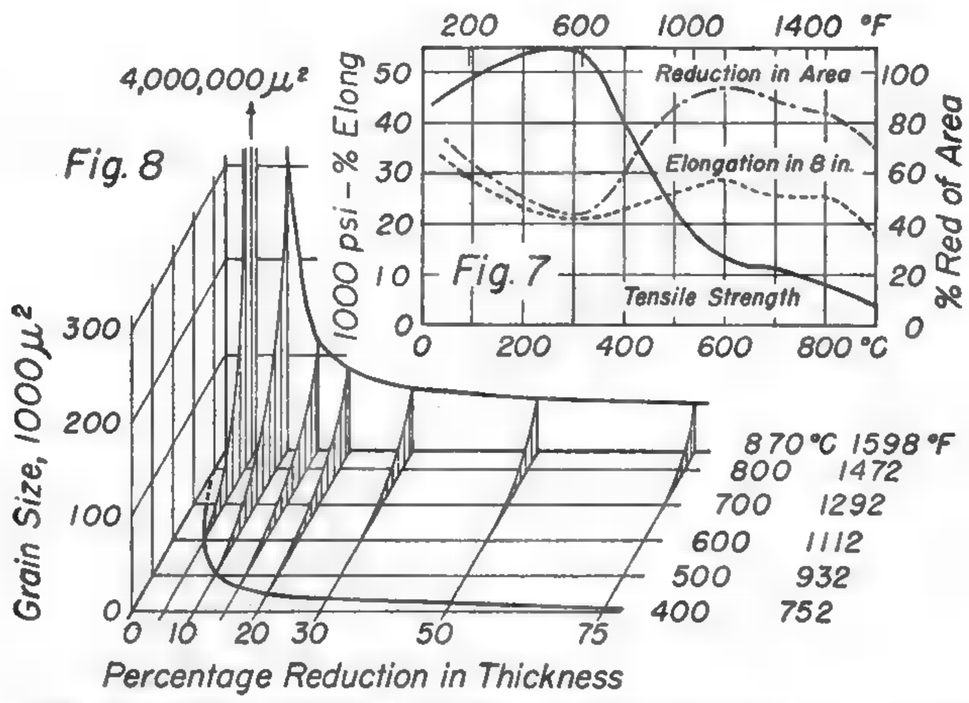

Fig. 7 Tensile properties of ingot iron at elevated temperatures (Kenyon[19]). **Fig. 8** Recrystallization of iron.

Aging of Iron and Steel

BY SAMUEL EPSTEIN*

AGING is a change that occurs in the properties of iron or steel at atmospheric temperature or at a moderately elevated temperature, after rapid cooling or after cold working. "Quench-aging" is the term used to denote the changes that take place in steel after a final operation consisting of fairly rapid cooling from an elevated temperature. "Strain-aging" is the term applied to the changes that take place when the final operation consists of cold working. Aging may result in an increase in hardness and strength; a loss in ductility and impact resistance; the reappearance, after cold working or after quenching, of a sharply defined yield point in the stress-strain curve of a tension test; an increase in coercive force; and similar changes in other properties.

* Research Engineer, Bethlehem Steel Company, Bethlehem, Pa.

Prepared for the Subcommittee on Aging of Iron and Steel, with membership as follows: J. J. Kanter, *Chairman* (Crane Co.), E. S. Davenport (United States Steel Corporation); Samuel Epstein, and Maxwell Gensamer (Pennsylvania State College).

The aging changes proceed relatively slowly at room temperature, but at an accelerated rate as the aging temperature is raised. This indicates that aging is a manifestation of a trend toward equilibrium and away from some unstable condition set up by rapid cooling or cold deformation, the most recent operation performed on the steel. Aging is generally assumed to be caused by the decomposition of a supersaturated solid solution.

Since carbon has a much higher solubility in austenite than in ferrite, the transformation of austenite to ferrite leads to a precipitation of carbide and to hardening. Indeed, such precipitation may contribute to the high hardness of quenched high-carbon steel. However, the term "aging" is generally used only with reference to precipitation phenomena in ferrite itself, below the A_1 transformation temperature. Such aging occurs in several alloys of iron—for example, the iron-copper alloys. Precipitation phenomena may account, in part, for the high creep-strength of some of the alloy steels used at elevated tem-

peratures. However, this article will deal only with aging effects in ordinary iron and steel and not in special ferrous alloys.

Interest in aging increased when it became apparent that the "blue heat phenomena" in iron and steel are associated with aging,[1] and when it was found that so-called "nonaging" steels can be produced by additions of aluminum, titanium[2] and other elements. Such aluminum-treated steel shows virtually no strain-aging, but nevertheless still exhibits a considerable degree of quench-aging. It also has a distinct yield point in the as-annealed condition. A recent investigation shows that steel treated with rather large amounts of titanium (about five times the carbon content) exhibits neither strain-aging nor quench-aging; neither does such steel show a yield point in the as-annealed condition.[3] It has also been found that heating low-carbon steel in moist purified hydrogen at about 1325 F (approximately 3 hr for 20-gage sheet) likewise produces a steel that shows no strain-aging, no quench-aging, and no yield point in the as-annealed condition.[4]

Elements That May Cause Aging Effects. The following elements are found in ordinary iron and steel: carbon, manganese, silicon, phosphorus, sulfur, oxygen and nitrogen. Of these, carbon and nitrogen have an appreciable solubility in ferrite directly below the A_1 temperature, and much lower solubility at room temperature. Thus, if the solubility at room temperature is less than the amount of the element present, precipitation and aging phenomena can occur. Figure 1 presents curves of this type, showing to what extent temperature will change the solubility of carbon, oxygen and nitrogen. All these solubility curves may be of uncertain accuracy and should therefore be regarded merely as approximations.

Silicon and phosphorus have solubility curves similar to those shown in Fig. 1. However, the solubility of each of these elements in ferrite at room temperature is much higher than the amount that is ordinarily present in iron and steel. Therefore silicon and phosphorus do not cause precipitation effects, although they may influence the aging phenomena by causing carbon, oxygen and nitrogen to precipitate more readily. Manganese also has a higher solubility in ferrite than the amount of manganese ordinarily present, so it should not give precipitation effects. Sulfur is present mainly as manganese sulfide inclusions and is not considered responsible for precipitation effects. However, it is known that manganese sulfide has a slight solubility in ferrite and it may therefore influence aging.

Carbon and nitrogen have been shown definitely to give rise to precipitation or aging effects when present in amounts ordinarily found in low-carbon iron and steel.[5,6] It will be observed in Fig. 1 that the solubility of nitrogen in ferrite at room temperature is not more than 0.001%, so precipitation effects caused by nitrogen may occur in steel containing more than this amount. Open hearth steel generally contains about 0.003 to 0.006% N, while Bessemer steel usually contains about 0.015% N and may contain more than 0.020%. The precipitated nitrogen in such steels may, under certain conditions, be observed under the microscope as nitride needles.

At one time oxygen was considered a main cause of aging in steel.[7] Magnetic aging effects, apparently caused by oxygen, have been reported in very pure iron, virtually free from carbon and nitrogen.[8] Oxygen has been reported as the main cause of strain-aging also.[5] On the other hand, several investigators have concluded that in iron or steel containing oxygen in amounts ordinarily present in such materials (for example, up to 0.035%), the oxygen does not cause quench-aging in the absence of carbon and nitrogen, although it may cause some strain-aging.[5,9–12] The most recent work has indicated that oxygen itself does not cause aging, although it may have a secondary influence on the amounts of carbon or nitrogen required to cause aging.[4]

This seems to contradict the well-known fact that strongly deoxidized steel is not susceptible to strain-aging. The probable explanation is that the strong deoxidizers, in combining with or "fixing" the oxygen (so that the oxygen can no longer give rise to precipitation-aging effects by going in and out of solution), fix the nitrogen in the same way. The strong deoxidizers are also very strong nitride formers. Strain-aging is thus obviated not because the oxygen is fixed, but mainly because at the same time the nitrogen is also fixed. It has been found that adding about 1 lb of vanadium per ton to rimming steel produces a nonaging steel. Previously all nonaging steel was killed steel.[13]

With reference again to the titanium-treated nonaging steel that does not strain-age, quench-age, or show a yield point in the as-annealed condition, the titanium undoubtedly fixes the carbon as well as the nitrogen. The experiments in which nonaging steel was produced by annealing in purified moist hydrogen indicate that the unfixed carbon and nitrogen must each be brought below 0.001% to

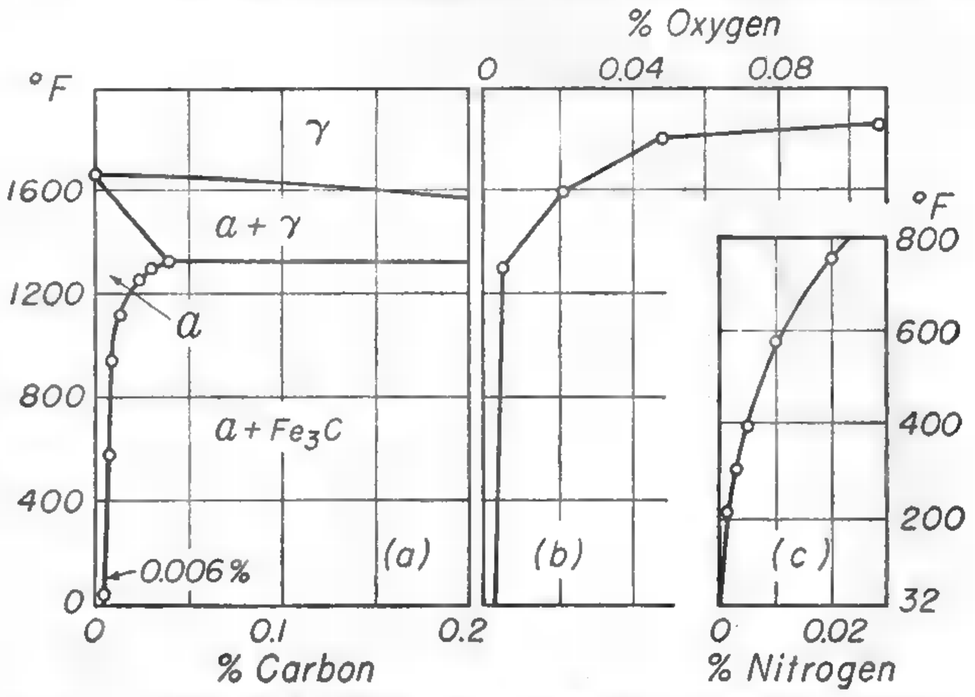

Fig. 1 Change in solubility with temperature of carbon, oxygen and nitrogen in fairly pure ferrite[16,8,6]

obviate strain-aging, quench-aging, and the presence of the yield point in the as-annealed condition.[4] The exact mechanism that produces the yield point in steel is still uncertain but precipitation-aging phenomena appear to be involved. The presence of as little as 0.001% of either carbon or nitrogen, in the unfixed condition, appears to be sufficient to cause the yield point to appear.[4] As a rough approximation based on present knowledge, the chief causes of the described aging effects appear to be as follows: nitrogen is the main cause of strain-aging; carbon is the main cause of quench-aging; carbon and nitrogen,

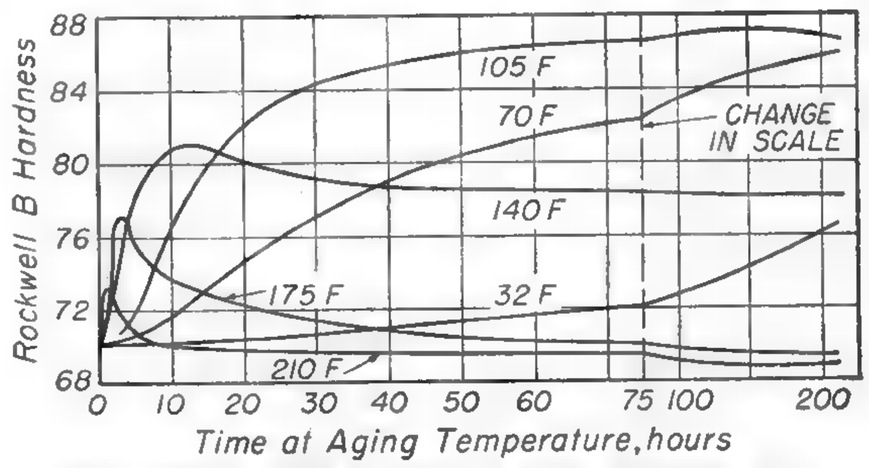

Fig. 2 Quench-aging of 0.06% C steel. Hardness after quenching from 1325 F and aging at indicated temperatures[5]

separately or together, cause the yield point; oxygen plays a relatively minor and indirect part in aging. In explanation of the effect of strong deoxidation in appreciably decreasing quench-aging,[14] it may be considered that although oxygen itself does not give rise to aging effects, it may cause carbon to do so. That is, oxygen may so greatly reduce the solubility of carbon in ferrite at room temperature that the carbon will precipitate and cause aging. When the oxygen is removed or fixed by a strong deoxidizer like aluminum, the room-temperature solubility of carbon may become greater; consequently the carbon is less likely to precipitate and cause aging.

Quench-Aging. In quench-aging above room temperature, the hardness increases more rapidly than in aging at room temperature, but the maximum hardness attained is lower. After the maximum hardness has been reached, further aging at elevated temperature causes a decrease in hardness (Fig. 2). This is sometimes called "overaging".

Table I. Quench-Aging of Low-Carbon Alloys

Composition, percentage				Brinell Hardness Number	
C	Mn	P	Si	Immediately after Quenching from 1300 F	After Aging 44 hr at 125 F Following Quenching
0.028	0.39	0.025	0.003	102	163
0.044	0.44	0.036	0.005	128	185

The magnitude of the quench-aging effects that may occur in low-carbon alloys is illustrated by Table I.[15]

In a series of iron-carbon alloys made from electrolytic iron without manganese and with 0.02 to 0.03% P, 0.007 to 0.008% Si, and less than 0.001% S, the results in Table II were obtained.[15]

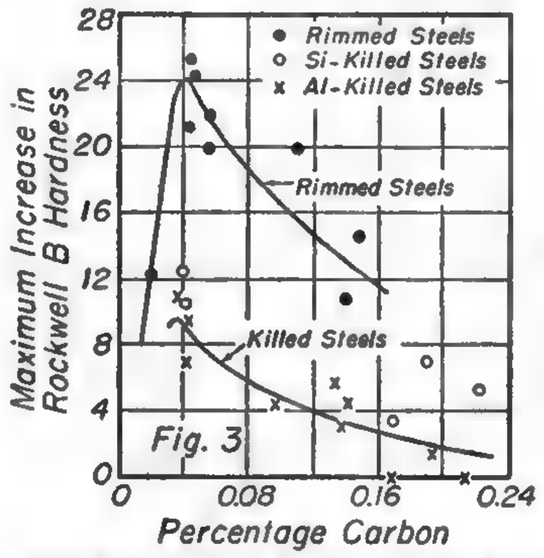

Fig. 3 Reduction in the aging effect as a result of strong deoxidation.[14] The silicon-killed steel contained about 0.15% Si and the aluminum-killed steel contained an equal amount of silicon with about 0.04% Al. The maximum aging effect occurred at about 0.05% C.

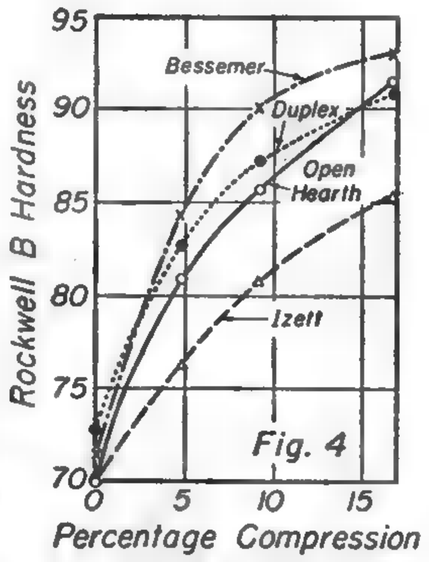

Fig. 4 Increase in hardness with cold work of Bessemer, duplex, open hearth and Izett steel.[17] The first three are aging steels and the last is an aluminum-killed nonaging steel. Hardness increased less rapidly with cold work in the nonaging steel. Compositions of steels:

Steel	Percentage C	Mn	S	P	Si	Al
Bessemer	0.08	0.47	0.035	0.102	...	...
Duplex	0.22	0.54	0.030	0.017	...	...
Open hearth	0.21	0.40	0.035	0.010	...	...
Izett	0.13	0.58	....	....	0.04	0.05

No appreciable age hardening occurred in alloys containing less than about 0.035% C. The age hardening effect reached a maximum in the 0.063% C specimen.

The extent of quench-aging is reduced appreciably by strongly deoxidizing the steel, particularly by killing with aluminum, as indicated in Fig. 3.

Strain-Aging. Here strain means "overstrain", that is, permanent deformation by straining beyond the elastic limit. In strain-aging, precipitation occurs presumably because overstraining causes local supersaturation along slip planes. Straining may result in two effects: (1) the increase in hardness that accompanies cold working in even the purest single-phase metal, and (2) the increase in hardness caused by the precipitation or dispersion of another phase induced by the straining. Strain-aging is usually determined by measuring the change in hardness or impact resistance with time after straining. During this time, the specimen is held either at room temperature or at a somewhat elevated temperature. Some precipitation may also occur during the straining. This is presumed to be the reason why cold working produces a greater increase in hardness in aging than in nonaging steels, as shown in Fig. 4. However, during cold working at room temperature, a very small increase in hardness results from aging during the straining itself. The differences in the increase of hardness for similar amounts of cold working, among the various steels shown in Fig. 4, probably occurred mainly as a result of aging between the time the samples were strained and the time they were tested for hardness after straining. In Fig. 4, no tests were made between 0 and 5% compression. Between 0 and 2% deformation, it is frequently observed that no hardening, but instead a slight softening, actually takes place. This phenomenon appears to be analogous to a slight softening sometimes observed in the early stage of quench-aging, designated as the "incubation period".

Table II. Quench-Aging of Iron-Carbon Alloys

	Percentage Carbon					
	0.019	0.033	0.043	0.063	0.087	0.166
	Brinell Hardness Number					
Immediately after quenching from 1300 F	85	79	89	123	127	136
After aging 8 days at 125 F following quenching	92	80	101	207	170	194
Increase in Brinell hardness	7	1	■	84	43	58

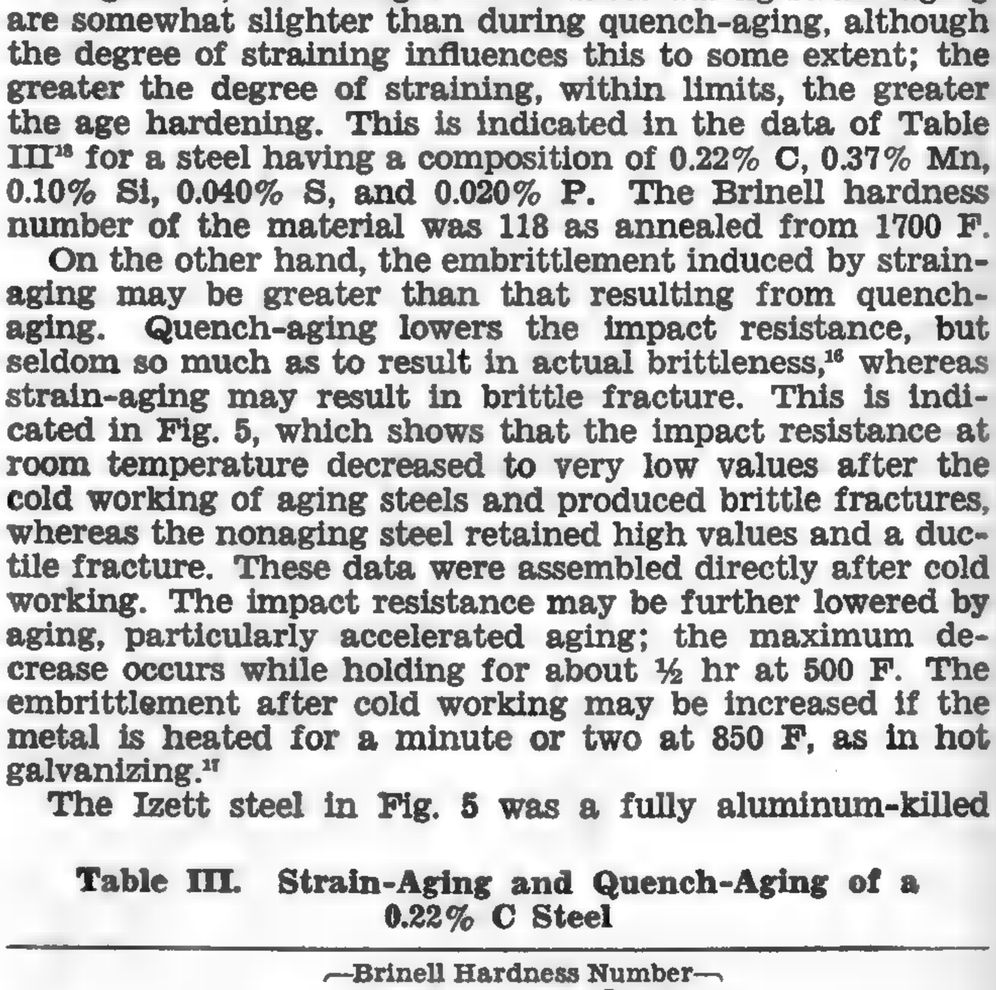

Fig. 5 Effect of cold work on impact resistance of aging and nonaging steels.[17] Charpy specimens with keyhole notches. Armco iron, duplex, open hearth, and Bessemer steel are aging; Izett is nonaging.

In general, the changes in hardness during strain-aging are somewhat slighter than during quench-aging, although the degree of straining influences this to some extent; the greater the degree of straining, within limits, the greater the age hardening. This is indicated in the data of Table III[18] for a steel having a composition of 0.22% C, 0.37% Mn, 0.10% Si, 0.040% S, and 0.020% P. The Brinell hardness number of the material was 118 as annealed from 1700 F.

On the other hand, the embrittlement induced by strain-aging may be greater than that resulting from quench-aging. Quench-aging lowers the impact resistance, but seldom so much as to result in actual brittleness,[16] whereas strain-aging may result in brittle fracture. This is indicated in Fig. 5, which shows that the impact resistance at room temperature decreased to very low values after the cold working of aging steels and produced brittle fractures, whereas the nonaging steel retained high values and a ductile fracture. These data were assembled directly after cold working. The impact resistance may be further lowered by aging, particularly accelerated aging; the maximum decrease occurs while holding for about ½ hr at 500 F. The embrittlement after cold working may be increased if the metal is heated for a minute or two at 850 F, as in hot galvanizing.[17]

The Izett steel in Fig. 5 was a fully aluminum-killed

Table III. Strain-Aging and Quench-Aging of a 0.22% C Steel

Treatment	Brinell Hardness Number: As-Quenched or Rolled or Both	Aged 2 Months	Increase of Hardness Because of Aging	Type of Aging
Quenched in water from 1250 F	151	181	30	Quench-aging
Cold rolled 10%	155	166	11	Strain-aging
Quenched in water from 1250 F and then cold rolled 10%	183	221	38	Quench-aging and strain-aging

mild structural steel normalized after rolling. It was thus a finer-grained steel than the other steels of Fig. 5, which were ordinary semikilled structural steels in the as-rolled condition. The slighter tendency to embrittlement of the Izett steel should probably be attributed not only to its nonaging quality but also to its fine grain size. The results of hardness tests have indicated that coarse-grained steels age more than fine-grained steels[14] both after quenching and aging and after deformation and aging. As measured by impact tests, the results were somewhat ambiguous, but there is no doubt that coarse-grained steels are more susceptible than fine-grained steels to embrittlement (brittle fracture) after straining and aging.

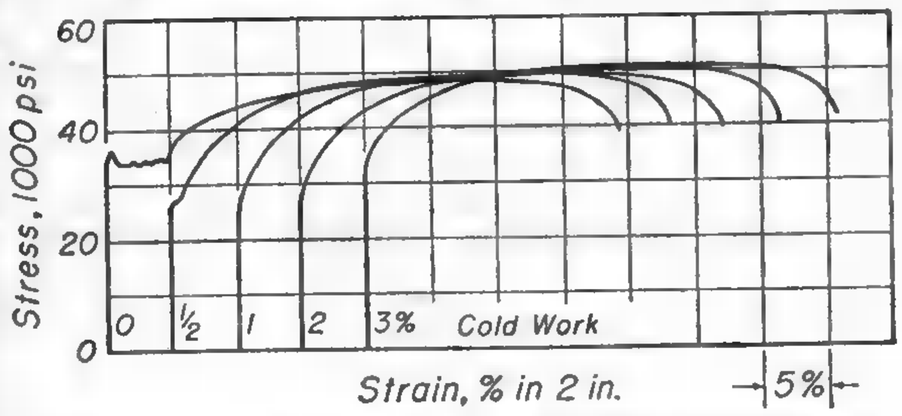

Fig. 6 Jogged stress-strain curve in annealed mild steel sheet.[19]

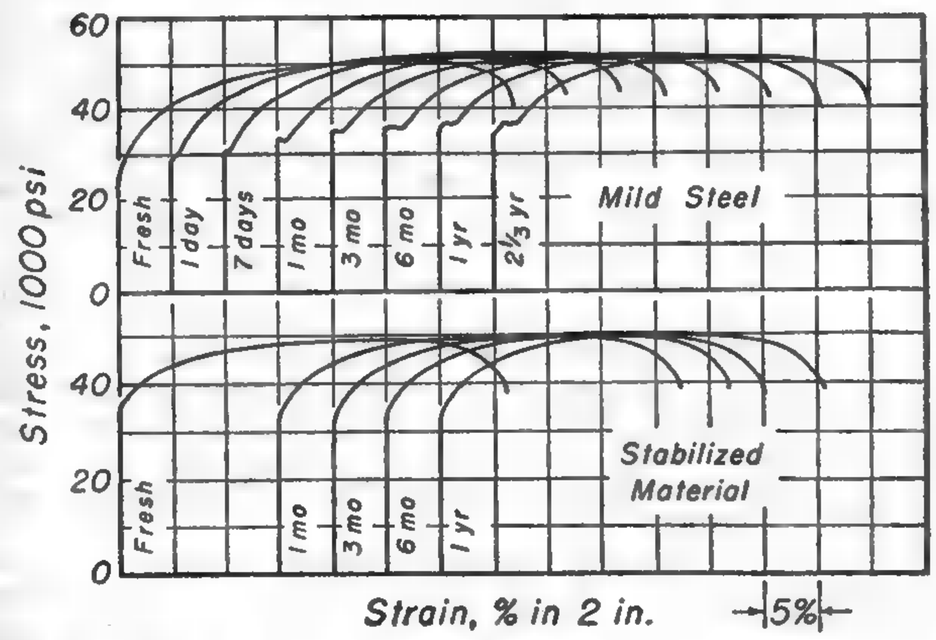

Fig. 7 Return of jogged stress-strain curve in ordinary mild steel during aging after straining. Retention of smooth rounded curve after aging in nonaging material.[21] Both materials were rolled 1% before aging. Typical percentage compositions of nonaging material treated with aluminum and titanium:

C	Mn	P	S	Si	Ti	Al
0.05	0.03	0.005	0.019	....	0.067	0.042
0.042	0.47	0.011	0.014	0.073	0.058	0.037

It should be emphasized here that to maintain high resistance to impact after cold working, steel should not merely be fully aluminum-killed, but should also be normalized after rolling, in order to become fine-grained (as in the Izett specimen shown in Fig. 5). The impact resistance of aging steel, such as ordinary rimming steel, can also be increased by normalizing after rolling. The sharp decrease in impact resistance of ferritic steels as the temperature is lowered, takes place at lower temperatures in nonaging fine-grained steels than in aging coarse-grained steels. This is indicated in Fig. 5.

A convenient method for determining the embrittlement, after various amounts of cold work, is the work-sensitivity or work-brittleness test,[38] which consists in drawing a tapered specimen through a die, notching it at points representing various increments of cold work, and breaking it through these notches in an Izod impact machine. The resultant work-embrittlement curve is characteristic of the steel. After the various increments of cold work, the impact resistance decreases less rapidly in the nonaging, fine-grained steels than in the aging, coarse-grained steels.

The behavior of iron and mild steel at the yield point, that is, the jog in the stress-strain curve that causes the drop in the beam in a tension test, is an interesting phenomenon and one not fully understood. Cold deformation causes the yield point to disappear and a rounded stress-strain curve is obtained instead, with no sharply defined proportional limit (Fig. 6). The disappearance of the jog and the rounding of the stress-strain curve have usually been attributed to loss of elasticity caused by the setting up of residual stresses.[20] Cold working before tension testing may bring the material to a condition where the rate of work hardening during the tension test is high enough to prevent any decrease in load, while the specimen is deformed beyond its elastic limit.[21]

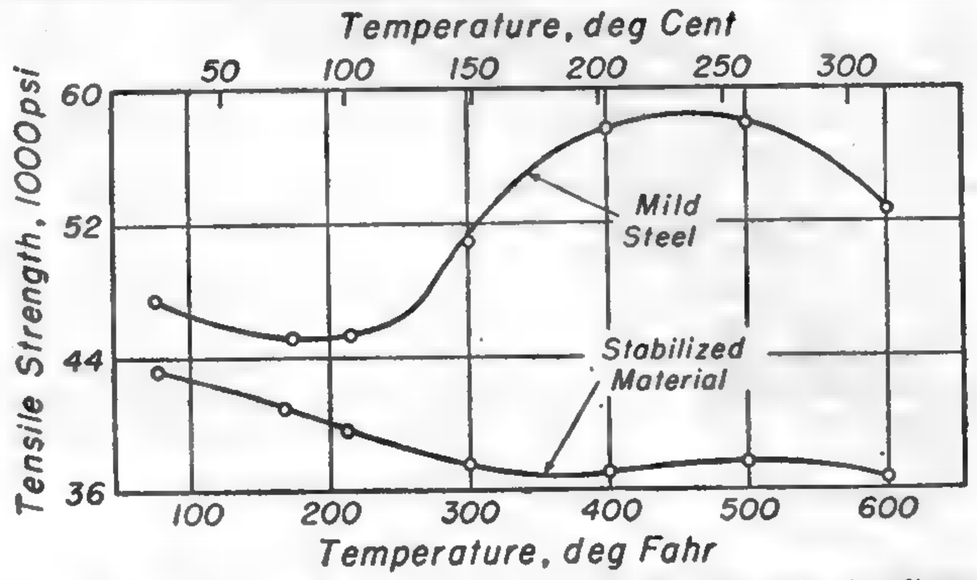

Fig. 8 Effect of testing temperature on tensile strength of ordinary mild steel and of nonaging steel.[22] The nonaging steel gives almost no indication of the "blue heat" phenomenon. The ductility in a tension test of the nonaging steel in the "blue heat" region is considerably higher than the ductility of ordinary aging mild steel sheet.

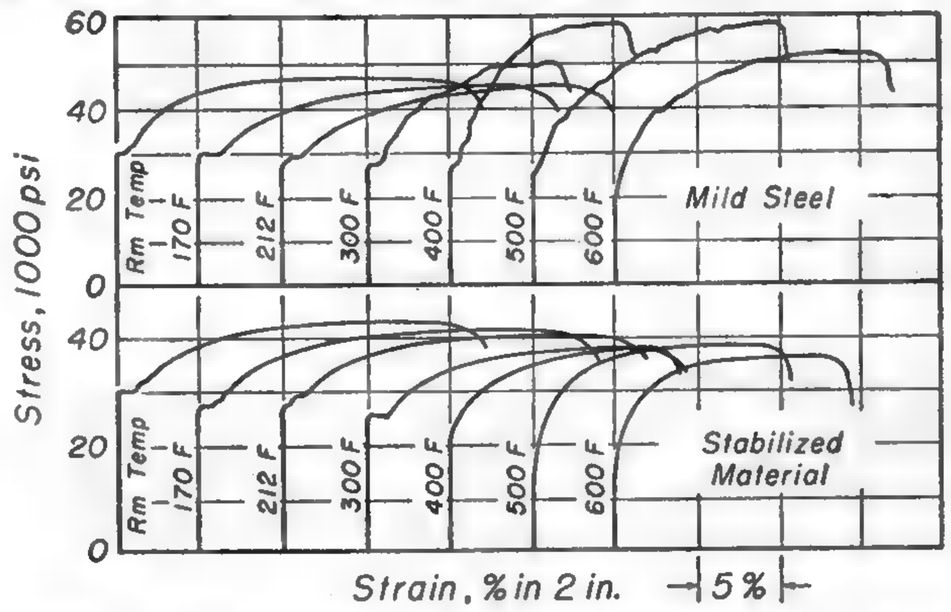

Fig. 9 Stress-strain curves of ordinary mild steel sheet and nonaging sheet tested at various temperatures.[22] The higher tensile strength and the "stepped" or "saw-toothed" stress-strain curve of the ordinary sheet in the "blue heat" region are characteristic. These features are absent in the nonaging sheet.

The jogged type of stress-strain curve is again obtained in ordinary mild steel, such as sheet, during aging after cold working. In nonaging steel, however, a rounded curve is still obtained after aging (Fig. 7).

It was early suggested that aging causes the increase in tensile strength observed in the vicinity of 400 F, the "blue heat" region. The suggested explanation was that at these elevated temperatures, precipitation and aging are so rapid that the test specimen increases in hardness from aging after cold work. (The cold work is the deformation that takes place in the tension-test specimen during testing.[1]) This hypothesis received striking confirmation in tension tests of nonaging structural and sheet steel.[21,22] Neither of these nonaging materials exhibited the pronounced increase in strength shown by aging steel, in the "blue heat" region. Thus the "blue heat phenomenon" is obviously an aging effect. Such results from tension tests on aging and nonaging sheet are shown in Fig. 8 and 9.[22] A tension test in the "blue heat" region is one of the simplest ways to distinguish aging from nonaging material.

The "blue heat" region is frequently referred to as the "blue brittle" region. This term is accurate in implying that the ductility in a tension test at these temperatures is appreciably lower. After deformation at temperatures in the "blue brittle" region, or after deformation at room tem-

perature followed by heating at "blue brittle" temperatures, a marked decrease is observed in impact resistance at room temperature. But there is no brittleness in notched-bar impact tests if the samples are tested while they are at the "blue heat" temperature, for example at 400 F. As a matter of fact, the impact resistance is nearly at a maximum during testing in the "blue heat" temperature (Fig. 5).

At temperatures considerably above the "blue heat" region, a minimum occurs in the curve of impact resistance versus temperature (Fig. 10). The minimum is assumed to result from an aging effect; that is, it is generally maintained that at the high speed of fracture in a dynamic impact test, any aging (hardening) during the instant of fracturing can occur only at the higher temperature, at which this reaction takes place rapidly. At lower temperatures, precipitation during a dynamic impact test cannot occur rapidly enough to cause hardening; consequently, there is no lowering of the impact resistance. It is not known whether nonaging steel shows a less pronounced minimum than aging steel in the curve of impact resistance versus temperature above the "blue heat" region.

Oddly enough, at approximately the same temperature as the minimum in the curve of impact resistance versus temperature, a minimum occurs also in the ductility during

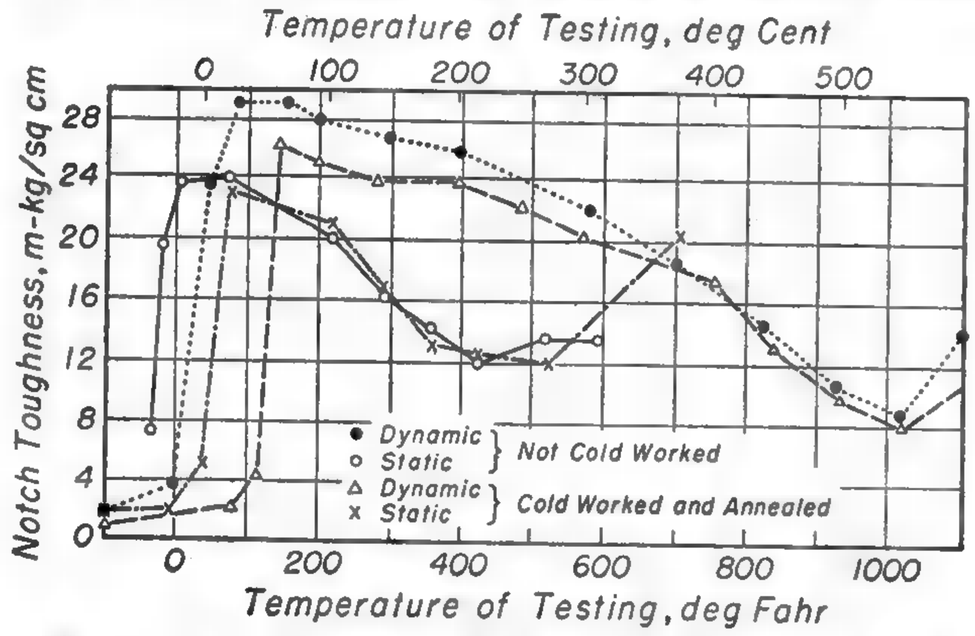

Fig. 10 Static and dynamic notched-bar tests at various temperatures with annealed and with cold worked and aged mild steel.[37] During slow bending, the energy absorption is at a minimum in the "blue heat" region, but in the impact test the minimum in energy absorption occurs at a considerably higher temperature. In both the impact and slow bend tests, the specimens were of the following dimensions: 160 by 30 by 16 mm; keyhole notch with circle 4 mm in diam, 15 mm deep.

a tension test. This has been termed the "secondary low-ductility range".[24] The degree of the secondary low ductility, which varies greatly in different steels, appears to be more severe in fully aluminum-killed steel. However, it seems rather doubtful that secondary low ductility is mainly a precipitation or aging effect. It has been suggested that the condition may be connected with the rate of recrystallization at this temperature, during and after deformation.[25] The rate of recrystallization may differ according to the degree of deoxidation, grain size, and rate of cooling of the steel.

Practical Aspects. In practice, the effects of strain-aging are possibly of greater importance than those of quench-aging. This is particularly true in the manufacture of low-carbon sheet and strip steel for stamping and deep drawing. The final mill operation on this product is frequently a light "skin pass" or temper-rolling that leaves the steel in an ideal condition for strain-aging. Unless the material is fabricated promptly, the increase in hardness, and loss in ductility by aging may cause failure in deep drawing.

The jog in the stress-strain curve at the yield point in a tension test, shows itself as "stretcher strains", during the drawing and stamping of sheet, and causes an undesirable roughening of the surface.[26] The jog is a characteristic of iron and steel in the soft condition, as after normalizing or annealing. This jog can be eliminated by slight deformation, as in the final "skin rolling" that is given the annealed sheet both for this purpose and for straightening. In aging material, the jog may return with time, so that, after leaving the steel mill and being stored in the customer's plant, the sheet may regain the tendency to stretcher-strain, accompanied by an increase in hardness. It has been reported that these aging effects do not occur in aluminum-killed, nonaging sheet[21] or in vanadium-treated, rimmed nonaging sheet[13] and that both of these types of sheet have good deep-drawing properties.

It has been reported also that very slow cooling, as in box annealing, further decreases the strain-aging tendency. The preferred heat treatment for the least amount of aging was reported to consist in heating above the transformation range, cooling at a relatively rapid rate, then reheating below A_1 and finally cooling very slowly.[21]

Cold deformation of structural steel, particularly when followed by reheating, as in galvanizing or welding, may lead to decided embrittlement. For example, a punched rivet hole in a thick structural member provides a severe notch condition (attributable in large measure to the cold working around the punched hole), which may cause brittle fracture.[17] A practical precaution is to ream out the cold worked steel after punching. However, the tendency to fracture in a brittle manner around a punched hole or in the presence of any other notch condition, is much less marked in aluminum-killed nonaging steel. This increased resistance to embrittlement is also maintained at lower temperatures and in the presence of cold work, whether followed by reheating or not. The benefits of the aluminum-killed steel in decreasing the chances of occurrence of embrittlement, are not fully realized in the as-rolled condition, but only after normalizing. Evidently the grain refinement that results from normalizing the fine-grained type of aluminum-killed steel, has an important influence in the avoidance of embrittlement. Ordinarily, fully aluminum-killed Bessemer steel exhibits as great resistance to embrittlement as the similarly killed open hearth steel of the same tensile strength.[39]

Bessemer steel makes screw stock that cuts more freely than open hearth steel. One probable reason is that the higher content of nitrogen in the Bessemer steel promotes aging.[27] At the elevated temperature reached during machining, aging steel becomes more embrittled by cold work than nonaging steel. Thus, in the aging steel, the chips become more brittle under the action of the cutting tool and break off more readily.

Nonaging steels have greater damping capacity. It has been suggested that for this reason they are less sensitive to notch effects in fatigue tests below the endurance limit.[28] It has also been suggested that since nonaging steels do not harden further after cold work, they are better able to withstand occasional overstresses considerably above the endurance limit, without embrittlement and fatigue failure;[29] in other words, that nonaging steels can withstand considerable cold work and plastic action without cracking —a property termed "crackless plasticity".[30] There is considerable uncertainty about the whole subject.

Two probable instances of quench-aging in which straining plays no part are temper brittleness, and the galvanizing embrittlement of malleable iron.

Temper brittleness is a decrease that occurs in impact resistance when hardened medium-carbon structural steel is held within, or is cooled slowly through, a certain range of temperature below the transformation range. This effect was first noticed in nickel-chromium steel, but has been observed also in carbon steel.[31] Temper brittleness is undoubtedly a precipitation or aging effect, and as with other aging phenomena, it appears to be less pronounced in strongly deoxidized steel.[32,33] Temper brittleness appears to be more pronounced in steel that contains higher percentages of manganese and chromium, while molybdenum is known to reduce this effect. The influence of molybdenum may be to reduce the rate of precipitation of the embrittling component, so that when enough molybdenum is present, embrittlement does not occur even during slow cooling from the tempering temperature.

Malleable iron may be decidedly embrittled by heating to 850 F, as in galvanizing. It has been shown that such embrittlement may be overcome by heating the castings to 1200 F, and quenching in water before galvanizing.[34] Although the mechanism of this immunizing treatment is by no means understood,[35] galvanizing embrittlement of malleable iron may possibly be an aging effect. The chemical composition of the iron, particularly the phosphorus and

Table IV. Effect of Cooling Rate From 1650 F Before Quenching From 1250 F on Quench-Aging (Harrison[18])

Heat Treatment Before Quenching in Water from 1250 F	Brinell Hardness Number: Tested Immediately After Quenching	Brinell Hardness Number: Tested After Aging 2 Months	Brinell Hardness Number: Change	Izod Impact Values, ft-lb: Tested Immediately After Quenching from 1250 F	Izod Impact Values, ft-lb: Tested After Aging 2 Months	Izod Impact Values, ft-lb: Change
Water-quenched from 1650 F	132	140	+ 8	108	97	− 11
Air-cooled from 1650 F	130	190	+ 60	100	34	− 66
Slowly cooled in furnace from 1650 F	124	192	+ 68	94	6	− 88

silicon content, is an important factor in galvanizing embrittlement.[36]

The prolonged annealing and slow cooling of malleable iron may possibly make it more susceptible to subsequent embrittlement by galvanizing. The data in Table IV point to an apparently analogous effect in steel; the more slowly cooled specimen is more susceptible to subsequent embrittlement in quench-aging than the more rapidly cooled specimen.[18] Somewhat similarly, concerning temper brittleness in steel, it has been found that if the steel is held for a long time at the tempering temperature, embrittlement occurs even during rapid quenching after tempering.[31]

The galvanizing embrittlement in malleable iron differs from that in the other examples mentioned, in that the fracture is intercrystalline.[36] Possibly the dispersion effects occur in the grain boundaries as in carbide precipitation in 18 Cr–8 Ni stainless steel. Usually, in quench-aging and strain-aging of mild steel, the dispersion effects take place throughout the grain and on slip planes. Fracture is mainly transcrystalline.

The Corrosion of Iron and Steel

By T. S. Fuller*

In 1903 Whitney[1] announced the results of experiments that led to the electrolytic theory of corrosion. Distilled water was boiled in test tubes to expel all the air and CO_2; polished samples of iron were added and the tubes were sealed while the water was boiling. The tubes stood in this manner for weeks without the slightest appearance of rust on the surface of the iron or any appearance of a corrosion product on the glass or in the solution. At the end of several weeks the tubes were opened and a small amount of air was admitted. A precipitate of ferric hydrate quickly settled out. A generally accepted interpretation of the results follows:

Iron goes into solution in pure liquid water until the water becomes saturated with iron ions and a state of equilibrium is established. The iron ions replace hydrogen ions and hydrogen is "plated out" on the surface of the iron. The film of hydrogen on iron, in the absence of oxygen, hinders further corrosion by insulating the iron from the water and by its own tendency to go back into solution in the water. This is called "polarization". Oxygen reacts with the hydrogen film, removes it from the iron surface by the formation of water, and also reacts with the dissolved iron to form a precipitate of ferric hydroxide. Both reactions are involved in the corrosion process; the removal of the hydrogen film allows the solution to contact the iron and the precipitation of ferric hydroxide reduces the amount of dissolved iron, thus encouraging further solution. The conclusion is reached

* Works Laboratory, General Electric Company, Schenectady

that iron goes into solution in liquid water in the absence of both an acid radical and oxygen and that corrosion is, therefore, essentially an electrolytic phenomenon. When the iron is dissolved by the water it first forms ferrous hydroxide, $Fe(OH)_2$; yet because of its solubility, the ferrous hydroxide is not noticeable until a further reaction with oxygen has taken place.

$$2Fe(OH)_2 + H_2O + O = 2Fe(OH)_3$$

The ferric hydroxide, $Fe(OH)_3$, settles out of the solution as a reddish-brown precipitate which, when exposed to air, gradually passes to ferric oxide, Fe_2O_3, commonly known as rust.

These reactions will not take place in dry air or in water free from oxygen but, since ordinary water always contains some dissolved oxygen, corrosion will always take place when iron or steel is exposed to moist air.

Experiments of Whitney, which led to the electrolytic theory, gave considerable impetus to the study of corrosion. Later Cushman and Walker developed a reagent, known as ferroxyl indicator, that demonstrates quite clearly the nature of ferrous corrosion.

The indicator has been described in detail by Cushman.[2] Briefly, it may be prepared by mixing dilute water solutions of phenolphthalein and potassium ferricyanide. If a more or less permanent record is desired, the solution is thickened with gelatin or agar. The action of the ferroxyl indicator is this: a solution containing phenolphthalein becomes pink in the presence of an excess of hydroxyl ions; potassium ferricyanide in the presence of ferrous ions gives a dark blue precipitate. Therefore, when the indicator is in contact with an iron surface, the positive areas—that is, points where iron is going into solution in the ferrous condition—are colored blue, and the negative areas, where there is ■ predominance of hydroxyl ions, are colored pink by these ions.

Rate of Corrosion. The rate of corrosion of every piece of iron or steel depends on the individual conditions existing in the particular locality in which the metal is in use, as well as on the precautions that have been taken to prevent corrosion.

The two substances besides iron necessary for ferrous corrosion are liquid water and oxygen. Corrosion phenomena are of many types. Iron samples that are wholly immersed corrode faster if the water is moving rapidly than if it is in a state of rest. The rate of corrosion of iron tanks or pipes holding water is much slower if they are kept full than if they are alternately wet and dry. Atmospheric corrosion proceeds much more rapidly in districts where the atmosphere is chemically polluted by sulfur vapors and the like than it does in districts where the atmosphere is free from contamination. The corrosion of iron or steel is accelerated or retarded by contact with other metallic elements, depending on whether the elements are electropositive or electronegative with respect to iron. The corrosion rate increases with rising temperature.

The rate of corrosion depends also on the character of the steel as determined by its chemical composition and heat treatment. Stainless steels with large amounts of chromium, and the various alloys of nickel, chromium, silicon and iron are highly resistant to corrosion. The addition of 0.25% Cu improves the resistance of steels to atmospheric corrosion but not to underwater corrosion.

The chemical and structural compositions of iron and steel vary throughout the mass and, because the several constituents have different electrical potentials, corrosion may be either accelerated or retarded thereby. The different electrical potential thus developed is usually comparatively great in badly segregated iron and steel or in metal containing impurities, all of which accelerate the corrosion.

The work of U. R. Evans emphasizes the influence of protective films on the corrosion rate.

Stainless Steels. Because of their high resistance to corrosion, considerable quantities of alloy steels containing large amounts of chromium, or chromium and nickel have come into general use. The most common of these are one containing about 12% Cr, and another containing 18% Cr and 8% Ni. The 12% Cr alloy can be heat treated to give excellent mechanical properties, varying over a wide range. The 18 Cr–8 Ni steel is austenitic in structure and therefore cannot be heat treated to give specific properties; those properties are imparted only by the hot and cold working processes. For maximum resistance to corrosion it is necessary that both alloys be heated and cooled in such a manner as to leave the carbides in solution. For information on the resistance of stainless steel to corrosion, see the article on page 557 in this Handbook.

Stainless steels are rendered somewhat more resistant to corrosion by a surface treatment called "passivation". (*See* "Cleaning, Pickling and Passivating of Stainless Steel", on page 584 of this Handbook.) This treatment does not ordinarily affect the appearance of a polished or machined surface and does not alter dimensions. It should be used after all machining, grinding, and polishing operations, since it removes any particles of the cutting or grinding tools that might be embedded in the metal.

Protective Coatings. Protective coatings for iron and steel form an important section of metal technology and may be grouped as paints, metallic coatings, chemical coatings, and greases.

1 *Paints.* Various specially prepared paints are used for protecting the surface of iron and steel from dampness such as sea water, from oxidizing gases, and from smoke. Therefore no one paint is suitable for all purposes and before a paint is applied, the nature of the corrosive influence present must be determined.

Some paints protect the surface merely by the formation of an impervious film, such as asphaltum and tar. Other paints exert a chemical protective action; such are the ones containing linseed oil as the vehicle and red lead as the pigment. The linseed oil absorbs oxygen from the atmosphere, thus forming a thick elastic covering. This reaction is hastened by boiling the linseed oil before using, and by adding salts of manganese or lead which are called "driers".

A few of the pigments used in paints are red lead, oxides of iron, lead sulfate, zinc sulfate, graphite, aluminum and hydrocarbons. The driers, vehicle and pigments used must be inert to the steel; otherwise corrosion will be hastened instead of prevented.

2 *Metallic Coatings.* The metallic coatings include hot galvanizing, sherardizing, hot tin dip, and electrolytic plates of tin, nickel, copper, chromium, cadmium and zinc. These are discussed in the METALLIC COATINGS SECTION.

3 *Chemical Coatings.* The chemical coatings include phosphate and black oxide coatings.

Phosphate Coatings. These are coatings produced by converting the surface of iron or steel parts to an insoluble phosphate, such as iron phosphate or zinc-iron phosphate. For further information, see page 732.

Black Oxide Coatings. This type of coating is produced by converting the surface of iron or steel to black iron oxide (Fe_3O_4) with a thickness of less than 0.0001 in.

The process consists in immersing the cleaned iron or steel parts in a highly concentrated solution of salts, sold on the market under many trade names. The solution is strongly caustic and must be maintained at a temperature of 290 to 300 F to provide suitable coatings. The time of treatment is approximately 15 min.

This coating affords very limited corrosion protection, perhaps 2 to 5 hr in the standard salt spray test, but it does produce a pleasing black color and provides a good base for the application of rust-inhibiting oils. Its applications are limited to indoor exposure where corrosive conditions are not severe.

4 *Greases.* Greases and oils of various grades are used to protect the surface of iron and steel by applying a thin film over the surface. This method is especially useful for parts of machines, tools, and steels which are to be put in storage or are to be shipped. For details of this method, see the article entitled "Rust-Preventive Compounds", page 734.

Deactivation. Much has been said and written lately about the deactivation of water. In general, the method consists of passing the water to be used in a closed system over scrap iron to remove the dissolved oxygen. Once the oxygen has been removed, theoretically the water may go on circulating indefinitely in the system without cor-

rosive action. Such installations have proved successful.

Dissolved gas can be removed from water by passing the water over an electrically heated, heat-resisting ribbon, allowing the gas liberated thereby to escape.

Iron may become immune to corrosion by being made cathode, that is, the negative pole in a cell, with a potential just sufficient to balance the solution pressure of the metal. This method is not used much because it is costly.

Mechanical De-aeration. Speller[3] in his book has given a very complete summary of the principles involved and the methods used in mechanical de-aeration. Dissolved gases can be removed from water, if the temperature and pressure conditions are so regulated that the gases become insoluble, and if a sufficient amount of time is allowed for their complete mechanical separation from the water. Most types of mechanical de-aerators function by agitating water exposed to favorable conditions of pressure and temperature. Many types and designs of mechanical de-aerators are in use.

Corrosion Tests. Several tests are made on iron and steel to determine their deterioration resulting from corrosion. The tests usually made are salt spray, total immersion, alternate immersion, accelerated electrolytic, subjection to atmospheric conditions and subjection to gases.

The test specimens are of various designs; often the finished object is subject to the test. The deteriorating effect of the immersion tests is determined by the loss in weight and physical properties as well as by the depth of pits and the appearance of the surface. The size of the specimens and the condition of the surfaces should be alike if possible, in order to obtain a satisfactory comparison.

The solutions used may be natural water, such as sea water, city water or mine water, or may be specially prepared solutions containing salts and acid. When preparing special solutions it is advisable to use distilled water; otherwise the impurities might increase corrosion.

The interpretation of results in all tests should be based on the relationship of the results to practical service conditions. Many factors make it difficult to obtain quantitative results and before drawing conclusions the following should be considered: the temperature and degree of aeration of the solution, the machined surface of the specimen before testing, the length of time during which the specimen was subjected to the test, the apparatus employed, and the care used in cleaning and drying the specimen before weighing.

Nonmetallic Inclusions in Steel

BY THE SUBCOMMITTEE ON NONMETALLIC INCLUSIONS IN STEEL*

ANY specimen of steel when examined closely enough will reveal the presence of particles of material incongruent with the metal lattice and demonstrating either definite nonmetallic or quasi-metallic properties.* Some of these are obviously of foreign origin and are entrained particles of refractory, slag and the like, that have been entrapped by the freezing steel. These are called exogenous, adventitious, or accidental inclusions. Others just as evidently have been precipitated from the liquid or solid metal as a result of chemical reactions or of solubility changes caused by varying temperature. Such inclusions are known as indigenous, natural, or native inclusions and must be considered an integral part of the heterogeneous and complex material known as steel. They are as much a part of steel as seeds are part of a fruit. Much erroneous thinking has resulted from considering all nonmetallic inclusions as something foreign and apart from steel—something not present if steel has been made properly.

Although the title of this section specifies only nonmetallic inclusions, it is difficult to make a clean-cut distinction between the inclusions that are purely nonmetallic and those of a quasi-metallic nature. The question of recognition or identification also arises, and what is even more important is the difficulty of differentiating the effects of inclusions on the properties of steel on the basis of chemical definition. The present article is expanded, therefore, to include some discussion of most of the obvious inclusions to be observed in a highly polished but unetched section of steel—carbides, nitrides, and even graphite.

The presence of inclusions in steel is not regarded as good or bad in itself but as a fact. In certain steels, correlations with service behavior may be accepted as evidence of the effects of inclusions; some of these instances are discussed below. It must be recognized, however, that in regard either to identification or to effects, situations not conforming to the majority pattern are to be expected, but these, in general, are outside the scope of this article.

*The members of this subcommittee are C. E. Sims, *Chairman* (Battelle Memorial Institute), C. R. Austin (Meehanite Metal Corporation), M. Baeyertz (Armour Research Foundation), Fritz Eberle (Babcock and Wilcox Company), Merrill A. Scheil (A. O. Smith Corporation), S. F. Urban (Titanium Alloy Manufacturing Company) and J. R. Vilella (United States Steel Corporation).

* This is not peculiar to steel but is common to most metals and alloys that have been molten.

As far as possible, a clear-cut distinction is made between the natural, precipitated inclusions and those of extraneous origin. This distinction is regarded as desirable because of the widely different sources, because ordinarily they are readily distinguished, and because of important differences in effects of the two types of inclusion.

Origin of Inclusions

Of the two kinds of nonmetallic inclusions that are usually recognized, exogenous inclusions are entrapped inadvertently in the steel, while indigenous inclusions separate from it because of a change in composition or temperature of the steel. Exogenous inclusions originate almost exclusively from particles of nonmetallic matter that are occluded in the steel while it is in the molten state. Indigenous inclusions may be produced in either molten or solid steel by the precipitation of nonmetallic substances in the form of droplets or particles, when these substances are produced in such amounts (by reactions or temperature changes) that their solubility in the steel is exceeded. In most instances, both exogenous and indigenous inclusions are composed of oxides, sulfides and nitrides, or various combinations of these.

The precipitation of indigenous inclusions from either liquid or solid steel follows the laws of heterogeneous equilibrium. The process of formation of an inclusion involves the separation of a second phase, known as the "inclusion", from the phase already present, known as the "metal". This happens when such changes occur in composition or temperature of the steel that the metal phase becomes unstable, but equilibrium may be approached by the precipitation of the inclusion phase. During the manufacture of steel new conditions, with which the steel tends to come to equilibrium, are being established continually. When the metal is in the liquid state, additions to the furnace or ladle will change the composition. In the solid state, changes in composition may be caused by reaction of the steel with furnace gases or other materials with which the steel comes in contact while hot. The composition and temperature of the steel and its surroundings determine the equilibriums involved. Depending on these factors, the inclusions may be solid or liquid and, in either instance,

may be a solution or a substance of fixed composition. Occasionally two or more phases are required in the inclusion for equilibrium with the steel.

Liquid iron at a given temperature may hold in solution a certain quantity of oxygen. If this amount of oxygen is present in the metal and the temperature is lowered, the solubility of oxygen in the metal is decreased, but equilibrium can be re-established by the separation of an oxide phase. The oxide forms droplets. If these are trapped by freezing of the metal before they rise to the surface, they are called inclusions. The addition of manganese, silicon and aluminum, or any other element that can combine with oxygen in the metal, will alter the amount of oxygen that can remain in solution in the metal without the precipitation of an oxide phase. The inclusions that may precipitate as the result of these conditions will be composed of that oxide which has exceeded its solubility in the metal. For example, the addition of manganese may produce (Mn, Fe)O inclusions. The addition of silicon may cause the precipitation of SiO_2 or liquid FeO-SiO_2 solutions. With the addition of aluminum, possible oxide phases are $FeO.Al_2O_3$ and Al_2O_3.

The change in the solubility of each oxide phase with change in temperature is important. With such deoxidizers as aluminum, the oxides included in steel have very small solubilities that change little with alteration in temperature. Therefore, once the deoxidation reaction is completed, virtually no more inclusions precipitate from the steel during teeming and solidification of the ingots. However, the solubilities of the oxides of manganese and silicon may change considerably with temperature. Thus, one may find inclusions that precipitated after the steel was teemed, as droplets of liquid FeO-MnO-SiO_2 solution. Although oxide inclusions have been used as examples, the same principles apply in the formation of sulfides, nitrides and other indigenous inclusions.

When equilibrium has been maintained between the inclusion and the steel, the phase or phases in the inclusion will be the ones that can exist in the presence of the metallic phase. Usually the lower oxides, sulfides and nitrides are found in such inclusions, but not always. For example, Fe_3O_4 rather than FeO is the stable phase below about 580 C. However, at the temperature at which iron oxide is formed in steel, FeO is the stable phase, and apparently it does not alter on cooling, except that crystals of Fe_3O_4 are occasionally found within FeO inclusions. The more common state may be exemplified by a rimming steel, wherein inclusions of (Mn, Fe)O precipitate from the metal on cooling. The higher oxides of manganese and iron do not occur. Similarly, the common sulfide inclusions that precipitate from steel on cooling have the composition (Mn, Fe)S. Sulfides containing a higher proportion of sulfur in relation to their iron and manganese contents, have not been observed. The same conditions prevail in the formation of a subscale by the reaction of elements in the steel with elements derived from the furnace gases, which diffuse into the solid steel. For example, when nitralloy is being heated in dissociated ammonia gas, nitrogen dissolves into the steel and reacts with the aluminum there. As a result, a subscale containing crystals of AlN forms just below the surface of the specimen. Graphite almost never forms as a primary phase in steels of ordinary composition, but sometimes does form by solution of metastable cementite and precipitation of graphite as small nodules during continued heating in temperature regions in which graphite is stable in the presence of iron.

Inclusions that have melting points above the temperature at which they precipitate from the steel will usually form idiomorphic crystals—that is, crystals with well-developed faces. Chromite and titanium cyanonitride inclusions are of this type. Ordinarily such inclusions do not elongate when steel is rolled or forged. When inclusions are liquid at the temperature of precipitation, they usually assume a droplet shape. Many of the siliceous inclusions are of this nature. Such inclusions often, although not always, deform during hot working of the steel. Sometimes inclusions may be a single phase at the time of formation in the steel, but during cooling, they may separate into two phases. A common example of this is the silicate-sulfide inclusions, which are a single phase at high temperatures but which, during cooling, separate into (Fe, Mn)S and a siliceous liquid. Sometimes metal-inclusion eutectic structures are observed. A common example of this type is the metal-(Mn, Fe)S eutectic structure observed in steels that have been treated with an appropriate amount of aluminum.

The distinction between exogenous and inherent inclusions is not always sharp. A nonmetallic particle in equilibrium with its surroundings in the furnace may suddenly become out of equilibrium with the metal in the ladle because of rapid alteration in the metal composition as a result of ladle additions and change in temperature during tapping. Such inclusions must seek equilibrium with the steel in the ladle, and again in the mold if carried there, where the temperature is lowered even further. Under these conditions, and when extraneous nonmetallic matter is inadvertently entrapped in the steel, equilibrium may be established prior to solidification, but more often the reactions are arrested by the effect of chilling. Exogenous inclusions may be of wide variety; for example grains of sand adherent to sandcast ferro-alloys, inclusions in ferro-alloys, and siliceous material eroded from ladle lining, well, stopper-head, or nozzle. In a steel containing residual aluminum, the aluminum may react with exogenous siliceous inclusions. The Al_2O_3 formed thereby will become a part of the inclusion, while a stoichiometric amount of FeO, MnO, or SiO_2 in the inclusion will be reduced to iron, manganese or silicon, respectively, and will dissolve in the steel. Complete reduction of such an inclusion by aluminum results in an alumina inclusion, which may be indistinguishable from alumina formed by other steelmaking reactions. The reaction of alloying elements in the steel with exogenous inclusions can occur only by diffusion of the reactants to the interface between the inclusion and the steel and by diffusion of the products away from the interface. Therefore, the size of the inclusion is determined by the size of the original occlusion and the stage at which the reaction is arrested by chilling of the steel. If equilibrium has not been attained during the solidification of the ingot, there is the possibility of considerable change in the character of such inclusions when the solid steel is being heated for rolling or is being heat treated.

Identification of Inclusions

Selection and Preparation of Specimens. 1 *Macroscopic Examination.* For a successful study and evaluation of nonmetallic inclusions in steel, consideration must be given to their location and general distribution. Steel ingots are heterogeneous and the ultimate bar or piece of steel reflects, in cross section, the heterogeneity existing in that portion of the ingot which it represents. This condition is revealed by suitable macroscopic examination. In general, the purpose of the investigation and the shape and condition of the material will determine the location from which specimens should be cut. The location should be selected so as to be truly representative of the parent metal, since any random sampling may fail to appraise the steel as a whole or to detect the specific condition that is to be uncovered. When rolled or forged materials are involved, transverse and longitudinal sections should be examined.

Deep-Etch Test. A deep-etch test in 1 to 1 hydrochloric acid (cp) is most commonly employed for macroscopic examination. The preparation of the sample and the details of the test are described in another section of the Handbook (*see* page 389). In the examination of the etched surface for nonmetallic inclusions, some experience is necessary for recognition of the appearance and type of such inclusions. Pits resulting from oxides and other nonmetallic inclusions should not be confused with pits occurring from the etching out of metallic aggregates. When nonmetallic inclusions are suspected in highly alloyed steels that may contain metallic aggregates, a comparison should be made of an annealed specimen and a hardened specimen etched alike. If the etching pits are the result of nonmetallic inclusions, they will appear to be similar in the annealed and the hardened specimen; if they are the result of metallic segregate, they will differ. It must be emphasized, however, that not every pit developed indicates the occurrence

of an inclusion, since pitting may also occur as a result of acid attack around carbide particles. Frequently, it may be helpful to examine the surface in the finely ground and only lightly etched condition under good binoculars prior to deep etching. Specimen and lighting should then be arranged so that the metal background looks white.

Fracture Test. Sometimes a fracture test is employed for the purpose of detecting internal defects or macroscopic nonmetallic inclusions in steel. This test is carried out by nicking preferentially on one side suitable sections of a billet or bar in the hardened condition, and striking the end close to the nicks with a sledge hammer. The fractured surface should be parallel to the rolling direction.

Sulfur Printing. The distribution of the sulfide inclusions can be brought out by sulfur printing. Sulfides containing chromium, titanium, zirconium, and vanadium, which offer a higher resistance to etching by acids, are not likely to respond to this method.

Magnetic Particle Inspection. Larger inclusions may be detected by the magnetic powder method of inspection, a continuity test based on the abrupt change made in a magnetic field by flaws or metallic discontinuities. Subsurface metallic discontinuities may be located by this method, depending on their size, location, depth beneath the surface, condition of the material and the procedure used. This method is described in an article on page 145.

Supersonic Inspection. Recently in a new method, supersonic waves have been used for detecting inclusion segregations, laminations and other flaws in steel. (*See* page 157).

2 *Selection and Preparation of Sample for Microscopic Examination.* Whenever possible, nonmetallic inclusions should be studied in the as-cast condition of the metal, since the deformation of the steel in the solid or plastic state alters the shape of the inclusions and tends to make their original appearance and distribution unrecognizable. Samples of forged or rolled materials should, therefore, be taken parallel to the direction of rolling. The success of the microscopic examination is determined largely by the proper preparation of the sample. In general, any method of polishing will be suitable that will produce a flat metal surface, free from scratches, flowed surface layers and films, and will keep the inclusions clearly outlined, leaving a satisfactory polish on their surface. Detailed instructions for metallographic polishing are given on page 159 of this Handbook. With the exception of alumina inclusions, which are hard and brittle and have a marked tendency to "wipe", most of the inclusions can be polished with little difficulty. Sometimes, it may be advantageous to harden the specimen in order to facilitate polishing, keeping in mind, however, that the thermal treatment involved may produce structural changes in certain types of inclusions. A previously deep-etched surface is not suitable for the preparation of specimens for microscopic examination unless the whole acid-affected surface layer, which may extend to a depth of ¼ inch or more, has first been removed by mechanical means. It is also not recommended to use graphite in conjunction with the dry-polishing papers, since graphite particles may be embedded in the surface of the metal and, after final polishing, may be mistaken for inclusions. Great care should be taken in cleaning and drying the prepared surface. Dried water spots, particles of the polishing mediums or dirt on the surface of the specimen may lead to erroneous conclusions. It is not advisable to etch the specimen before micro-examination with polarized light, because the surface roughness produced by etching causes scattering reflections. Heat-tinted specimens should not be used since such treatment may cause oxide films on the surface of the inclusions.

General Characteristics. Nonmetallic inclusions in steel differ from metallic substances by their lower mechanical strength, by their relative brittleness, especially at low temperatures, by their lower density and inferior electrical conductivity, and by their lower coefficient of reflection. According to their nature and mode of formation, they are either crystalline or vitreous, refractory or fusible, plastic or brittle, of lower or higher hardness, opaque or translucent or transparent, colored or colorless, of higher or lower reflectivity and refractivity, resistant to chemical reagents or easily attacked by them. Their nature, constitution, and morphological characteristics are controlled to a considerable degree by the manner and extent of the deoxidation and by the conditions of cooling. A study of the thermal equilibrium diagrams of the various systems of compounds of which nonmetallic inclusions consist is very helpful for their identification. These diagrams show the phases resulting from their mutual combinations, their respective compositions, constitutions and melting relationships.

Certain types of inclusions are characteristic of the deoxidation practice employed. For example, in rimmed steel to which only enough deoxidizers are added to maintain the FeO and MnO content within certain limits, the oxide (Fe, Mn)O and the sulfides FeS, (*Fe,* Mn)S and (*Mn,* Fe)S occur, as well as complex compositions consisting of the single phases associated with eutectic mixtures. Silicates and alumina inclusions tend to be absent in this type of steel. In silicon-killed steel to which no aluminum or other similarly strong deoxidizers have been added, iron-manganese silicates or manganese silicates of varying silica contents are observed. If deoxidation by silicon is followed by a large enough aluminum addition to result in a noticeable amount of residual aluminum, the deoxidation products consist mainly of hard and brittle alumina inclusions. Alloying elements are responsible for inclusions derived from the special element added. Thus, in steels deoxidized with Zr-FeSi, zirconium ferrous silicate, zirconium nitride and zirconium nitride-carbide solid solution crystals may be encountered. In steels treated with FeCr, chromium-bearing silicates, chromite ($Cr_2O_3 \cdot FeO$) and chromium oxide (Cr_2O_3) or complex chromite-oxide inclusions may be found. Steels deoxidized by titanium may contain TiO_2FeO (ilmenite) if the residual titanium is low. If the residual titanium is high, TiO_2 (rutile) is likely to occur. Titanium steels are also likely to contain TiN and titanium nitride-carbide solid solution crystals. Alloying elements usually participate also to some extent in the formation of sulfides. However, because of their solubility in the generally predominant (Mn, Fe)S, these alloyed sulfides seldom appear as separate, distinguishable constituents, but ordinarily occur as solid solutions or complex sulfide inclusions.

Examination in Reflected White Light. After proper preparation of the polished surface (*see* page 159) the specimen is usually examined in reflected white light as the first step in the identification of nonmetallic inclusions. For this examination a background of experience is very helpful; the experienced metallographer can identify readily, at sight, the majority of inclusions to be found in steel, recognizing them by characteristic color, shape, size and distribution.

For example, MnS is characterized by a dove-gray color, a tendency to form in globules (except when they form as part of a eutectic) located in primary grain boundaries, and plasticity during hot rolling. FeS, on the other hand, is likely to be canary yellow and tends to form in thin continuous films in the grain boundaries. Silicates may be opaque, translucent or transparent, but usually occur as globules in cast steel and are nearly always plastic during hot rolling. Inclusions of alumina occur as clusters of fine crystals that are very hard and tend to pull out and scratch during polishing. Zirconium or titanium nitrides are yellow cubic crystals. Data given in Table I show the common properties of many inclusion-forming materials

Knowledge of the composition and finishing practice of the steel under examination is always a great help in identifying inclusions. As was pointed out in the previous section, inclusions are characteristic of the steels in which they occur. In fact, if the inclusions do not correlate accordingly, there is room for suspicion that the steel is not as represented.

Accidental or adventitious inclusions do not, of course, follow any such pattern, and if occasional noncharacteristic inclusions are found, it is proper, as a first assumption, to regard them as exogenous. Other ways in which many exogenous inclusions may be recognized are by unusually large size, irregular shapes and heterogeneous structure.

Visual examination, however, is neither infallible nor always adequate, and there are occasions when more searching means of identification are desirable. Some such methods are described below. A word of caution is needed: Polishing for identification of inclusions requires

care and skill. All too often particles of dust or polishing grit, stains and holes are mistaken for inclusions. No attempt at identification should be made until the inclusions are clean and clearly resolved.

Examination by Reflected Plane-Polarized Light. As a further aid in the identification of the inclusions, the unetched specimen may be examined with reflected plane-polarized light. The usual metallurgical microscope is satisfactory for such examination if accessory equipment is added, with which to obtain and analyze the plane-polarized light. Certain precautions are necessary in utilizing this equipment and in interpreting the results. The microscopist should have a thorough knowledge of the petrographic microscope and the theory of polarized light. Limitation of space prevents an adequate discussion here; however needed information can be found in the literature on the subject (*see* references following this article).

Examination under crossed nicols may enable the investigator to distinguish between the isotropic (vitreous and cubic-system inclusions) and those having anisotropic properties. These characteristics, together with color reflected through the inclusion from the inclusion-metal interface, may be advantageous in identification.

The method of identification by reflected polarized light contains tables of properties of substances that may be encountered as nonmetallic inclusions. It should be noted that inclusions in iron and steel rarely consist of a single pure component; therefore, their properties are not likely to correspond precisely to the pure mineral. The minerals described, however, will help to identify inclusions, if the optical characteristics can be determined.

Table I

Distinctions to Be Observed for the Identification of Inclusions in Steels and Irons with Reflected Polarized Light

System Used Below for Property Designation

1 Name and Formula
- *a* Crystal system
- *b* Melting point
- *c* Hardness (Mohs' scale)
- *d* Color by reflected white light
- *e* Color by transmitted white light (plane-polarized light, crossed nicols)
- *f* Index of refraction
- *g* Common occurrence
- *h* Remarks

Inclusion Minerals That Always Remain Dark During 360-deg Rotation

1 Ferrous oxide, FeO
- *a* Isometric
- *b* 1360 C (2480 F)
- *c* 5.5 to 6.5
- *d* Medium gray
- *e* Opaque
- *g* In scale, and as more or less rounded single-phase globules in rimming and similar steels low in silicon and manganese.
- *h* Somewhat malleable at steel rolling temperatures.

2 Magnetite, $FeO.Fe_2O_3$
- *a* Isometric
- *b* 1327 to 80 C (2421 to 2516 F)
- *c* 5.5 to 6.5
- *d* Light gray
- *e* Opaque
- *g* In scale
- *h* Not malleable at steel rolling temperatures

3 Titanium nitride, TiN
- *a* Isometric
- *c* 9 to 10
- *d* Yellow
- *e* Opaque
- *g* In steels and irons treated with ferrotitanium
- *h* Not malleable at steel rolling temperatures. May contain TiC in solid solution. Color in reflected white light varies from yellow to pink to violet with increasing carbon content. Pink sometimes called cyanonitride. The inclusions are strongly angular and easily pitted in polishing.

4 Zirconium nitride, ZrN
- *a* Isometric
- *b* 2950 C (5342 F)
- *d* Yellow
- *e* Green
- *g* In steels and irons treated with ferrozirconium
- *h* Not malleable at steel rolling temperatures. May contain ZrC in solid solution, which produces varying colors by reflected white light—orange, brown, violet, blue. The inclusions are strongly angular and they may be distinguished from TiN by etching tests. They are softer and easier to polish than TiN.

Translucent Isotropic Inclusion Minerals

1 Manganous oxide, manganosite, MnO
- *a* Isometric
- *b* 1700 C (3092 F)
- *c* 5 to 6
- *d* Very dark gray
- *e* Green
- *f* N = 2.16 (Li)
- *g* In steels and irons high in manganese which have not been deoxidized with other more effective deoxidizers, for example, aluminum and silicon.
- *h* Somewhat malleable at steel rolling temperatures. Usually contains more or less FeO in solid solution. Color by reflected white light changes from dark gray to medium gray with increase in FeO. Color by transmitted light changes from green to red or brownish red to opaque with increase in FeO.

2 Manganous sulfide, alabandite, MnS
- *a* Isometric
- *b* 1620 C (2948 F)
- *c* 3.5 to 4
- *d* Medium gray
- *e* Green
- *f* N = 2.70 (Li)
- *g* Steels and irons except those with very low manganese content
- *h* Very slightly malleable at steel rolling temperatures, malleability increases with increase in FeO in solid solution. Usually contains FeS in solid solution. In stainless steels probably also contains Cr in solid solution. Color by reflected white light changes from medium gray to grayish white, with pearly luster, with increase in FeS. Color by transmitted white light changes from green to greenish yellow or brown to opaque with increase in FeS.

3 Iron aluminate, hercynite, $FeO.Al_2O_3$
- *a* Isometric
- *b* Above 1700 C (3092 F)
- *c* 7.5 to 8
- *d* Medium to dark gray
- *e* Colorless, green, yellow brown, reddish brown, opaque when rich in iron oxides.
- *f* N = 1.80
- *g* In steels and irons treated with aluminum and in some inclusions derived from refractories.
- *h* Not malleable at steel rolling temperatures. Change in color and translucence due to solid solution. Opaque varieties are lighter gray by reflected white light. Frequently occurs as equiaxed euhedral crystals. Not so difficult to polish as inclusions rich in Al_2O_3.

4 Chromite, $FeO.Cr_2O_3$
- *a* Isometric
- *b* Above 1780 C (3235F)
- *c* 5.5
- *d* Medium gray
- *e* Red, reddish brown, yellowish brown, or opaque, depending on the thickness.
- *f* N = 2.07 to 2.16
- *g* In chromium produced by the aluminothermic process and in any steel containing residual aluminum and appreciable amounts of nitrogen.
- *h* Not malleable at steel rolling temperatures. Usually found as very fine network in primary austenite grain boundaries in the form of euhedral crystals. Has limited solubility in high-temperature austenite.

5 Silica glasses
- *a* Noncrystalline
- *b* Variable
- *c* Approximately 7
- *d* Light to very dark gray, sometimes with bright internal reflections.
- *e* Colorless or all colors, depending on contamination with other oxides.
- *f* Variable
- *g* In steels and irons that contain silicon and that have not been thoroughly deoxidized with other more effective deoxidizers, for example, aluminum; and in some inclusions from refractories.
- *h* Varying degrees of malleability at steel rolling temperatures. May be more or less milky because of precipitation of other minerals in finely divided state within the glass on cooling. In cast or weld metals transparent spherical glassy silicates exhibit the dark optical cross by transmitted white polarized light.

Opaque Minerals Showing Anisotropic Behavior

1 Ferrous sulfide, troilite, FeS
- *a* Hexagonal
- *b* 1180 to 1190 C (2156 to 2174 F)
- *c* 3 to 4
- *d* Light tan or yellow
- *e* Opaque
- *g* In steels and irons very low in manganese
- *h* Malleable at steel rolling temperatures. Under reflected plane-polarized light with nicols crossed, properly oriented grains show four extinctions in 360 deg.

2 Graphite, C
- *a* Hexagonal
- *c* 1 to 2
- *d* Light to dark gray
- *e* Opaque but shows strong anisotropic reactions
- *g* One of the principal constituents of cast iron and malleable cast iron. Also found in graphitic steels. May be found in still tubes, steam lines, die and tool steels after prolonged exposure to elevated temperatures.
- *h* Graphite is somewhat pleochroic and the plane glass vertical illuminator polarizes light sufficiently to cause graphite to appear light or dark, depending on its crystallographic orientation. Graphite in steels will go into solution if heated well above the transformation temperature.

Translucent Anisotropic Minerals with Weak Birefringence

1 Alumina, corundum, Al_2O_3
- *a* Hexagonal
- *b* 2050 C (3722 F)
- *c* 9
- *d* Medium gray
- *e* Colorless
- *f* No = 1.77 Ne = 1.76 (Na)
- *g* In steels and irons treated with aluminum, and in some inclusions derived from refractories.
- *h* Not malleable at steel rolling temperatures. Color by transmitted light changed variously by impurities in solid solution. Occurs as equiaxed or elongated grains with irregular surfaces, or euhedral crystals. These have a tendency to group together in clumps or small clouds of particles. During rolling or forging these groups are formed into irregular rows of particles in the direction of working. These inclusions are rarely pure and may contain FeO

and SiO_2. The inclusions rich in Al_2O_3 are difficult to polish and frequently their anisotropic behavior is masked by reason of their transparency and highly reflecting metal inclusion interface, or by rounding the edge of the cavities left by their removal.

2 Mullite, $3Al_2O_3.2SiO_2$
a Orthorhombic
b 1816 C (3301 F)
c 7.5
d Medium to dark gray
e Colorless, pink
f Ng = 1.654, Nm = 1.644, Np = 1.642
h Frequently occurs as long euhedral crystals in glass inclusions.

3 Quartz, SiO_2
a Hexagonal
b 1600 to 1750 C (2912 to 3182 F)
c 7
d Medium to dark gray
e Colorless
f Ne = 1.55, No = 1.54

4 Cristobalite, SiO_2
a Pseudo-isometric (tetragonal?)
b 1696 C (3085 F)
c 6-7
d Medium to dark gray
e Colorless
f No = 1.487, Ne = 1.484
h Usually associated with glass

Translucent Anisotropic Minerals with Strong Birefringence

1 Fayalite, $2FeO.SiO_2$
a Orthorhombic
b 1205 C (2201 F)
c 6.5
d Medium to dark gray
e Colorless, light green, yellowish green, yellowish brown
f Ng = 1.886, Nm = 1.887, Np = 1.835
h Frequently contains $2MnO.SiO_2$ in solid solution

2 Ferric oxide, hematite, Fe_2O_3
a Hexagonal
c 5
d Medium to light gray
f No = 3.22, Ne = 2.94 (Na)
g Frequently occurs as outer layer of scale

3 Chromic oxide, Cr_2O_3
a Hexagonal
b 1900 C (3452 F)
d Medium to light gray
e Green, depending on the thickness
f N = 2.5±
g In stainless steels and other high-chromium materials
h Not malleable at steel rolling temperatures. These inclusions are harder than chromite.

4 Aluminum nitride, AlN
a Hexagonal
b 2150 to 2200 C (3902 to 3992 F)
d Dark to very dark gray
f Birefringence high (indices not available). Often shows brilliant polarization colors.
g In chromium produced by the aluminothermic process and in chromium steels containing aluminum.
h Frequently occurs as euhedral crystals.

Examination in Reflected Unpolarized Light After Etching. As indicated in the preceding section, much information can be derived from shape of inclusions and their color and optical activity in transmitted light. When this method of approach has been exhausted and the nature of inclusion material is still in doubt, etching is recommended. If the microscope used is not equipped for studies with polarized light, then etching is the only method available. In this situation it should be understood that the identification will not be so reliable as when both methods are employed.

The effect of certain etching reagents on inclusion material is shown in Table II. In using this table, it must be remembered that the effect of the etchants shown applies only to the inclusions described, and that there is no way of predicting the effect on inclusion types not shown. Similarly, if one of the two sequences of etching shown is used, then the other sequence should not be used without complete regrinding and repolishing.

Identification by Extraction. When visual and surface etching methods leave something wanting, nonmetallic inclusions may be extracted for more detailed study.

If the inclusions in question are of sufficient size, they may be extracted mechanically with the aid of a jeweler's screw driver containing a sharpened phonograph needle. The technique is simply the process of forcing the needle into the metal almost adjacent to the inclusion, which will then be displaced, usually in fragments.

Another method that may be used is to dissolve away the steel with dilute mineral acids or with alcoholic iodine solution. However, such chemical methods should be used with considerable discretion because many of the inclusions are also attacked. Generally speaking, chemical extraction should be used only on killed steels.

Electrolytic extraction, in which the specimen is made the anode in an electrolytic cell, has been very successfully used. When the electrolyte is properly buffered, sulfides and even carbides can sometimes be retained intact while the metal is dissolved.

Table II. Scheme for Etching Identification Tests

Appearance with Reflected White Light (× 200, × 500, × 1000)

Gray or Black Inclusions

Etch 10 sec in 10% alcoholic nitric acid

More contrast	Unattacked
(*a*) FeO in FeO.FeS eutectic darkened	Etch 5 min in 10% chromic acid in water
Attacked	**Unattacked**
(*a*) Removes FeS.MnS, rich in MnS (*b*) Darkens FeO.MnO	Etch 5 min in boiling alkaline sodium picrate
Attacked	**Unattacked**
(*a*) Removes FeS.MnS, rich in MnS (*b*) Removes FeO.MnO	Etch 5 min in 5% alcoholic hydrochloric acid
Attacked	**Unattacked**
(*a*) Removes FeO.FeS (*b*) Removes FeO (*c*) Removes remaining FeO.MnO (*d*) Removes $MnO.SiO_2$	Etch 10 min in a 20% aqueous solution of hydrofluoric acid
Attacked	**Unattacked**

After extraction, the inclusions may be examined by standard petrographic techniques,[16] they may be subjected to ordinary chemical analysis or examined for mineral constituents by X-ray diffraction.

A different approach developed by Baeyertz involves preparing a thin section for examining inclusions by transmitted light, according to petrographic procedures.

Effects of Inclusions

One of the criteria by which steel quality and fitness for some particular uses are judged is the content and character of nonmetallic inclusions. The fact that they are nonmetallic and, therefore, incongruent with the metal lattice has often been considered sufficient evidence of undesirability. It is a fact, however, that the true import of inclusions in regard to steel properties has never been satisfactorily clarified, and opinions vary widely. Nevertheless, as was mentioned earlier, certain correlations noted be-

tween observed inclusions and service behavior of steel may be taken as evidence of their effects. It is apparent, however, that total contents are not sufficient data on which to evaluate all effects.

An analogy might be drawn between inclusions in steel and certain low organisms such as bacteria. Because some of the latter have been found to be responsible for many distressing and fatal diseases, anathema has been cast on the whole breed. Yet it is true that the vast majority of such organisms are either benign or beneficial, and it is probably true that the higher animals could not exist without them to dispose of waste, fix nitrogen and prepare soil. Similarly, although it is known that some inclusions have harmful effects, it may well be that some of the properties that are considered characteristic and useful in steel would not exist were it not for a very fine precipitation of inclusions. Precipitation hardening, for example, is attributed to the critical dispersion of precipitated particles.

Indigenous and exogenous inclusions are discussed separately for two principal reasons. In the first place, indigenous inclusions have a fairly homogeneous macrodistribution and any effect will be common throughout the steel, whereas the sporadic occurrence of exogenous inclusions limits effects to their locality. In the second place, exogenous inclusions are generally much larger and are often imperfectly "wetted" by the steel, both of which factors tend to intensify their effects.

Effects of Indigenous Inclusions. *Machinability.* The machinability or free-cutting quality of most steels is markedly enhanced by an increase in the sulfur content. Such an increase naturally produces more numerous or larger sulfide inclusions. Just how far this improvement will continue with increasing sulfur has not been determined, but apparently it continues up to the point where sulfur content makes the steel all but unrollable. Although other factors in the addition of sulfur may also affect machinability, it is believed that the actual presence of the sulfide inclusions has the greatest effect.

This effect has been explained by some on the basis of the embrittling effect of sulfides, and by others on the basis of internal lubrication. Selenium, which forms selenides with the general appearance and characteristics of sulfides, has much the same effect as sulfur on machinability. The metallic inclusions of lead in leaded steels are outstanding in their ability to improve machinability.

Refractory oxide inclusions, such as silicates or alumina, have been designated as distinctly harmful to machinability because of abrasive action, although the case against them is largely circumstantial evidence. On the other hand, some chromium oxides have been credited with improving the machinability of austenitic stainless steels.

Grain Size. The inhibition to grain growth in "fine-grained" steels below their grain-coarsening temperature has been ascribed to a mechanical barrier in the grain boundaries, which prevents diffusion across them. Although this barrier is apparently too fine to be observed and identified with the ordinary microscope, strong circumstantial evidence predicates its presence, and it is thought to be of the nature of nonmetallic inclusions.

Because of the known behavior of fine-grained steels, it has been postulated that the grain-boundary inclusion substance (still unknown) has an appreciable solubility in alpha iron at high temperatures but precipitates in the boundaries of the newly formed austenite grain during transformation while heating. There the inclusion substance effectively prevents grain growth until it is redissolved in austenite at the grain-coarsening temperature.

Alumina has been mentioned widely as one of the growth-inhibiting materials, because of the generally fine-grained nature of aluminum deoxidized steels. There are reasons, however, to believe that aluminum nitride is a more likely agent. The nitride seems to be an improbable factor in the steels deoxidized with titanium or zirconium, because the nitrides of these elements are very insoluble. The sulfides or suboxides of these elements and of vanadium appear to be possible factors in grain-growth inhibition, whereas the carbides have less potentiality because of generally higher solubility in gamma than in alpha iron.

Ductility and Notched-Bar Impact Properties. The mechanical properties of steel, as measured by the ordinary tensile and notched-bar impact tests, are affected directly by the quantity of inclusions present but even more strongly by the size and distribution of the inclusions.

These effects are best shown with sulfide inclusions, because they are more readily controlled in quantity and type. The quantity, of course, will vary directly with the sulfur content, while the type and distribution can be controlled by the deoxidation practice. The effects are much more evident in cast steel, which has almost no directional properties, but can also be shown in wrought steel if specimens are taken both longitudinal and transverse to the direction of rolling.

When sulfides are precipitated as relatively large globules and far apart, as in silicon-deoxidized steels, they have the minimum effect for a given quantity. However, when aluminum or some other strong deoxidizer is used in an amount that will cause the sulfides to precipitate as part of a eutectic, in which form they constitute a nearly continuous chain or film envelope around the primary grains, the sulfides have the maximum effect on ductility. In a cast steel, the ductility and notched-bar impact values may be reduced by 50% with the eutectic sulfides, as compared with the globular type. In rolled steel, the effect is usually not noted if the specimen is taken in the direction of rolling, but it may be exaggerated in the transverse direction.

The effect of quantity alone, when other factors are equal, has been noted even in steels with very low sulfur contents. For instance, in a Ni-Cr-Mo steel,[19] an increase in sulfur content from 0.007 to 0.013% caused a consistent drop in the notched-bar impact value from 30 to 26 ft-lb in longitudinal tests and 19 to 14 ft-lb in transverse tests.

In a medium-carbon silicon-killed cast steel,[10] an increase in sulfur from 0.02 to 0.06% (tripling the sulfide content) caused a decrease in elongation from 34.0 to 29.5%, in reduction of area from 61.5 to 46%, and in Izod value from 51.5 to 27 ft-lb.

In rolled steels, a comparison of a C1019 and a B1112 steel will suffice. These steels have the following approximate compositions:

	Percentage			
	C	Mn	S	P
C 1019	0.19	0.85	0.05 max	0.045 max
B 1112	0.10	0.75	0.20	0.10

Tested in the hot rolled condition, they showed average properties as listed in Table III.*

Because of variations in content of elements other than sulfur, all differences in properties cannot be ascribed to sulfur. Higher phosphorus in the B 1112 undoubtedly affects the Charpy value, for example. However, it will be observed that whereas the values for longitudinal ductility are not greatly reduced by the higher sulfur content, the transverse ductility is affected to a much greater extent. No similar data seem to be available in regard to the effect of the quantity of oxide inclusions, and it is only presumed that they would act in a similar manner.

Brittle Fracture. From time to time in the examination of cast or forged steels, extremely brittle conditions are encountered in which the fractures are characterized by smooth, undulating, or coarsely crystalline surfaces. These have sometimes been called "rock candy" fractures but are probably more accurately termed "intergranular" fractures in which the primary grain boundaries are involved. The condition may occur at any time after the steel is cast, even after it is fully heat treated.

Although it seems that the cause of brittle fracture may sometimes be ascribed to a ferrite network,[20] or to massive carbide precipitation in the primary grain boundaries of raw steel, or even to hot tears, the majority of such fractures appear to be caused by a precipitation of inclusions in the primary grain boundaries, either during freezing or during slow cooling from ■ high temperature used in heat treating or forming. Aluminum nitride and manganese sulfide inclusions have been identified as two substances that behave in this manner. Both of these materials have an appreciable solubility in gamma iron—a solubility that

*Unpublished work at Battelle Memorial Institute

Table III. Mechanical Properties of Two Hot Rolled Steels

Steel	Tensile Strength, psi		Yield Strength, psi		Elongation in 0.75 in.		Reduction in Area, per cent		V-Notch Charpy, ft-lb	
	Long	Trans	Long	Trans	Long	Trans	Long	Trans	Long	Trans
C 1019	64,000	61,800	36,300	32,700	43.5	36.0	66.5	53.7	88.5	35.0
B 1112	66,900	62,500	39,900	35,900	37.5	22.6	60.5	24.5	18.0	9.0

varies with temperature. Other substances may be involved in individual instances and any material that will form a fairly continuous network, however thin, in the steel will have the same effect.

Hot Shortness. Iron sulfide, which precipitates as films in the primary grain boundaries, has an effect on hot shortness that has been widely expounded. Manganese sulfide also, when it precipitates in eutectic form, has much the same effect, although to a lesser degree. Such sulfides have been blamed for excessive hot tears (in steel castings, for example) but there seems to be no clear-cut evidence that they have been responsible for rolling difficulties.

Fatigue. A deleterious influence of nonmetallic inclusions on the fatigue endurance properties of steel is probably one of the most widely expected effects, and yet experimental evidence does not support belief in any important detriment to endurance values from indigenous inclusions in their ordinary range of occurrence. Throughout a wide range of steels, endurance values for polished bars bear a significantly constant relation to tensile strength.

Any such general statement has limitations; for example, in a certain ingot, it was found that the butt cut had an oxide inclusion content about 50 times as great as the upper cuts.* Specimens from the upper cuts showed endurance values of 55% of the tensile strength; no definite value could be determined for the butt cut because of the erratic behavior of the specimens, one of which broke at a fiber stress as low as 47% of the tensile strength at ▮ million cycles.

Fatigue testing is naturally a study of notch propagation, and the reason why indigenous inclusions have so little effect on endurance values is thought to be that they do not produce internal notches in steel. In other words, there is no cavity around an indigenous inclusion; it is wetted by the steel, and there is a bond between steel and inclusion. Thus, the inclusions support some of the stress, even though the modulus of elasticity may be different. There is no apparent reason why an oxide or sulfide inclusion should have any more effect than carbides on endurance.

It should be emphasized that this discussion concerns only the small, naturally precipitated inclusions. Inclusions are thought to harm endurance values more in very hard steels, such as ball or roller bearings. A study of many references to fatigue failures caused by inclusions indicates that the inclusions in question were probably adventitious in origin. Reference to these is made in the next section.

Corrosion. In stainless steel, the effect of inclusions on corrosion resistance has been termed definitely harmful, and sulfide inclusions on polished surfaces are sometimes thought to tend to localize corrosive attack. Localized corrosion, however, is usually an electrolytic phenomenon and most inclusions are too insoluble in water or are too nonconductive to make an electrolytic couple in either atmospheric or submerged corrosion. On the whole, normal variations in the corrosive environment have far more influence than the variations in inclusions.

Weldability. Normal amounts of oxides, sulfides, and nitrides are not harmful to most welding processes. Sulfides are considered to have the most deleterious effect on weldments, because of the characteristic of hot shortness imposed on the zone of fusion during solidification and cooling through the range of hot shortness, when stresses can produce separation of the metal.

Rolled plate, forgings and castings of steel are successfully joined to each other by many processes, such as metal-arc welding, submerged-arc welding, flash butt welding, gas welding and resistance welding.

Experience teaches that certain qualities are desirable in the steel for each particular process of welding.[21] This acknowledges that size and distribution of inclusions may affect the capacity of steels to be fabricated by welding into structures adequate for the service requirements. In metallic arc welding, 0.05% S in the parent metal may have no deleterious effect on the weld metal. When segregated MnS inclusions occur in the parent metal, as is possible in semikilled steels or between the core and case of rimmed steel, these inclusions react with explosive violence during welding and create gas pockets at the fusion line. It is not uncommon to find in highly segregated steel that the inclusion material will be melted out of a ghost band beyond the junction line of the weld and parent metal. High-quality welds are difficult to obtain with high-sulfur free-machining steels. The presence of 0.15 to 0.30% S in the parent metal causes porosity and cracking in the weld metal deposited with mild steel electrodes. Satisfactory welds have been made with the new all-mineral electrode of low hydrogen content. The lime-silica ratio of the coating apparently fixes the sulfur in a harmless form and is important to the soundness of the weld metal. The low hydrogen content of this electrode helps to hold back underbead cracking. When sulfur segregations are suspected in steel for welding and a sulfur print, exposed for one minute, shows concentrations exceeding ⅛ in. in diam and more than 2 per sq in., the steel is considered detrimental for arc welding. The amount of sulfur in root beads and fillet weld metal for heavy plate welding should not exceed 0.04%; otherwise there will be a strong tendency to crack. The tendency for welds to crack as a result of sulfur inclusions, can be controlled by the selection of electrodes and preheat schedules.

The welds of stainless alloys, nickel or monel, on carbon steel are more sensitive to sulfide inclusions than they would be with mild steel electrodes. The high-nickel alloys are especially susceptible to cracking in the presence of small amounts of segregated MnS. Opinions vary as to the amount of sulfur that can be present and still produce crack-free deposits, but this is placed between 0.025 and 0.05% S.

Submerged-arc welding presents a greater problem from the difficulty with sulfides in the parent metal than multi-pass arc welding, because more parent metal is fused. Because of this manner of solidification in thick, single-bead, submerged-arc weld deposits, the sulfur dissolved from segregated areas of the parent metal can cause cracking along the coarse columnar grains, which may not be observed readily by X-ray inspection. Cracking at the weld stock junction may also be overlooked because of porosity. Killed steels are preferred to rimmed or semikilled steels because they are less segregated.

In summarizing the effect of inclusions on metal-arc welding, it may be stated that sulfides are always undesirable, that oxides are less undesirable and that silicates are least harmful.

In spot welding, 0.05% S has no deleterious effect on the welding of steel. The sulfur content of mild steel when spot welded to stainless steel should be lower than 0.05% to avoid cracking of the stainless steel. Resistance welding of free-machining SAE 1112 steel containing 0.16 to 0.23% S resulted in a brittle condition at the weld, by reason of a nearly continuous line of inclusions (derived from the manganese and iron sulfides in the parent metal) which appeared at the weld line.

Inclusions in steel have a detrimental effect on flash welding. This effect varies with the number, size and distribution of the inclusions. Two weaknesses inherent in flash welding contribute to the detrimental effect of the inclusions. Numerous inclusions may allow sufficient slag to remain on the flashing edges immediately before upsetting to form a discontinuity in the weld line. All stringer-type inclusions necessarily follow the upsetting pattern of

*Unpublished work at Battelle Memorial Institute

the metal and form an end-grain effect in the flow lines on either side of the weld areas. Stringer inclusions of oxides, sulfides and silicates extruded with the upset metal can reduce the ductility of the weld area and produce poor performance in bend and fatigue tests.

To minimize the effects of coarse inclusions, some importance is attached to the direction of rolling and the location of the edge to be flashed, with respect to its location in the ingot. Depending on the size and shape of the inclusions, a higher quality weld will result if the weld is made normal to the direction of rolling than if made parallel to it. Under some conditions, it is economical to locate the welding edge to some area of the metal that is fairly clean. Using the rimmed portion of a rimming steel is an example.

High-sulfur free-machining steels are not considered weldable by flash welding. Concentrations of the sulfide inclusions produce a very uneven burn-off, creating uneven spacing along the edges during the flashing period. This condition is conducive to cold welding and insufficient extrusion at final bump, resulting in weld weakness. It is believed, however, that steel containing as much as 0.08% S uniformly distributed can be successfully flash welded.

The effect of inclusions on atomic hydrogen weldability is not well understood. In the welding of SAE 4335 steel, it has been recognized that welding metal containing 0.008% S is freer from objectionable porosity than metal containing 0.012% S. Some authorities place the limit for sulfur at 0.015%. The amount of aluminum used for deoxidation of the steel is apparently important so as not to produce eutectic sulfides. In some instances, sulfides of the eutectic type appearing in the parent metal have been thought responsible for poor atomic hydrogen weldability, an inferiority made evident by a deep boiling and scumming action during the welding process, with resulting undercutting, porosity and cracks. On the other hand, a small residual aluminum content suppresses porosity in the presence of sulfur. It is apparent that hydrogen is very reactive with sulfide inclusion material and cleanliness is felt to be essential to high-quality welds.

In oxyacetylene welding, metal that contains less than 0.05% S causes no trouble. The probability of cracking increases as the sulfur content is increased. Sulfur segregations, such as cause difficulty in arc welding, would be expected to cause deleterious results in oxyacetylene welds.

Effect of Exogenous Inclusions. *Surface Appearance.* Owing to their larger size, exogenous inclusions are more likely to have a detrimental effect on certain properties of steel than the microscopic natural inclusions. However, nonmetallic inclusions are often blamed for apparent defects in steel, when their origin is actually traceable to other causes. Thus, pitting, which is encountered occasionally in the polishing of stainless steel surfaces, is not infrequently ascribed to nonmetallic inclusions, whereas a closer examination may reveal that improper polishing technique or lack of cleanliness is the real culprit. It cannot be denied, however, that large adventitious inclusions, particularly when agglomerated or drawn out into rows, may produce imperfections or blemishes on the surface of polished stainless steel that impair its usefulness, although such occurrences are generally rare.

Service Failures. Occasionally, stringers of adventitious inclusions may lead to ruptures and seams on the inside surface of tubes in piercing, but as a rule even the large accidental inclusions do not constitute a problem in fabrication processes.

The large adventitious inclusions may have a more serious effect on the performance of steel parts in service. Experience has shown that little trouble is to be expected from such inclusions in statically stressed ductile materials. However, their occurrence in highly cold worked steel or in higher-carbon or alloy steels, particularly when the latter are in the quenched and only slightly tempered condition (for instance, in spring steel), may lead to failures under impact or repeated stresses if the inclusions are located in critical regions and if their orientation is unfavorable in relation to the existing stresses. Any nonmetallic inclusion of macroscopic size, situated in a critical zone in or near the surface of a dynamically stressed part, may be compared to a notch with a triaxially stressed condition at the root, which causes a great strength reduction of the metal under repeated stress. Examination of the fracture surfaces of failed ball or roller bearings often discloses patches of green or brown slaglike material from which the cracks appear to have started. However, it should be well understood that even macroscopic inclusions may have no detrimental effect whatever if they are located away from the critically stressed zone. The presence of large adventitious inclusions in critical regions of dynamically stressed material undoubtedly constitutes a threat to the life of the part, but experience has also shown that fatigue failures, resulting from poor fillets, tool marks, keyways, stamped numbers, accidental scratches, and similar imposed stress-raisers, greatly outnumber failures resulting from nonmetallic inclusions. *See also* the article on page 243.

Weldability. Refractory and slag inclusions that appear at the welding surfaces of steel for arc welding, and are large enough to view visually with the unaided eye or with a 5 × hand lens, are objectionable because they contribute to sidewall defects during welding, with consequent lowering of strength and impairment of X-ray quality. Upon detection such defects should be chipped out and the surface weld should be repaired before attempting the welding of heavy sections. Laminations or near-laminations caused when refractory or slag material is rolled out, can be a source of trouble in arc welding, by forming gases with the filler material. In general, exogenous refractory inclusions consisting of alumina and silicates have given little difficulty in arc welding except when the inclusions are large.

Any slag inclusions or laminations at the welding edge for flash welding are very injurious, because they result in a notch effect along the outbent fiber and weaken the weld area. Inclusions that tend to laminate plates or forgings are objectionable for pressure welding processes because the heat and pressure open the cavity around the filling.

Exogenous inclusions in sheet or plate for spot welding, when these occur close to the surface to be welded, are harmful because of their effect on the electrical resistance of the steel, an effect that results in overheating and flashing with consequent weakness of spot welds.

Functions of the Alloying Elements in Steel

BY J. M. HODGE* AND E. C. BAIN*

ALLOYING elements are added to steel to enhance the properties. Some elements may be used in high percentage to obtain increased resistance to corrosion, as in the stainless or heat-resisting alloys. This function is discussed in detail in the articles on pages 549 to 580, concerning these types of alloy steels. Alloying elements may be added sparingly to impart greater strength and corrosion resistance to low-carbon as-rolled steels for use in welded structures, as described in the article concerning high-strength low-alloy steels, on page 534. Alloying elements may be used to impart resistance to abrasion, as in tool steels (page 658), or to enhance electrical or magnetic characteristics (pages 587 to 599). In a sense, these are specialized functions, utilized in specialized and somewhat limited applications of alloy steels, and since they are discussed in detail in other sections of this Handbook such functions will not be discussed further in this article. Many of these specific functions are discussed also in the various articles about individual alloying elements.

By far the largest tonnage of alloy steels is of the types containing generally 0.25 to 0.55% C, or less if for carburized parts—widely used in automotive and aircraft machinery and almost always quenched and tempered for high strength and toughness. This article will deal primarily with the functions of the alloying elements in this high-tonnage class of alloy steels.

* Carnegie-Illinois Steel Corporation, Pittsburgh

Prepared for the Subcommittee on Alloying Elements in Steel

Manganese, silicon, nickel, chromium, molybdenum, vanadium, aluminum and boron are commonly incorporated in these steels to enhance the properties obtainable after quench-hardening and tempering. Alloy steels of these types were utilized in large tonnages before the mechanisms were understood by which the alloying elements accomplished the improvements.

These alloy steels are ordinarily quench-hardened and tempered to the level of strength desired for the application. Even though the strength level at which the steel is used may be as low or lower than that which could be achieved by the microstructure (fine pearlite or upper bainite) developed by a simple cooling from forging or normalizing temperature, quench-hardening and tempering are performed, indirectly reflecting the engineering and economic basis of the demand for this type of steel. The microstructure (tempered martensite or bainite) produced by quenching and tempering these properly designed alloy steels is characterized by a greater toughness or capacity to deform without rupture at any strength level. Similarly, under the adverse state of stress below a notch in bending, the tempered martensite may flow considerably at a testing temperature far below that at which a pearlitic steel of equal strength would break in a brittle manner; the Charpy or Izod values are thus improved. The basic phenomenon of developing this favorable microstructure by heat treatment is manifest in plain carbon steels, but only in small sections; thus the most important effect of the alloying

elements in these steels is to permit the attainment of this microstructure, and the accompanying superior toughness, in larger sections.

Alloying Elements Dissolved in Austenite. The general effect of elements dissolved in austenite is to decrease the rates of transformation of the austenite at subcritical temperatures. This mechanism is described in the article concerning isothermal transformation, on page 607. The only one among the common alloying elements to behave exceptionally in this regard is cobalt. Since the desirable products of transformation in these steels are martensite and lower bainite, formed at low temperatures, this decreased transformation rate is essential; it means that pieces can be cooled more slowly, or larger pieces can be quenched in a given medium, without transformation of austenite to the undesirable high-temperature products, pearlite or upper bainite. This function of decreasing the rates of transformation, and thereby facilitating hardening to martensite or lower bainite, is known as *hardenability* and is the most important effect of the alloying elements in these steels. Thus, by increasing hardenability, the alloying elements greatly extend the scope of enhanced properties in hardened and tempered steel to the larger sections involved in most applications.

The several elements commonly dissolved in austenite prior to quenching, increase hardenability in approximately the following ascending order: nickel, silicon, manganese, chromium, molybdenum, vanadium and boron. The effect of aluminum on hardenability has not been accurately evaluated, but at 1% Al, as used in "nitralloy" steels, the

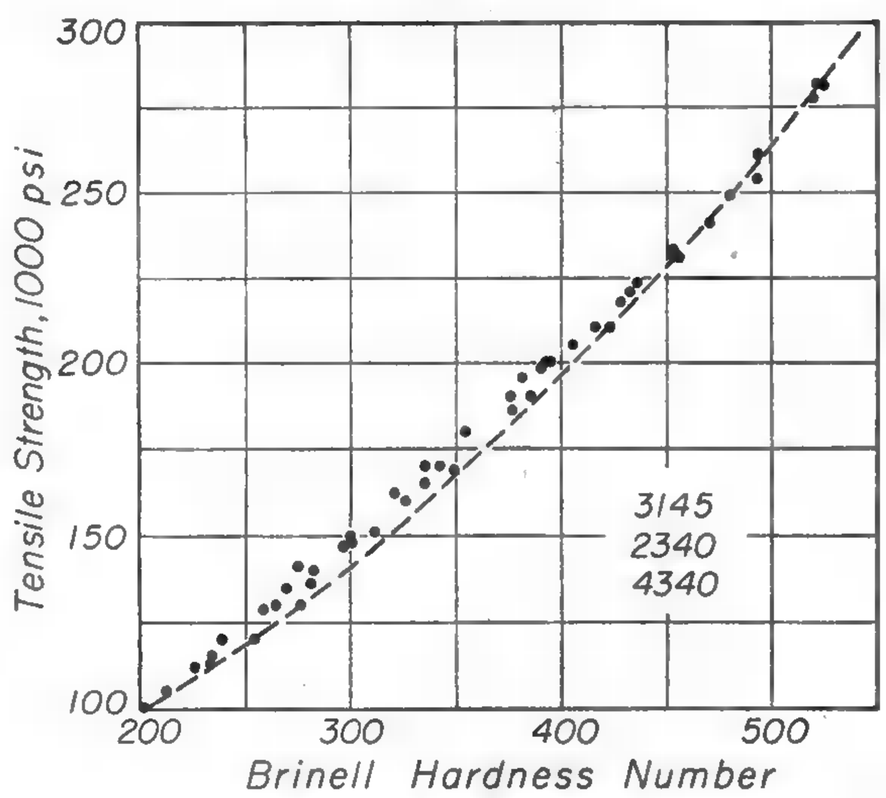

Fig. 1 Relationship between hardness and tensile strength for three quenched and tempered alloy steels

effect on hardenability seems to be relatively small. Multiplying factors that express the hardenability effects of these elements will be found in the article concerning the calculation of hardenability, page 494. Further, it has been found that the addition of several alloying elements in small amounts is more effective in increasing hardenability than the addition of much larger amounts of one or two.

In order to increase hardenability effectively, it is essential that the alloying elements be in solution in the austenite, and the steels containing the carbide-forming elements—chromium, molybdenum and vanadium—require special consideration in this respect. These elements are present predominantly in the carbide phase of annealed steels, and such carbides dissolve only at higher temperatures and more slowly than iron carbide. Hence, for effectiveness, heating schedules should be set up in such a way as to dissolve an adequate proportion of these elements. It is uneconomical to heat at such low temperatures that the carbide-forming elements are largely undissolved.

Since the basic function of the alloying elements in these steels is to increase hardenability, the selection of a steel and the choice of suitable austenitizing conditions should be based primarily on the assurance of adequate hardenability. More than adequate hardenability is rarely a disadvantage, except in economy.

Alloying Elements in Quenching. Since the sections treated are often relatively large, and since the alloying elements have the general effect of lowering the temperature range at which martensite is formed, the thermal and transformational stresses set up during quenching tend to be greater in these alloy steel parts than those involved in quenching the necessarily smaller sections of plain carbon steels. In general, this means greater distortion and risk of cracking.

The alloying elements, however, have two functions that tend to offset these disadvantages. The first and probably the most important of these functions is that of permitting the use of a lower carbon content for a given application. The decrease in hardenability accompanying the decrease in carbon content may be offset very readily by the hardenability effect of the added alloying elements, and the lower-carbon steel will exhibit a much lower susceptibility to quench cracking. This lower susceptibility results from the greater plasticity of the low-carbon martensite and from the generally higher temperature range at which martensite is formed in the lower carbon materials. It has been found that quench cracking is seldom encountered in materials containing 0.25% C or less, and that the susceptibility to cracking increases progressively with increasing carbon content.

The second function of the alloying elements in quenching is to permit slower rates of cooling for a given section, because of increased hardenability, and thereby generally to decrease the thermal gradient and, in turn, the cooling stress. It should be noted, however, that this is not altogether advantageous, since the direction as well as the magnitude of the stress existing after the quench, is important in relation to cracking. In order to prevent cracking, the surface stresses after quenching should be either compressive or at a relatively low tensile level and, under certain circumstances, lowering the cooling rate may lead to increased tensile stresses at the surface, thus increasing

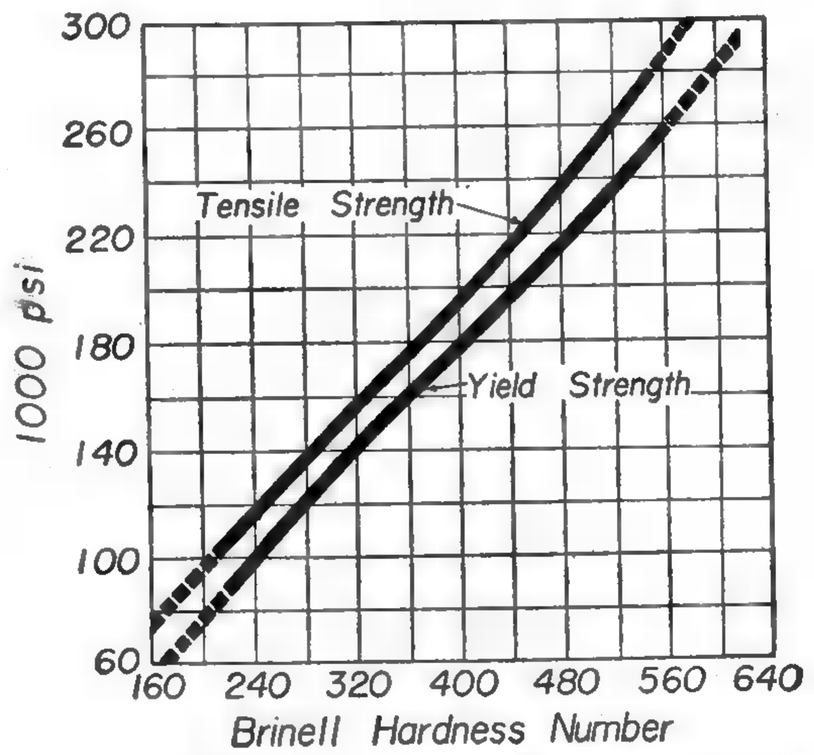

Fig. 2 Statistical mean of the relationships among Brinell hardness, tensile strength and yield strength in quenched and tempered alloy steels

the tendency to crack. In general, though, unless a study of the particular piece being quenched indicates that it falls within this category of increased susceptibility with decreased quenching rates, the use of a less drastic quench suited to the hardenability of the material, will result in lower distortion and greater freedom from cracking.

Furthermore, the increased hardenability of these alloy steels may permit heat treatment by "austempering" or "martempering", and thereby the level of adverse residual stress before tempering may be held to a minimum. In "austempering", the work piece is cooled rapidly to a temperature in the lower bainite region and is allowed thereafter to transform completely at some chosen temperature. Since this transformation occurs at a relatively high temperature and proceeds rather slowly, the stress level after

transformation is quite low and distortion is held to a minimum. In "martempering", the piece (1) is cooled rapidly at the surface to a temperature that permits very little martensite to form, if any, (2) is equalized at this temperature, and (3) is then cooled slowly so that transformation throughout the whole section occurs more or less simultaneously, thereby holding transformational stresses at a very low level and minimizing distortion and danger of cracking.

Alloying Elements in Tempering. Hardened steels are softened by reheating, but this effect is not the one actually sought in tempering. The real need is for increasing the capacity of the piece to flow moderately without fracture, and this is inevitably accompanied by a loss of strength. Since the tensile strength is very closely related to hardness in this class of steels as heat treated, it is satisfactory to follow the effects of tempering by measuring the Brinell or Rockwell hardness. The results of a careful study of this relationship for three steels is shown in Fig 1.

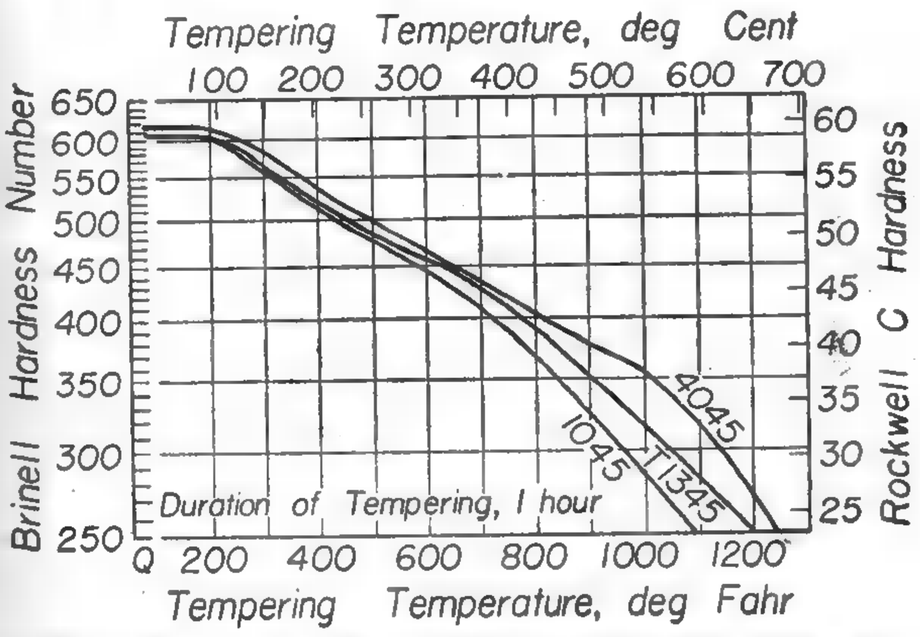

Fig. 3 The softening of 1045, T1345 and 4045 steels at various temperatures (one-hour tempering)

The dotted line in this plot represents the commonly used relationship of Scott and Gray. Probably the stress at the limit of the elastic range correlates well also with hardness, but since the elastic limit is a property difficult to measure and confused by initial stress in the specimen, the data are less well related. The statistical mean of these relationships among Brinell hardness, tensile strength and yield strength, is shown in Fig. 2, drawn from many data.

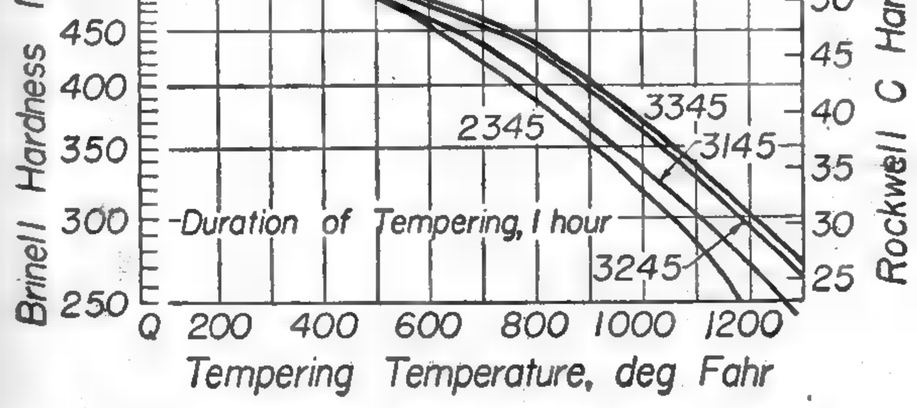

Fig. 4 The softening of 2345, 3145, 3245 and 3345 steels at various temperatures (one-hour tempering)

Figures 3, 4, 5 and 6 show the softening pattern of many familiar 0.45% C steels with increase in the tempering temperature for one hour. Somewhat shorter or longer intervals at temperature would show little difference in hardness values. As a first approximation, the softening pattern of steels similar but differing in carbon content through the range from 0.25 to 0.55% C may be estimated from Fig. 7. This illustrates the general effect of carbon content on this softening pattern in terms of Rockwell C hardness units to be added to or subtracted from the 0.45% C value at different levels of tempering temperature, but accurate data that would permit a strictly quantitative relationship of this type are not available. It will be noted that the effect of carbon content on the hardness of the tempered steels is much greater at the lower tempering

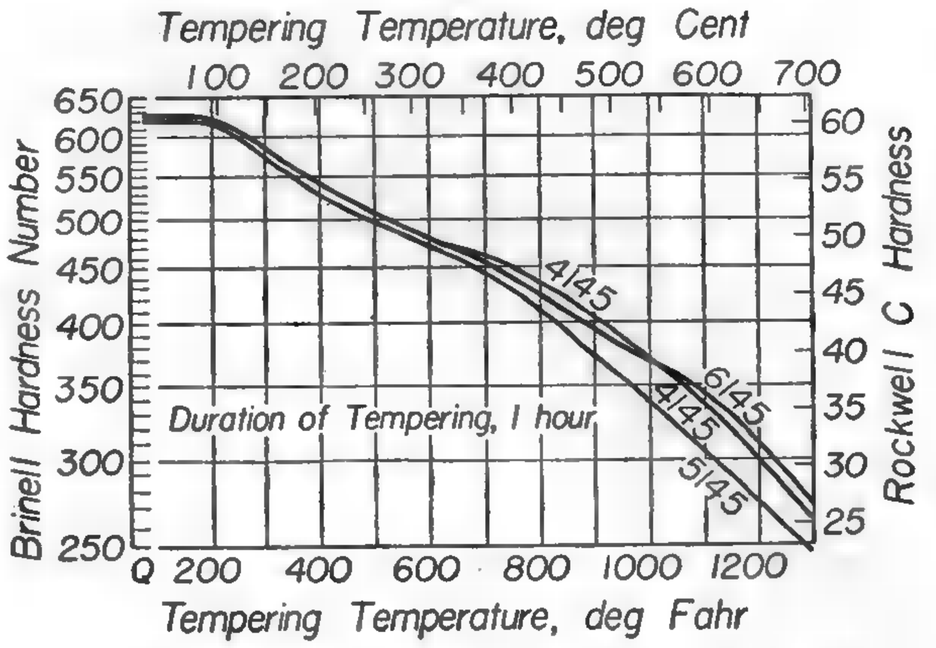

Fig. 5 The softening of 4145, 5145 and 6145 steels at various temperatures (one-hour tempering)

temperatures than at temperatures at 1200 F and higher, and that the effect likewise decreases when there is more than 0.50% C. These charts, used together, make it possible to estimate the strength from a given tempering treatment applied to a given type of steel.

It will be seen that the general effect of the alloying elements is to retard the softening rate, so these alloy steels will require a higher tempering temperature to obtain a given hardness. However, the individual elements show significant differences in the magnitude of their retarding effect. Nickel, silicon, aluminum and, to a large extent,

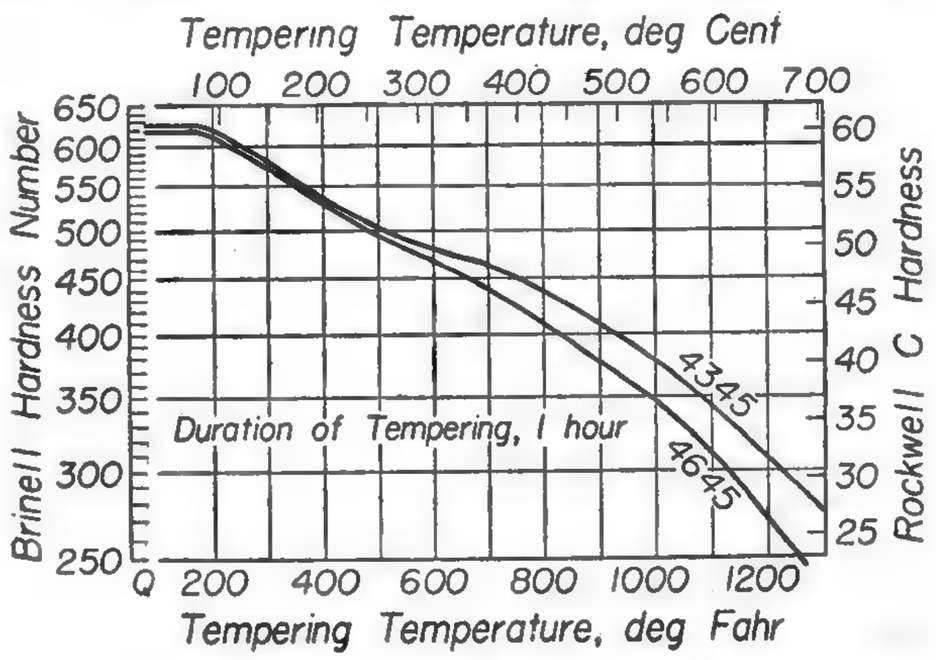

Fig. 6 The softening of 4345 and 4645 steels at various temperatures (one-hour tempering)

manganese, which have little or no tendency to occur in the carbide phase, and merely remain dissolved in ferrite, have only a minor effect on the hardness of the tempered steel—an effect that would be expected from the general pattern of solid solution hardening. Chromium, molybdenum and vanadium, on the other hand, which migrate to the carbide phase when diffusion is possible, bring about a retardation of softening, particularly at the higher tempering temperatures. These elements not only raise the tempering temperature but, when they are present in higher percentages, the rate of softening is no longer a continuous function of the tempering temperature; that is, the softening curves for these steels will show a range of tempering temperature in which the softening is retarded or, with relatively high alloy content, in which the hardness may actually increase with increase in tempering temperature. This characteristic behavior of the alloy steels containing the carbide-forming elements is known as

secondary hardening and results presumably from a delayed precipitation of fine alloy carbides.

As mentioned previously, the primary purpose of tempering is to impart a degree of plasticity or toughness to the steel in contrast with the brittleness of the martensite, and the loss in strength is only incidental to this very important increase in toughness. The increase in toughness after tempering reflects two effects of tempering: (1) the relief of residual stress set up by the quenching operation, and (2) a precipitation, coalescence and spheroidization of iron and alloy carbide, resulting in a microstructure of greater plasticity. In addition to their effects on the microstructure, as discussed above in connection with the softening behavior, the alloying elements have a secondary function. The higher tempering temperatures for a given hardness, which has been seen to be a characteristic of these alloy steels, particularly of the ones containing the carbide-forming elements, will presumably permit greater relaxation of the stress and thereby improve the resulting properties. Furthermore, as discussed in the section on quenching, the hardenability of these steels may permit the use of less drastic quenching practices, so that the stress level before tempering will be lower, thereby permitting the use of these steels at a higher level of hardness, since the higher temperatures are not then required for relief of quenching stresses. It should be noted, however, that this latter is only a secondary function of the alloying elements in tempering; the effect is primarily a reflection of the hardenability function of the alloying elements.

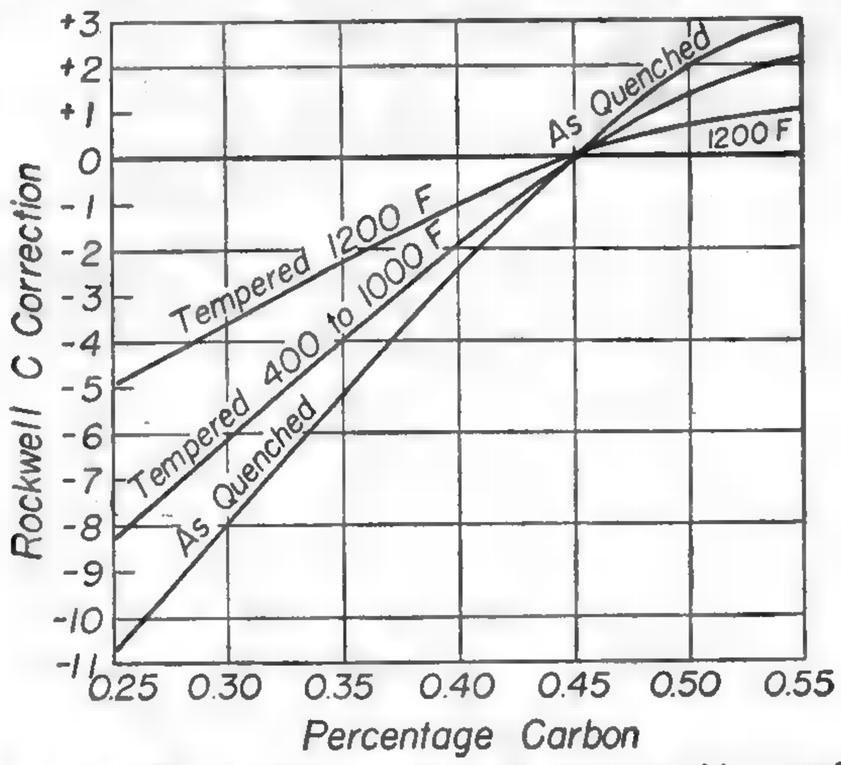

Fig. 7 The effect of carbon content on the hardness of tempered steel

Still another secondary function of the alloying elements in tempering is to permit the use of steels with lower carbon content for a given level of hardness, since adequate tempering may be assured by taking advantage of the retardation of softening brought about by the alloying elements. This results in greater freedom from cracking and generally improved plasticity at the given hardness. Here again, however, the function of the alloying elements in tempering is a secondary function; their primary function is to increase the hardenability sufficiently to offset the effect of the decreased carbon content.

The increase in plasticity on tempering is discontinuous in these alloy steels and their behavior under the stress condition of a notch shows a characteristic irregularity at approximately 500 to 600 F. The quenched martensitic steel gains toughness, as reflected in the notched-bar impact test, by tempering at temperatures as high as 400 F, but after tempering at higher temperatures this type of steel loses toughness until it may be less tough than the untempered martensite. Still higher temperatures for tempering restore greater toughness. The mechanism of this behavior is not fully understood, but it seems to be associated with the first precipitation of carbide particles, and is presumably a grain boundary phenomenon since fractures of steels tempered in this region tend to be intercrystalline. Thus, there is a range of tempering temperatures (about 400 to 700 F) never used for these steels; the tempering temperature is either 400 F (max) or more than 700 F. Although this phenomenon is common to all these alloy steels, the alloying elements have a secondary function in this connection; a combination of carbon and alloy contents of suitable hardenability may be chosen, which would permit tempering to the desired strength at temperatures outside this undesirable range.

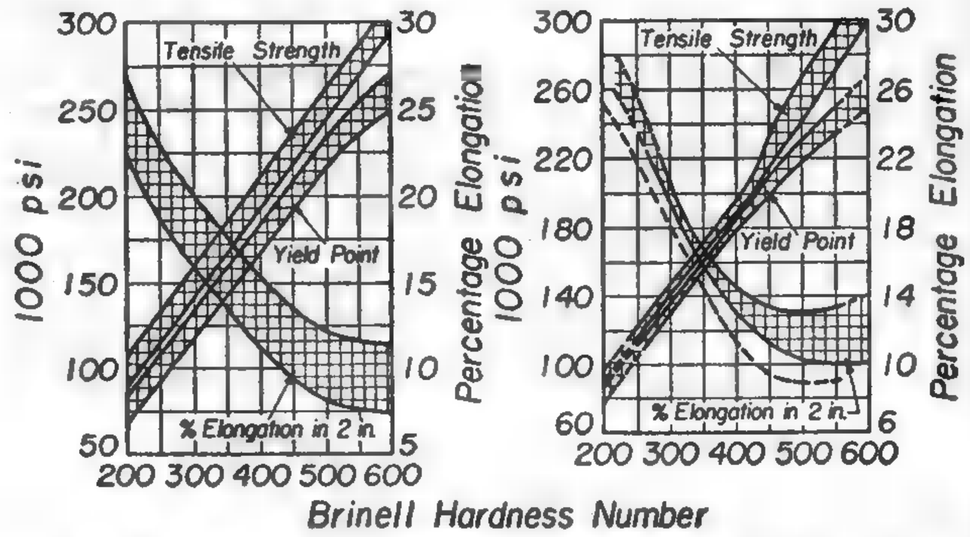

Fig. 8 The range of tensile properties in several quenched and tempered steels as a function of hardness. *Left*, data of Janitzky and Baeyertz. *Right*, more recent Cr-Ni-Mo steels

Temper brittleness is another example of a discontinuous increase in plasticity after tempering steels of these types. This phenomenon is manifested as a loss of toughness observed after slow cooling from tempering temperatures of 1100 F or higher, or after tempering in the temperature range between approximately 850 and 1100 F. Thus, a steel that is susceptible to this type of embrittlement may lose much of its plasticity, as indicated by a notched-bar impact test, during slow cooling from a tempering temperature of 1150 F, although the same steel will be very tough if it is quenched from the same tempering temperature. This expedient of quenching from the tempering temperature is a common practice to insure freedom from loss of toughness. However, in steels that are susceptible to temper brittleness, embrittlement will also be observed after tempering at 850 to 1100 F, particularly if the tempering times are protracted, and under such circumstances quenching from the tempering temperature will never restore the toughness completely. This phenomenon is also not fully understood, although the behavior suggests that something which dissolves at temperatures of 1100 F and above, precipitates in a damaging form at

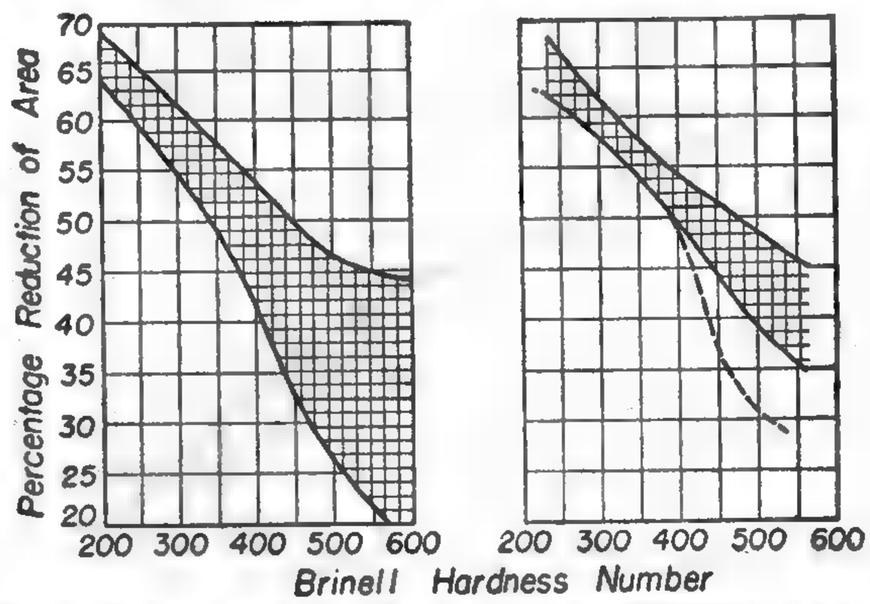

Fig. 9 The range of reduction of area in several quenched and tempered steels as a function of hardness. *Left*, data of Janitzky and Baeyertz. *Right*, more recent Cr-Ni-Mo steels

the lower temperatures, either during slow cooling or during reheating to these temperatures. High manganese, phosphorus and chromium appear to accentuate this behavior; and molybdenum has a definite retarding effect. Here again the carbon and alloying elements may be chosen so that the susceptibility to temper embrittlement is minimized, or the desired strength level may be obtained by tempering either below 850 F or above 1100 F, and then quenching.

Marked Similarities Among the Steels. This article has

emphasized hardenability as the primary function of the alloying elements in alloy steels and it has been found that, if the hardenability and heat treatment are such as to obtain a tempered martensitic microstructure, the mechanical properties of steels are markedly similar regardless of the alloy combination used to obtain the requisite hardenabilities. This similarity among the properties of heat treated steels was noted early by Janitzky and Baeyertz and has since been verified by many investigators. Figures 8 and 9 show these property bands as determined by Janitzky and Baeyertz and also as more recently determined on a wide range of Mn-Ni-Cr-Mo steels. For comparison, the more recent plots include the values for a simple carbon-manganese steel (treated to tempered martensite) which is plotted as a dotted line.

This should not be interpreted as implying that these tempered martensitic steels are alike in every respect, regardless of composition, because the composition is responsible for differences in preservation of strength at elevated temperatures, for differences in abrasion resistance, in resistance to corrosion and even, to a certain extent, in toughness. However, the similarities are sufficiently marked to permit reasonably accurate predictions of the mechanical properties of tempered martensitic steels, regardless of composition, and thereby to justify the emphasis on hardenability as the most important function of the alloying elements.

The most recent and comprehensive study of this nature has been made by Patton. The average values of the mechanical properties of tempered martensite as found in this study are shown in Fig. 10. Although this study represented a compilation of data concerning a very wide variety of alloy steels from a wide range of sources, with inevitable differences in treating and testing, the results still fell within quite narrow bands. Therefore these curves can be used to predict the properties of any of the common alloy

Table I. Specific Effects of Alloying Elements in Steel

Element	Solid Solubility: In Gamma Iron	Solid Solubility: In Alpha Iron	Influence on Ferrite	Influence Exerted Through Carbide: Influence on Austenite (Hardenability)	Influence Exerted Through Carbide: Carbide-Forming Tendency	Influence Exerted Through Carbide: Action During Tempering	Principal Functions
Aluminum .. Al	1.1% (Increased by C)	36%	Hardens considerably by solid solution	Increases hardenability mildly, if dissolved in austenite	Negative (graphitizes)	.....	1 Deoxides efficiently 2 Restricts grain growth (by forming dispersed oxides or nitrides) 3 Alloying element in nitriding steel
Chromium .. Cr	12.8% (20% with 0.5% C)	Unlimited	Hardens slightly; increases corrosion resistance	Increases hardenability moderately	Greater than Mn; less than W	Mildly resists softening	1 Increases resistance to corrosion and oxidation 2 Increases hardenability 3 Adds some strength at high temperatures 4 Resists abrasion and wear (with high carbon)
Cobalt ..... Co	Unlimited	75%	Hardens considerably by solid solution	Decreases hardenability as dissolved	Similar to Fe	Sustains hardness by solid solution	1 Contributes to red hardness by hardening ferrite
Manganese . Mn	Unlimited	3%	Hardens markedly; reduces plasticity somewhat	Increases hardenability moderately	Greater than Fe; less than Cr	Very little, in usual percentages	1 Counteracts brittleness from the sulfur 2 Increases hardenability inexpensively
Molybdenum Mo	3%+ (8% with 0.3% C)	37.5% (Less with lowered temperature)	Provides age-hardening system in high Mo-Fe alloys	Increases hardenability strongly (Mo > Cr)	Strong; greater than Cr	Opposes softening, by secondary hardening	1 Raises grain-coarsening temperature of austenite 2 Deepens hardening 3 Counteracts tendency toward temper brittleness 4 Raises hot and creep strength, red hardness 5 Enhances corrosion resistance in stainless steel 6 Forms abrasion-resisting particles
Nickel ..... Ni	Unlimited	10% (Irrespective of carbon content)	Strengthens and toughens by solid solution	Increases hardenability mildly, but tends to retain austenite with higher carbon	Negative (graphitizes)	Very little in small percentages	1 Strengthens unquenched or annealed steels 2 Toughens pearlitic-ferritic steels (especially at low temperature) 3 Renders high-chromium iron alloys austenitic
Phosphorus. P	0.5%	2.8% (Irrespective of carbon content)	Hardens strongly by solid solution	Increases hardenability	Nil	.....	1 Strengthens low-carbon steel 2 Increases resistance to corrosion 3 Improves machinability in free-cutting steels
Silicon ..... Si	2%+ (9% with 0.35% C)	18.5% (Not much changed by carbon)	Hardens with loss in plasticity (Mn < Si < P)	Increases hardenability moderately	Negative (graphitizes)	Sustains hardness by solid solution	1 Used as general-purpose deoxidizer 2 Alloying element for electrical and magnetic sheet 3 Improves oxidation resistance 4 Increases hardenability of steels carrying nongraphitizing elements 5 Strengthens low-alloy steels
Titanium ... Ti	0.75% (1%+ with 0.20% C)	6%+ (Less with lowered temperature)	Provides age-hardening system in high Ti-Fe alloys	Probably increases hardenability very strongly as dissolved. The carbide effects reduce hardenability	Greatest known (2% Ti renders 0.50% carbon steel unhardenable)	Persistent carbides probably unaffected. Some secondary hardening	1 Fixes carbon in inert particles (a) Reduces martensitic hardness and hardenability in medium-chromium steels (b) Prevents formation of austenite in high-chromium steels (c) Prevents localized depletion of chromium in stainless steel during long heating
Tungsten ... W	6% (11% with 0.25% C)	33% (Less with lowered temperature)	Provides age-hardening system in high W-Fe alloys	Increases hardenability strongly in small amounts	Strong	Opposes softening by secondary hardening	1 Forms hard, abrasion-resistant particles in tool steels 2 Promotes hardness and strength at elevated temperature
Vanadium... V	1% (4% with 0.20% C)	Unlimited	Hardens moderately by solid solution	Increases hardenability very strongly, as dissolved	Very strong (V < Ti or Cb)	Maximum for secondary hardening	1 Elevates coarsening temperature of austenite (promotes fine grain) 2 Increases hardenability (when dissolved) 3 Resists tempering and causes marked secondary hardening

steels within plus or minus 10%, if the hardenability and heat treatment are such as to obtain a microstructure consisting essentially of tempered martensite.

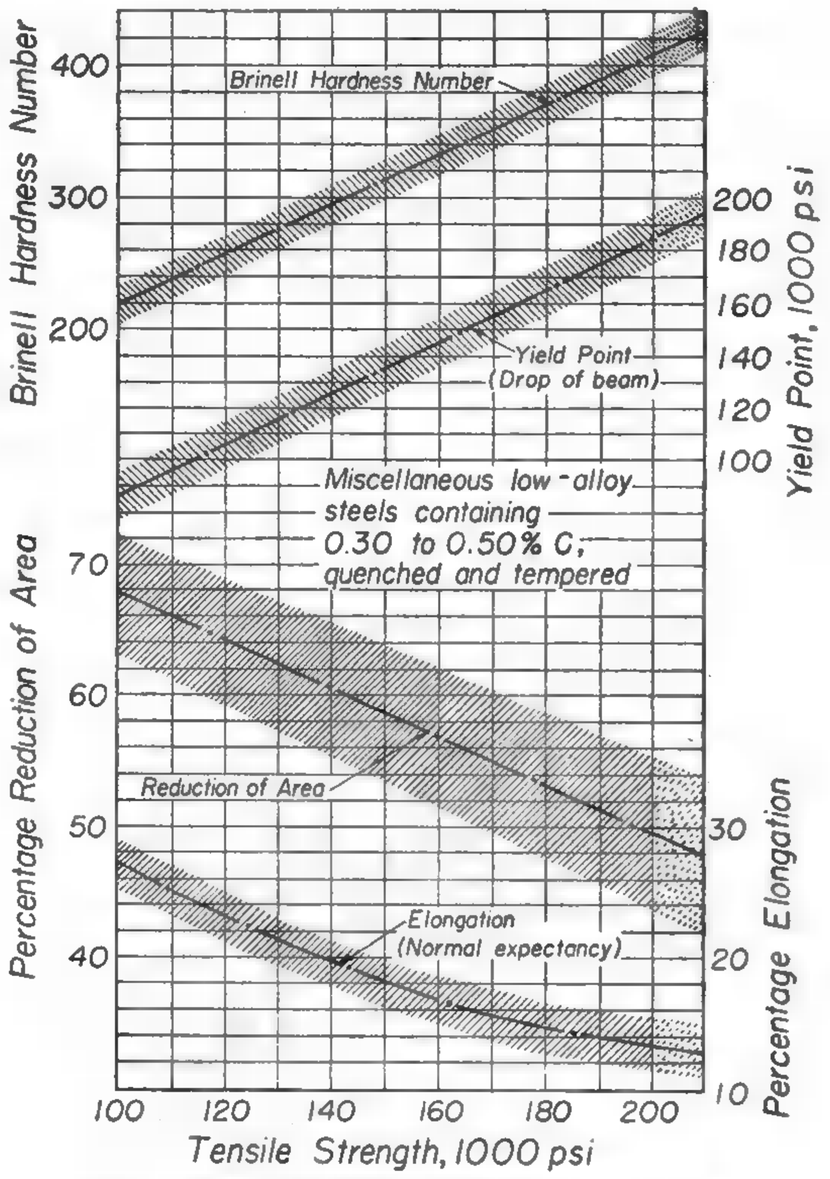

Fig. 10 Most probable mechanical properties of tempered martensite (Patton)

Selection of Steels. Throughout this article emphasis has been placed on the fact that hardenability is the primary consideration in the selection of a steel to obtain certain desired properties or for a specific application. However, in every instance there will be a wide choice among the carbon and alloy combinations that may be used to obtain this hardenability; consequently the final selection will be based on the secondary functions of the alloying elements, or perhaps on economy. The following outline lists the steps to follow in selecting a suitable steel.

1 The question of the need for a heat treated steel should be answered first. If the allowable elastic deflection is exceedingly small, possibly a soft steel in approximately designed section is indicated, since the maximum stress would necessarily be very low.

2 The carbon content selected should be one that will give the desired strength level after tempering at a temperature that will avoid the range from 500 to 600 F and will minimize possible temper embrittlement. If toughness is of paramount importance, or if the section is one that favors quench cracking, the carbon content should be as low as is consistent with the desired strength level. If the application involves wear resistance, as in sliding parts, or the repeated application of heavy loads, as in springs, higher carbon contents are indicated.

3 The total effective alloy content must, first of all, insure the needed hardenability compatible with the section and the quenching practice to be used.

4 When adequate hardenability is assured, most of these steels have ample toughness for parts of good design. Under these conditions, the choice of alloying elements can be based primarily on economy. For the occasional applications in which extraordinary toughness is considered essential, such as ordnance material or critical aircraft parts, full use should be made of the secondary functions of the alloying elements. If these parts are to be of high hardness, the addition of nickel will be useful; while at the lower levels of hardness the higher tempering temperatures, made possible by the addition of the carbide-forming elements, are distinctly advantageous. For applications involving toughness at low temperatures the use of nickel is indicated, together with low carbon contents and an adequate amount of alloying elements to insure tempered martensite. These characteristics can be evaluated approximately and compared by notched-bar tests.

Table I summarizes the specific effects of the alloying elements and may also be helpful in arriving at a choice of an appropriate composition for particular applications.

5 The heating for hardening should be such as to insure effective solution of the alloying elements without permitting excessive grain growth, and the quenching practice should be such as to insure full hardening in the composition chosen, with due regard to the danger of quench cracking and distortion. The tempering temperature can be derived approximately from the charts of Fig. 3, 4, 5, 6 and 7, and should be chosen so as to avoid the range from 500 to 600 F and also the danger of temper embrittlement.

Chromium in Steel

By Walter Crafts*

CHROMIUM is alloyed with iron to form useful steels containing from less than 1% to more than 30% Cr. In low-carbon ranges the steels are ductile, but with higher carbon contents, the steels may be made very hard. Consequently chromium is one of the most versatile and widely used of the alloying elements in both plain chromium and complex steels. Chromium confers outstanding resistance to corrosion, oxidation and wear, and is the essential component of stainless iron and steel. More extended reviews of the characteristics of chromium steels are given in monographs on iron-chromium alloys.[1,2]

Effect of Chromium in Ferrite and Low-Carbon Iron Alloys. In high-purity iron alloys, a chromium content less than 12% permits the formation of austenite and forms the compound FeCr (sigma phase) between 30 and 65% Cr, but through the rest of the iron-chromium system there is a continuous body-centered cubic structure with a gradually changing parameter. As shown by Adcock[3] in Fig. 1, the hardness of the alloy attains a maximum at about 70% Cr. However, iron containing about 3% Cr or less is somewhat softer than unalloyed iron.[4,5] This initial tendency to soften is also evident in some low-chromium, low-carbon steels of the structural type, in which chromium exerts a toughening rather than a hardening influence, at both atmospheric and subzero temperatures.[6, 7, 8]

Chromium increases the hardness or tensile strength of low-carbon or relatively pure iron alloys to a lesser degree than other alloying elements.[9] This fact is reflected in the properties of 0.10% C steels shown by Thum in Fig. 2.[10] The relative softness and resulting malleability of steels that contain as much as 30% Cr has contributed greatly to the successful fabrication and use of stainless irons and steels. The recrystallization or softening temperature of cold worked ferrite is raised to a significant degree by chromium.[11]

The ferritic low-carbon steels containing more than 15% Cr do not form austenite on heating, and tend to be relatively coarse-grained unless submitted to cold working. Grain growth is restrained and the toughness is improved by the addition of nitrogen. Such steels are serviceable without excessive embrittlement at relatively high temperatures. After heating in the range between 750 and 1100 F, low-carbon steels that contain 18 to 30% Cr develop

* Research Metallurgist, Union Carbide and Carbon Research Laboratories, Inc., Niagara Falls, N.Y.

Prepared for the Subcommittee on Alloying Elements in Steel

abnormal embrittlement. Steels with more than 30% Cr have useful ductility in the proper condition of heat treatment, but the utility of such alloys may be limited by the formation of sigma phase after heating under certain conditions.

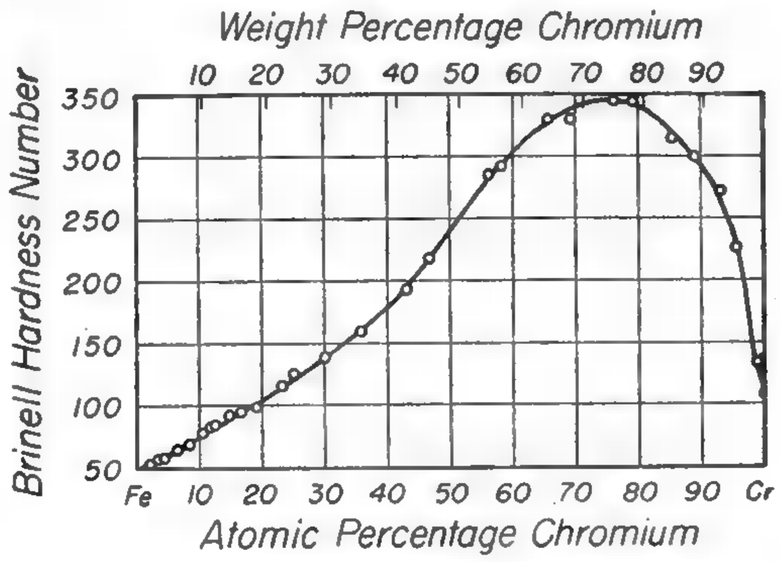

Fig. 1 Brinell hardness of iron-chromium alloys (F. Adcock[3])

Effect of Chromium on Medium-Carbon or High-Carbon Steels in the Pearlitic Condition. Chromium increases the time required for isothermal transformation of austenite, both in the pearlitic range higher than 1000 F, and in the bainitic range at lower temperature. The transformation of austenite to pearlite is retarded to a greater extent in lower-carbon steels. In the medium-carbon and low-carbon steels, the increase of chromium to more than 2 or 3% suppresses the formation of pearlite to such an extent that bainite is formed during continuous cooling at rates slow enough to avoid martensite formation. In normalized medium-carbon steels containing as much as 2 or 3% Cr, the transformation is depressed and the pearlitic structure becomes finer, with corresponding increase in tensile strength, as the content of chromium is increased. In steels that contain higher percentages of chromium, the pearlite produced by isothermal transformation is a confused sublamellar structure which, according to the results of Lyman and Troiano,[12] is formed by initial transformation to cementite and subsequent conversion to more stable Cr_7C_3.

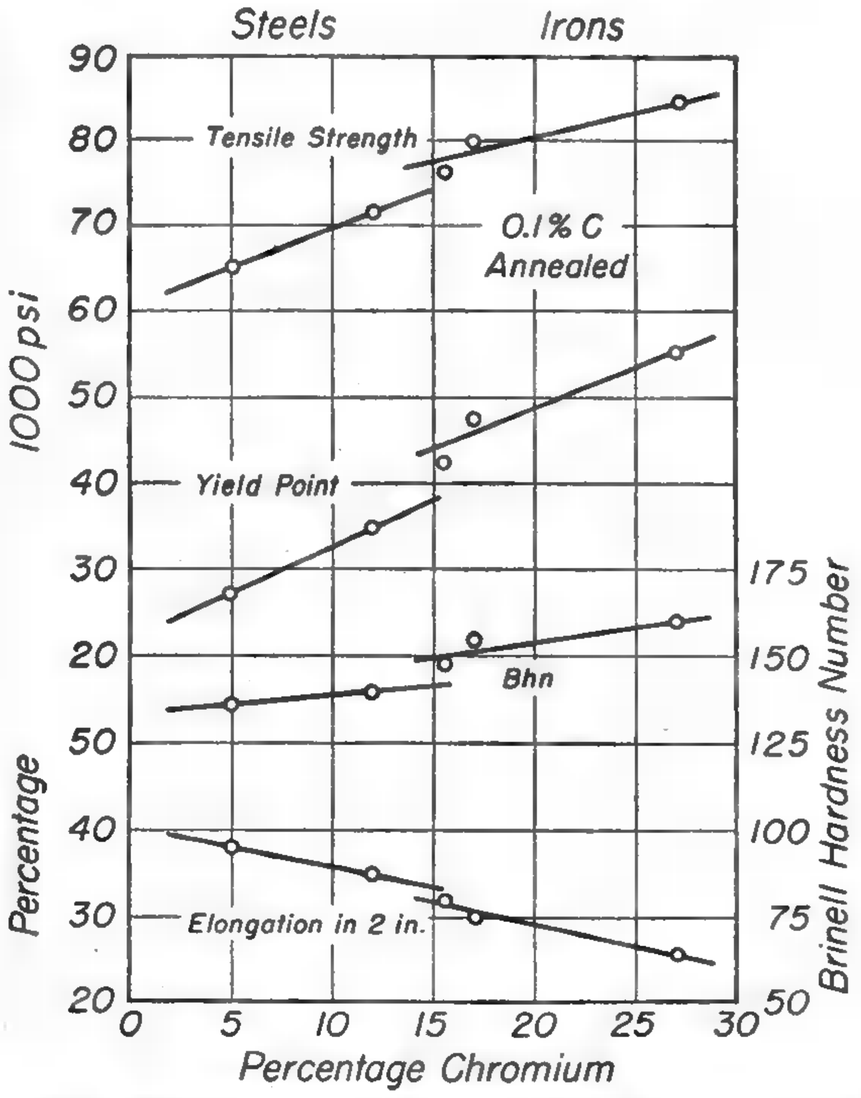

Fig. 2 Mechanical properties of annealed chromium steels containing 0.10% C (Thum[10])

Effect of Chromium on Behavior During Heating for Hardening or for Normalizing. Chromium restricts the range of carbon content and temperature within which austenite may be formed free from ferrite in low-carbon steel, or free from carbide in high-carbon steel. As indicated in Fig. 3,[13] the single-phase austenitic field extends over a range from just more than 12% Cr when the carbon content is zero, to 20% Cr with 0.57% C. The "eutectoid" composition is reduced from about 0.8% C to hardly 0.3% C at 15% Cr. In the range of carbon content of structural

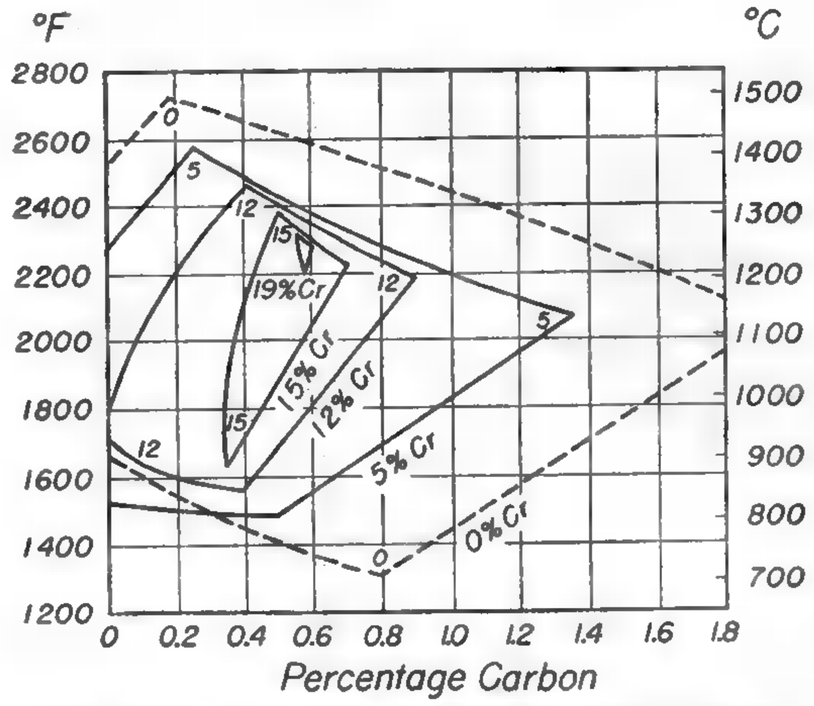

Fig. 3 Range of austenite in chromium steels (Tofaute, Kuttner and Buttinghaus; see Bain.[13])

and heat treating steels that contain less than 12% Cr, it is apparent that the steels may be completely austenitized at the temperatures commonly employed in heat treatment. In steels that contain more than 12% Cr and a low or medium percentage of carbon, some ferrite may be present at all temperatures. The high-carbon, high-chromium steels require high heating temperatures to dissolve all the carbides; these steels can be made completely austenitic at high temperatures only in a limited range of composition. (*See* PHASE DIAGRAM SECTION.)

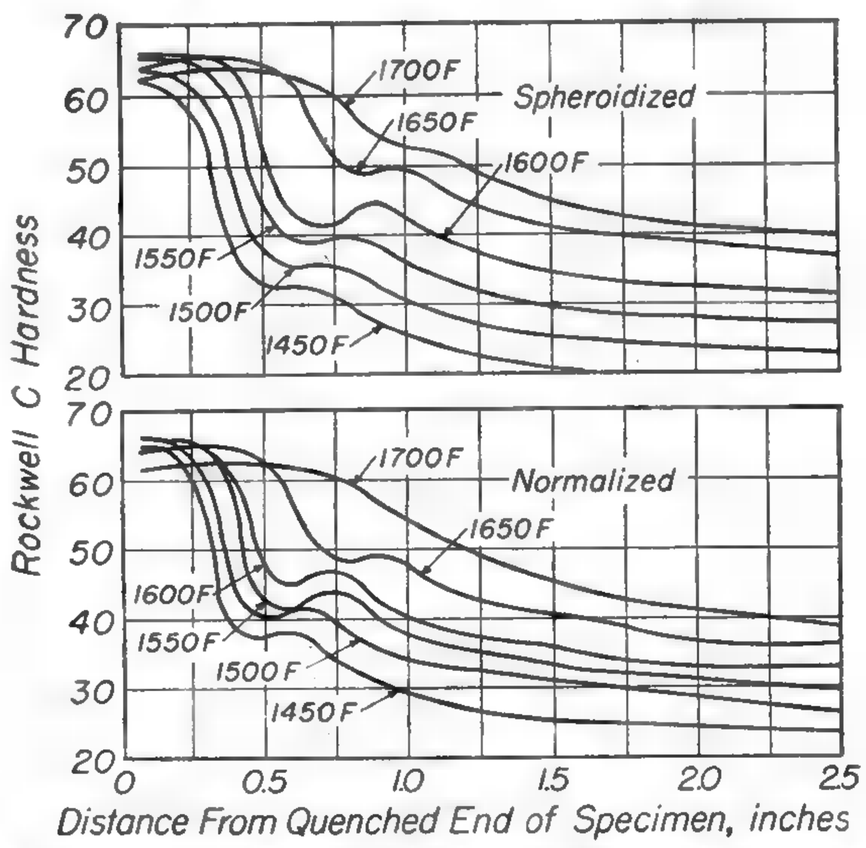

Fig. 4 Effect of quenching temperature and initial condition on hardenability of SAE 52100 steel (Rowland, Welchner and Marshall[14])

In certain steels the presence of carbide or ferrite in the austenite before cooling, is beneficial to the control of grain size, retained austenite, hardenability and related properties, such as toughness and weldability. In SAE 52100 bearing steel (1.0% C, 1.5% Cr), which is usually quenched with carbides in the austenite, it was demonstrated by Rowland, Welchner, and Marshall,[14] as shown

in Fig. 4, that at the usual quenching temperature of 1550 F, only a fraction of the hardenability was realized, but that maximum hardness, fine grain and relatively little retained austenite were produced. Likewise, the carburized case of chromium carburizing steel contains carbides but little retained austenite. One of the specific effects of chromium is to promote "normality" and thereby avoid soft spots in carburized steel, by preventing divorce of ferrite and carbide.

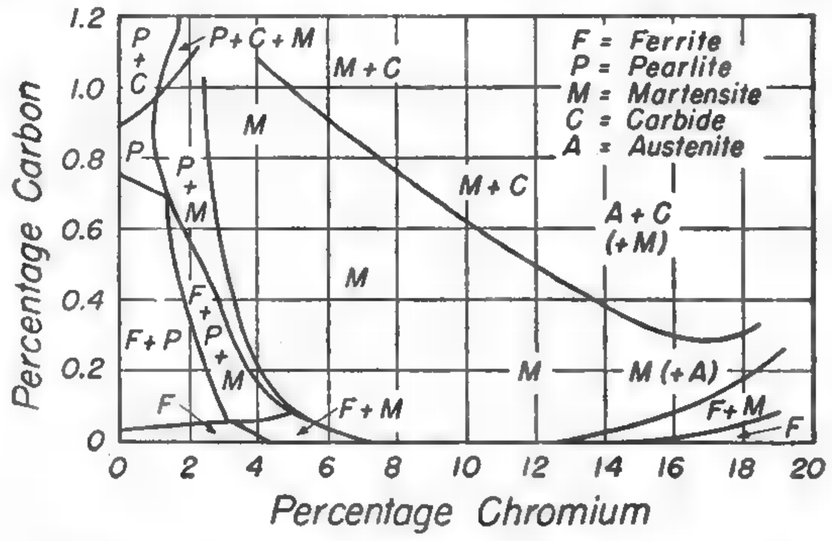

Fig. 5 Constitution of chromium steels normalized in ½-in. cubes (Bain and Grossmann)

Where high chromium contents restrict the solubility for carbides, as in type 440 (12 to 18% Cr cutlery and tool steels), austenitizing temperatures between 1800 and 2100 F are employed in order to dissolve a maximum of carbides in the austenite. Incomplete solution of ferrite is also utilized to avoid excessive hardening during the welding of steels, such as 4 to 6% Cr steel tubing for oil stills, and low-carbon 12% Cr steel.

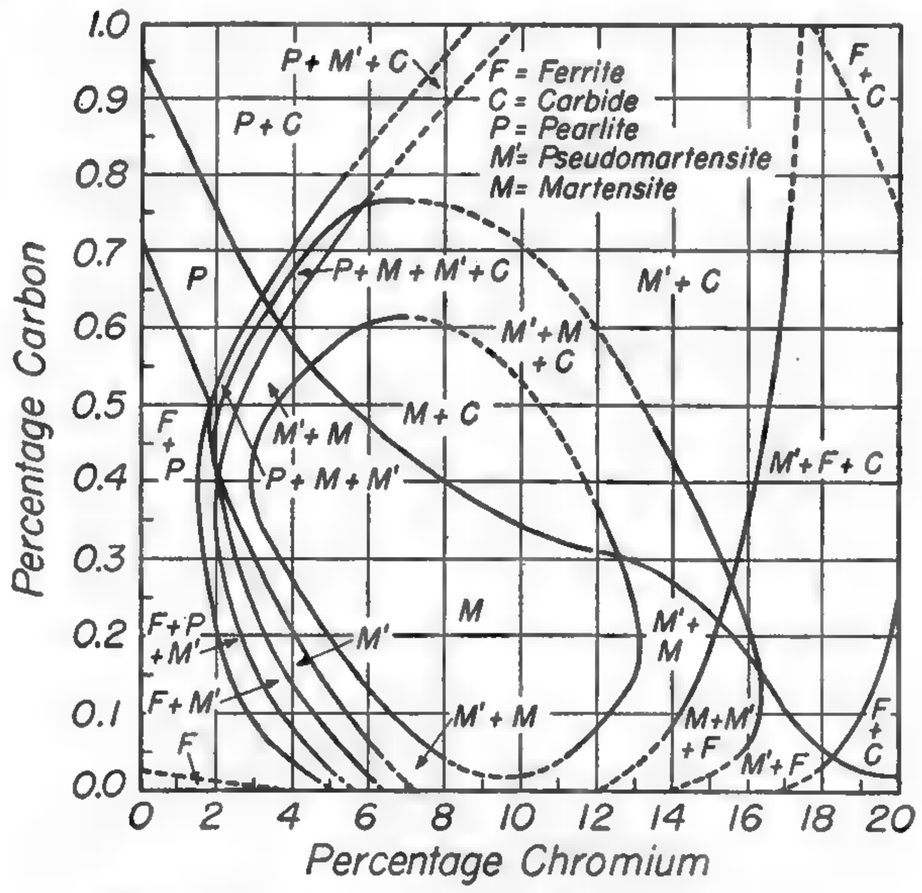

Fig. 6 Constitution of chromium steels normalized in bars 1 in. in diam

Effect of Chromium on Behavior During Cooling from the Austenitic State. During cooling from the austenitizing temperature, the transformation of austenite is retarded by chromium, so that the harder constituents are formed. The structures resulting from normalizing chromium steels in ½-in. cubes are indicated in Fig. 5 and in bars 1 in. in diam, in Fig. 6. It will be noted that there is a field of martensite at medium carbon contents with approximately 8% Cr. This represents the most readily hardenable combination of carbon and chromium. With lower chromium contents the steels transform more readily to ferrite, pearlite and bainite. It will be noted that the martensitic field is larger in the smaller specimens because of the faster cooling rate, and a similar change is produced by higher contents of manganese and other elements that increase hardenability. The steels that contain 2% Cr or less are therefore considered pearlitic; 2 to 5% Cr steels are bainitic; 5 to 18% Cr steels are air-hardening with medium and high carbon contents; and low-carbon steels that contain more than 15% Cr are ferritic.

When, by virtue of high chromium contents or rapid cooling, certain chromium steels do not transform to ferrite, pearlite, or bainite at elevated temperatures, these steels have a relatively slight tendency to retain austenite because of incomplete formation of martensite. As shown by Grange and Stewart,[16] the M_s temperature is lowered only to a moderate degree with higher chromium contents.

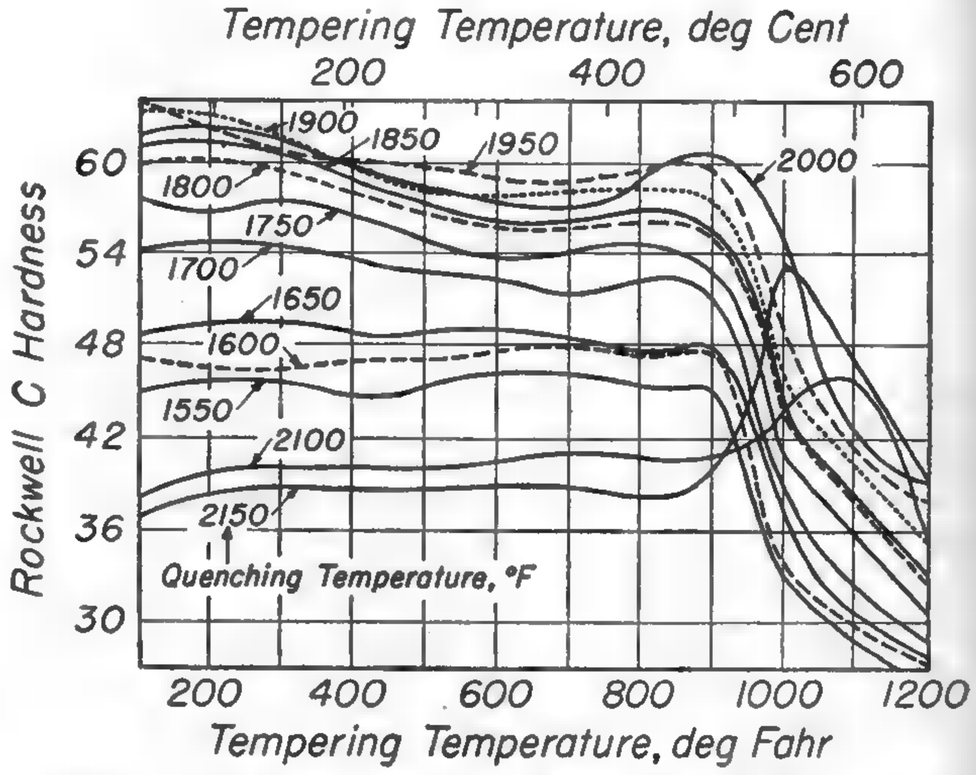

Fig. 7 Effect of tempering on the hardness of 1.6% C, 17% Cr steel quenched from various temperatures (Gill[17])

Effect of Chromium on the Tempering of Quenched Steels. Chromium steels apparently resist softening during tempering, as suggested by Bain,[13] by diffusion and reconcentration of chromium in carbides formed from martensite. Retarded softening becomes more noticeable as the tempering temperature is raised, until a maximum effect is reached at 800 F and higher temperatures. In hardened steels containing 1% Cr, the resistance to softening amounts to about 5 Rockwell C units, and rises to 12 Rockwell C units in steels that contain 3.5% Cr, as compared with comparable chromium-free steels. In high-carbon, high-chromium steels, as shown in Fig. 7 by Gill,[17] strong secondary hardening results from tempering, after austenitizing at a temperature sufficiently high to absorb an effective amount of carbide. It is probable that this secondary hardening is caused both by the formation of martensite (from austenite retained after quenching from the hardening temperature) during cooling from the tempering temperature, and by the tempering of martensite that was formed during quenching from the hardening temperature.

In spite of the strong secondary hardening character of chromium steels, they are readily softened for machining by tempering at high temperatures. The transformation temperature during heating (Ac_1) rises abruptly from about 1350 to 1450 F in steels that contain 3% Cr or more, so that high softening temperatures may be employed. When the chromium content exceeds about 2%, the more stable carbides are the trigonal Cr_7C_3 from 2% to about 9% Cr and the cubic Cr_4C ($Cr_{23}C_6$) at higher chromium contents. Bainite and tempered martensite formed in steels containing as much as about 10% Cr, contain iron carbide, which transforms to a chromium carbide when heated to more than about 900 F, in the composition range shown in Fig. 8.[18] The stability of the carbides in chromium steels is helpful in obtaining a spheroidized structure and avoiding graphitization. In tempering and in service at elevated temperatures, graphitization is inhibited by approximately 1% Cr, or even less. This effect of chromium in avoiding graphitization is utilized also to increase the carbide stability and wear resistance of cast iron.

Tempering brittleness common to martensitic steels tempered in the range from 400 to 700 F is not influenced appreciably by chromium in the small amounts used in steels of the SAE type.[1, 2, 10] In hardenable steels that contain more chromium, the embrittling range is raised to between 750 and 1000 F; for example, in the 12% Cr steels used for turbine blades and cutlery. Chromium steels that have been tempered in the embrittling range have decreased resistance to corrosion, as well as low impact strength. Consequently the steels are used either in the hardened condition (after stress relieving below 700 F) or after tempering at temperatures of 1100 to 1300 F—higher than the temperatures that will cause brittleness. Chromium is not effective in reducing the susceptibility to temper brittleness caused by long holding or slow cooling from tempering temperatures in the range from 1000 to 1200 F.

Special Effects of Chromium in Steel. Chromium is used for improving the mechanical properties in steel and also for increasing the resistance to oxidation, corrosion and wear. Chromium is also used in steels for nitriding and for permanent magnets.

Resistance to Corrosion. Additions of chromium develop the general order of resistance to atmospheric corrosion illustrated in Fig. 9.[19] Although full protection requires 12

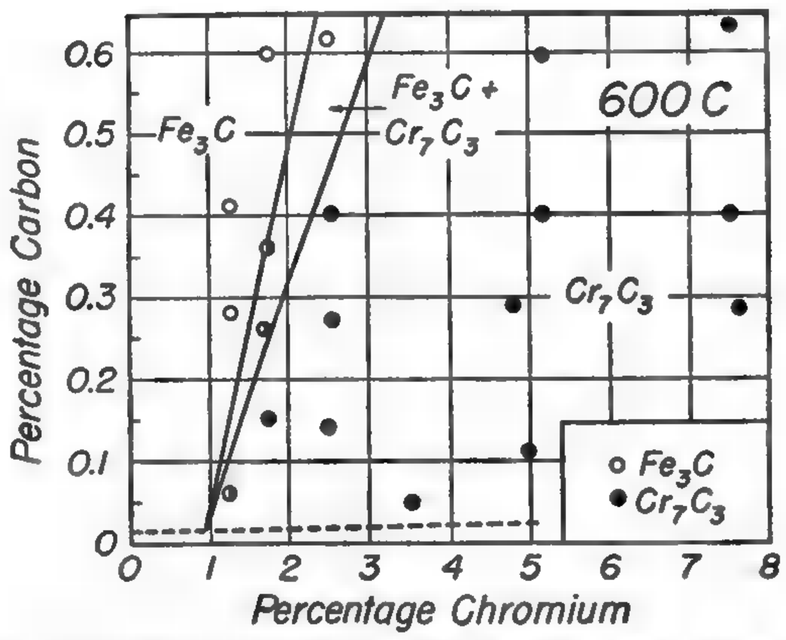

Fig. 8 Carbides in chromium steels quenched and tempered at 600 C (1112 F) (Crafts and Offenhauer[18])

to 18% Cr, 1% Cr is used in conjunction with copper, silicon and phosphorus to improve resistance to corrosion in structural steel and to exercise the specific toughening effect of chromium in phosphorus steel.[7, 20] In steel that contains 3% Cr, the rust becomes tougher and more adherent, so that benefit is derived from the improved resistance to corrosion as well as from better adherence of paint.[8]

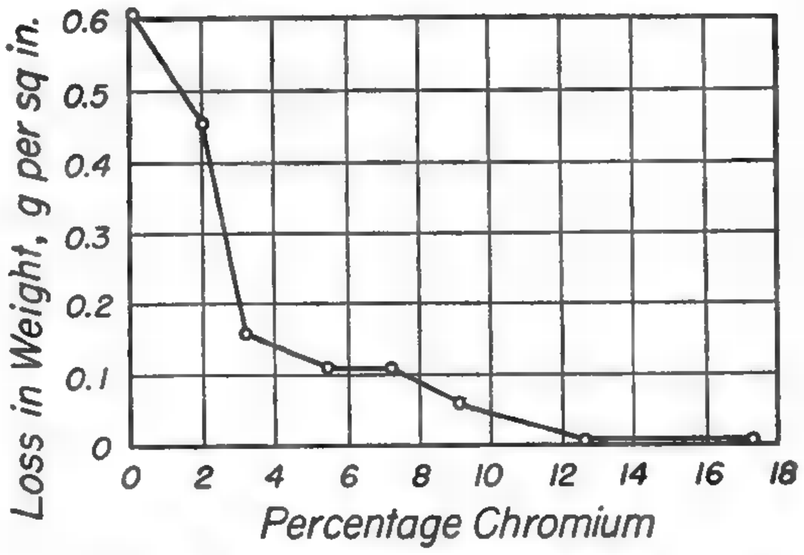

Fig. 9 Corrosion of chromium steels in an industrial atmosphere (Binder and Brown[19])

This steel also has remarkable resistance to sea water.[21] Low-carbon 12 and 18% Cr steels are used in the cold rolled condition for certain types of cutlery and for automotive trim. Because of the blue-white color, such steel matches the color of chromium plate well. The low-carbon plain chromium steels with as much as 30% Cr are resistant to oxidizing acids, such as boiling nitric and dilute aerated sulfuric acid.

The hardenable 12 to 18% Cr steels may contain as much as 2% C, depending on the required hardness. After heat treatment and with cleanly prepared surfaces, these steels are resistant to atmospheric attack and oxidizing and fruit acids. They are frequently modified by nickel, molybdenum, vanadium and the like, to intensify special properties, and are useful for the best grades of cutlery, turbine blading and engineering applications. All the higher-chromium steels, and especially the 12% Cr steel used for steam turbine blading, have a high damping capacity that increases the resistance to vibrational stresses.

The most commonly used stainless steels are of the austenitic chromium-nickel type, which combines ease of forming and welding with high resistance to corrosion. The steels are used for resistance to acid in chemical and food-handling plants, as well as for furnace parts, extremely low-temperature service, architectural trim, and for structural members and surfaces of lightweight equipment such as airplanes and railroad cars. This family of steels contains from 12 to 25% Cr and from 7 to 35% Ni, although the combination most generally used is 18% Cr—8% Ni. These steels are annealed by rapid cooling from 1800 to 2100 F and may contain titanium or columbium to inhibit precipitation of intergranular carbide, molybdenum to increase resistance to less oxidizing acids, and several other elements for special properties. After cold rolling, this type

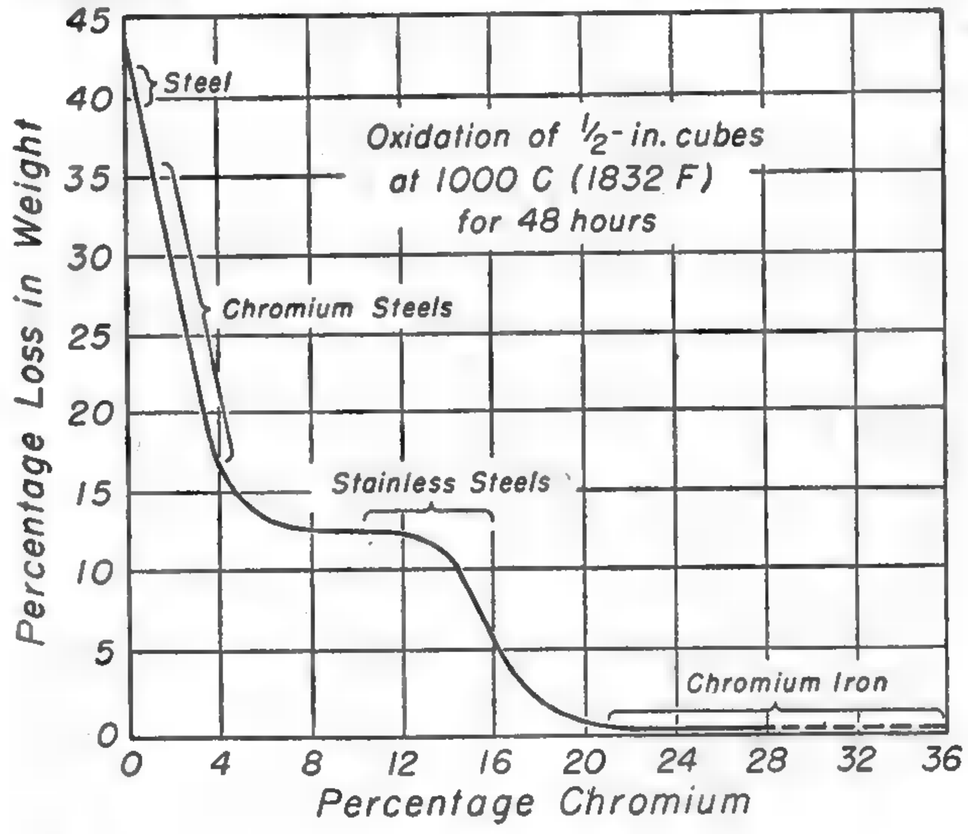

Fig. 10 Oxidation of chromium steels at 1000 C (MacQuigg)

of steel has high load-carrying ability when in the form of thin sheet and strip.

Resistance to Oxidation. Resistance to oxidation at elevated temperatures is increased by chromium in the manner illustrated in Fig. 10.[22] The 4 to 6% Cr level is used for resistance to sour oil in still tubes. Valves for internal-combustion engines are made of 8% Cr silicon steel, 12% Cr steel, and complex steels of higher chromium content. Steels with 12, 18, and as much as 28% Cr are used for resistance to oxidation, depending on the severity of the conditions. The higher chromium steels are sensitive to grain growth and may be given a persistent fine grain size by the presence of about 0.20% N.[23] The austenitic steels, such as 25% Cr—20% Ni steel and modified types, are used for furnace and gas turbine components, because of high creep strength. Manganese-chromium steels have specific resistance to sulfur-bearing atmospheres. A 37% Cr—7½% Al alloy is resistant to oxidation at temperatures approaching 2400 F, and is useful for resistance elements. Normally chromium has little effect on creep strength; the maximum improvement is noted at about 12% Cr.

Resistance to Wear. Wear resistance is an outstanding property of chromium steels because they are capable of developing high hardness, and also resist the surface oxida-

tion that accompanies and aggravates wear. For example, Ellis[15] found that 3, 8, and 15% Cr steel grinding balls wore less in proportion to their chromium contents if air or an oxidizing atmosphere was present; but they were no better than ordinary balls in nonoxidizing atmospheres. High-carbon steel containing 1.5% Cr, high-carbon tool steels containing 12 to 18% Cr, and cast iron with as much as 30% Cr, are usually applied where resistance to wear and abrasion are primary requirements. The chromium hot work steels and piercing-point steels probably owe their special value largely to the type of scale at the surface.

Chromium is a component of nitriding steels to assist in developing a suitable initial microstructure and in forming a hard nitrided case. Although nitriding steels also usually contain aluminum or vanadium, plain chromium steels from 1 to 18% are successfully nitrided. Chromium-vanadium steel is also used for reaction vessels in the synthesis of ammonia and alcohol.

Copper in Steel

By C. H. Lorig*

THE copper-bearing steel containing about 0.25% Cu is well known and is widely used for structural purposes and sheet because of its resistance to atmospheric corrosion. Copper in quantities as large as about 4% is also used to a limited extent in steels to give increased fluidity to the melt, and to improve tensile and yield strengths with only minor loss in ductility. Copper is being used in one type of stainless steel in amounts as great as 10% to improve resistance against certain corrosive mediums and to increase machinability.

In the solid state, the iron-copper alloys may consist either of homogeneous solid solutions of the one metal in the other, or of heterogeneous mixtures of these solid solutions. The maximum solubility of copper in alpha iron is 1.4%, but it decreases with decreasing temperature, becoming constant below 1200 F at 0.35%. Gamma iron dissolves 4.5% Cu at 1530 F, 8.5% at 2000 F, and possibly about 10% at 2690 F.

Table I. Hardness of Annealed Iron-Copper Alloys

Copper, per cent	0.0	0.5	1.0	2.4	2.7	4.0
Rockwell B hardness	27	58	72	95	94	95

In steel, copper is found only in solid solution (both as iron-rich and as copper-rich solid solution phases). It does not appear in the carbide phase or as intermetallic compounds with iron. Because of the limited solubility of copper in alpha iron, the alloys and most steels containing more than 0.6% Cu can be hardened by precipitation. Lattice changes during precipitation hardening have been correlated with hardness values, and it has been shown that the principal increase in hardness takes place prior to the precipitation of the copper-rich phase.[1]

Because of selective oxidation of the iron, copper tends to concentrate on the surface beneath the scale when copper-bearing steels are heated under oxidizing conditions. This concentration of copper at the surface can lead to surface checking during hot working when the hot working temperature for the steels is near or above the melting point of copper. Surface checking has been observed in steel containing as little as 0.25% Cu. Because nickel raises the hot working temperature at which checking occurs, copper-bearing steels are frequently alloyed intentionally with nickel in proportions of at least one-third the copper content to minimize surface checking.

Table III. Yield Ratios of Copper Steels (0.02% C)

Copper, per cent	Yield Ratio After Normalizing	Yield Ratio After Normalizing and Precipitation Hardening
0	0.78	0.78

1.0	0.80	0.88
1.5	0.89	0.92
2.0	0.91	0.92
2.5	0.91	0.92
3.0	0.91	0.91

The Effect of Copper in Ferrite and Low-Carbon Iron Alloys. Rockwell hardness values of annealed, vacuum-melted iron-copper alloys, made from electrolytic iron and electrolytic copper, are given in Table I.[2]

The tensile properties of annealed iron-copper alloys are given in Table II.[3]

When as much as 2% Cu is present in low-carbon steels, the copper has little influence on ductility, but has a most noticeable influence on yield strength, particularly for normalized steels and for steels hardened by precipitation. The yield ratios of normalized and of normalized and precipitation-hardened copper steel containing 0.02% C, are given in Table III.

tion of copper in iron, which will respond to the precipitation-hardening treatment. Air-cooling suffices to keep the copper in solution in sections as large as several inches in diameter. To obtain the full benefit from precipitation hardening, the air-cooled material needs to be heated only to the precipitation temperature. The maximum hardening effect is produced by reheating, or by interrupting the cooling during air quenching, at 840 to 930 F. On the average, precipitation hardening of low-carbon steels containing from about 1.0 to 1.5% Cu produces an increase of 20,000 psi in tensile strength and

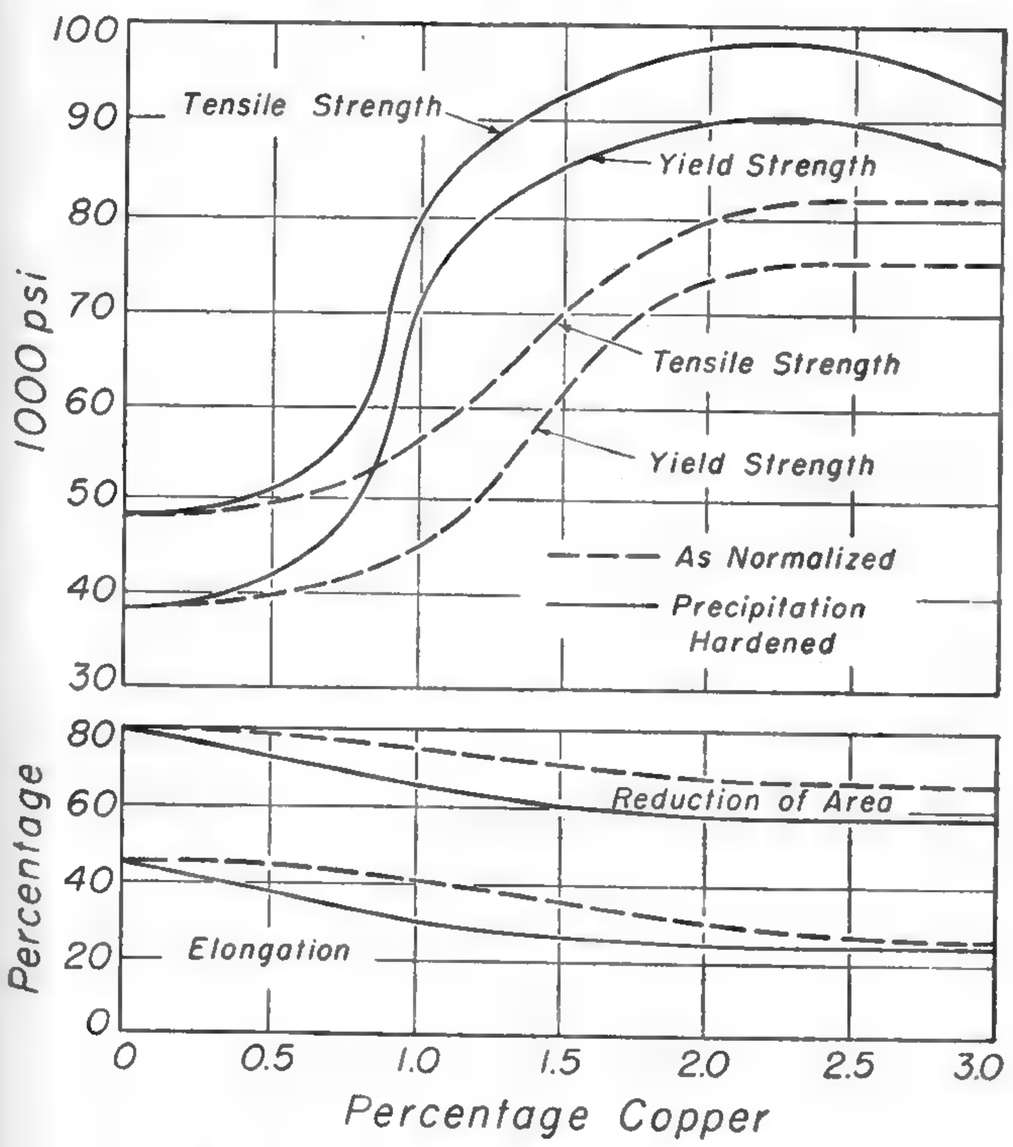

Fig. 1 Effect of copper on tensile properties of normalized and of normalized and precipitation hardened 0.02% C steels

25,000 psi in yield strength over the respective properties of the same steel in the normalized condition. The increase in strength is accompanied by some loss in ductility as determined by elongation, reduction of area, and notched-bar impact values, but the steel is not rendered notably brittle.

Typical curves showing the effect of copper on tensile properties of normalized and of normalized and precipitation-hardened 0.02% C wrought steel are given in Fig.

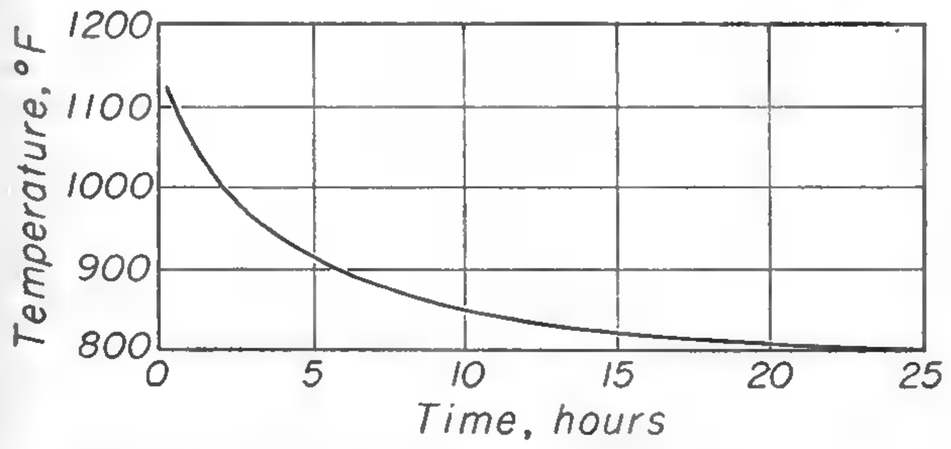

Fig. 2 Time-temperature relation for maximum increase in hardness resulting from precipitation hardening

1. Figures 2 to 4 show the time-temperature relations for maximum increase in hardness during precipitation hardening; Fig. 3[5] shows the influence of carbon content on the maximum increase in strength after precipitation hardening; Fig. 4[5] shows the influence of cooling rate prior to precipitation hardening, on the increase in strength resulting from precipitation hardening.

Other elements added in small amounts to copper steels have little influence on the increase in hardness resulting from precipitation hardening. According to Halley,[6] the precipitation-hardening rate, however, was more than doubled by reducing the silicon content from 0.188 to

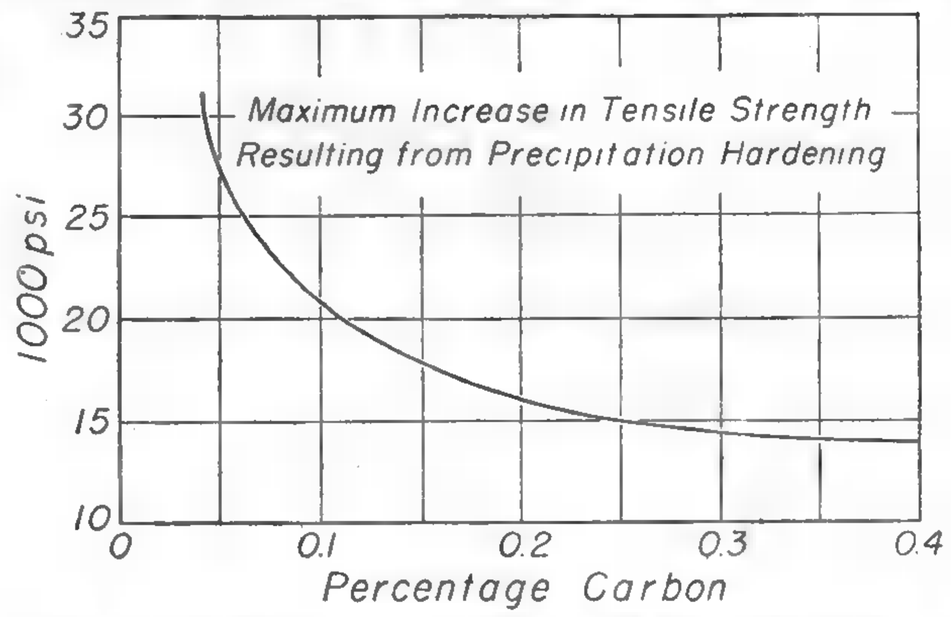

Fig. 3 Influence of carbon content on the maximum increase in tensile strength resulting from precipitation hardening

0.020% in a steel containing approximately 0.10% C, 0.12% P, 1.00% Cu and 0.50% Ni.

Small additions of copper in steel are effective in minimizing atmospheric corrosion. Figure 5 shows the effect

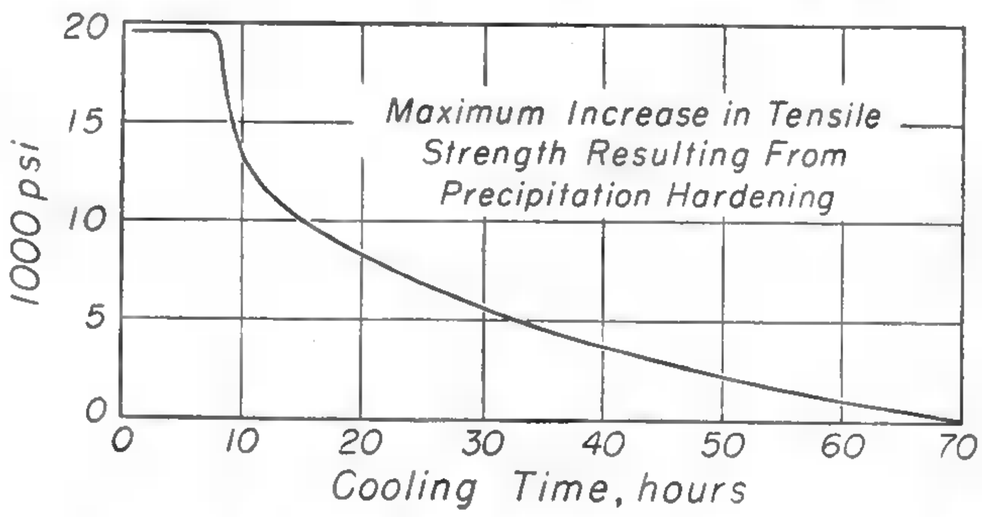

Fig. 4 Influence of cooling time, prior to precipitation hardening, on the increase in strength resulting from precipitation hardening

of copper on corrosion of low-carbon steels exposed to the atmosphere for three years.[7]

In carburizing tests, Smith* observed that copper in amounts less than 3% had very little effect on the depth of carburization of iron, but high-copper specimens, lightly oxidized before carburizing, showed somewhat irregular cases attributed to the protective action of a film of copper formed beneath the thin oxide scale.

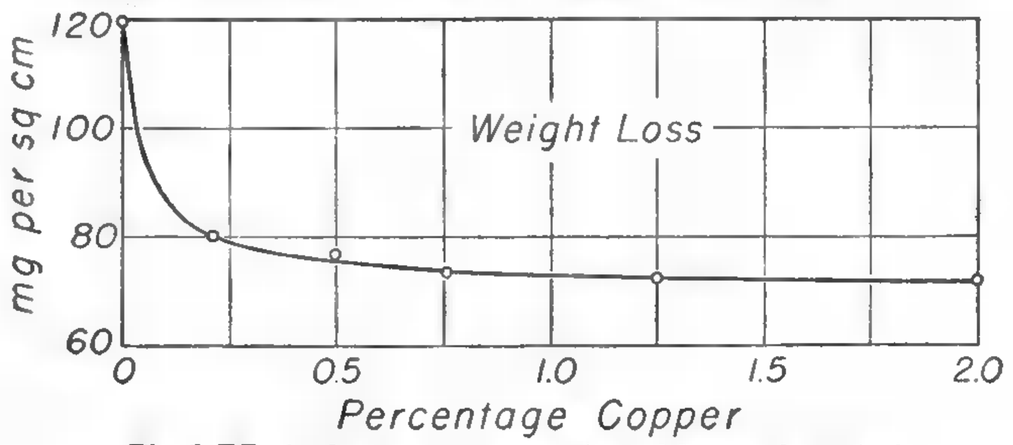

Fig. 5 Effect of copper on corrosion of low-carbon steels exposed to the atmosphere for three years

The Effect of Copper on Medium-Carbon or High-Carbon Steels in the Pearlite Condition. Copper has a very mild effect in retarding the rates of nucleation and growth of pearlite, and in decreasing the interlamellar

* C. S. Smith, American Brass Company, unpublished report.

spacing of pearlite. As the carbon content of copper-containing steel increases, the response to precipitation hardening decreases.

The Effect of Copper on Behavior During Heating for Hardening or for Normalizing. Because copper and cementite apparently do not alloy, the copper content evidently does not affect the rate of solution of cementite in austenite, while a steel is being heated for normalizing or for hardening. The eutectoid carbon content apparently is not changed by copper.

The Effect of Copper on Behavior During Cooling from the Austenitic State. The structures obtained while cooling copper-bearing steels from the austenitic state are substantially the same as those obtained with copper-free steels of the same carbon content. In alloys containing moderate amounts of copper, however, the copper that exceeds the solubility limits separates out as a copper-rich constituent, epsilon, in the form of very small particles not usually distinguishable under the microscope. If more than 8% Cu is present, the excess copper separates out as a distinct phase in the grain boundaries.

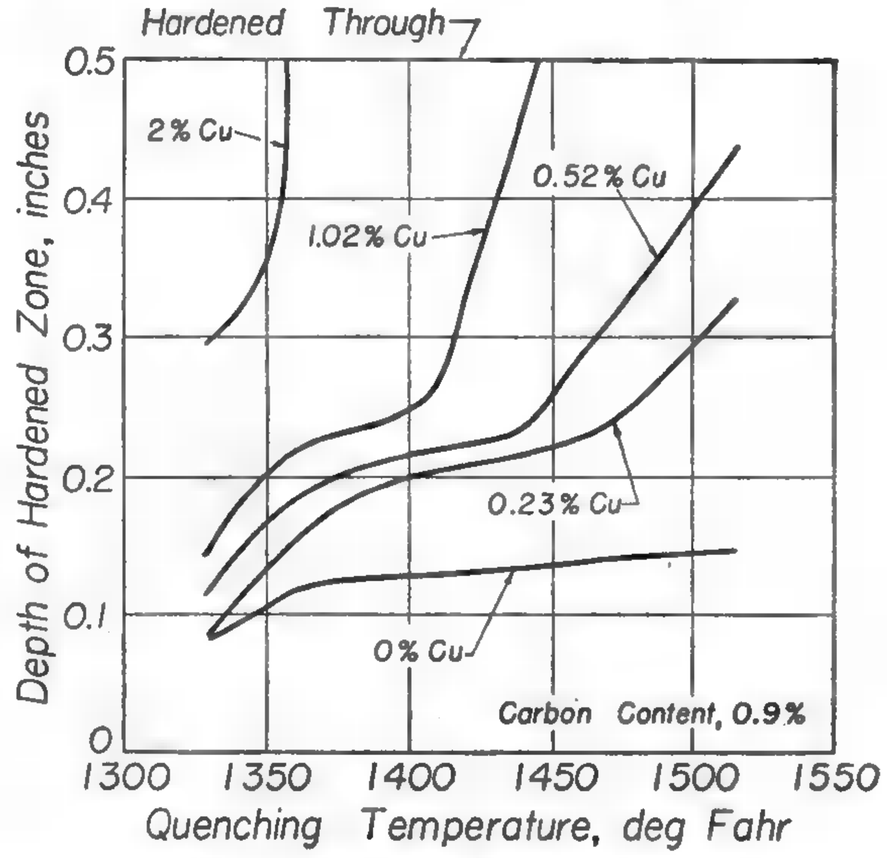

Fig. 6 Effect of copper on the depth of hardening in a quenched 0.9% C steel

The effect of copper on hardenability is similar to that of nickel. Although copper favors deep hardening, its relative effect is much greater in the high-carbon than in lower-carbon steels. The effect of copper on depth of hardening in a quenched 0.9% C steel is shown in Fig. 6.[8]

There is some evidence that copper widens the temperature range throughout which annealing produces spheroidized cementite.[8]

It has been reported[10] that steels containing from 1.11 to 1.27% C and from 3 to 4.85% Cu graphitized rapidly at temperatures above 2010 F. Reed,[11] however, failed to observe graphitization in high-copper, high-carbon steels that had been subjected to long annealing at 1832 F.

The Effect of Copper on the Tempering of Quenched Steels. Copper in amounts from 1 to 5% has little influence on the structure of oil-quenched and tempered steels containing between 0.65 and 1.20% C.[12]

No data are available to show the softening pattern of quench-hardened copper-bearing steels with increasing tempering temperature. For a steel containing 0.25% C and 1.05% Cu, quenched in water from 1500 F (but apparently not fully hardened) and tempered between 600 and 1200 F, data showed that the effects of softening by tempering and hardening by precipitation are superimposed, as illustrated in Fig. 7, when the tempering is at temperatures that cause precipitation hardening.[13]

Special Effects of Copper in Steel. *Properties at Elevated Temperature.* Short-time tensile tests at elevated temperature, on normalized copper-bearing and copper-free steels of the same carbon content, showed that copper has a tendency to reduce ductility but to influence tensile strength only a little. The information available indicates that the creep strength of steel is not improved by copper.[14] Copper appears to render iron somewhat more resistant to oxidation at high temperatures; the greatest effect is attained with copper contents between 0.25 and 0.50%. This improvement in oxidation resistance probably results from the fact that the scale formed on copper steels is slightly more adherent, and hence offers more protection against oxidizing atmospheres.

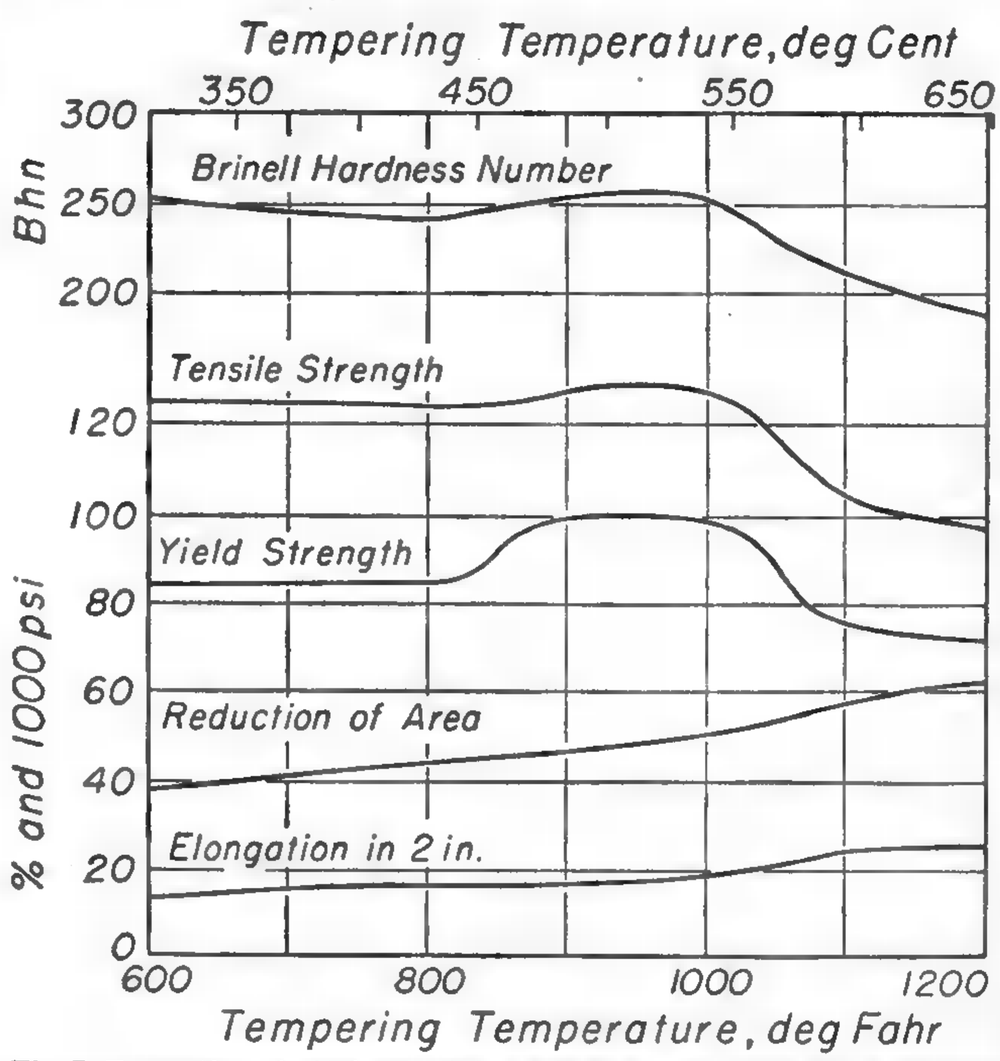

Fig. 7 Properties of steel containing 0.25% C and 1.05% Cu, quenched in water from 1500 F and tempered at various temperatures

Resistance to Corrosion. Field and service tests have demonstrated that the life of iron and steel exposed to the corrosive action of the atmosphere is increased materially by the addition of 0.15 to 0.25% Cu. Higher percentages of copper seem to provide no further benefits.

The results of field tests, under conditions of partial or total immersion in various types of water and under conditions of exposure underground, indicate that the

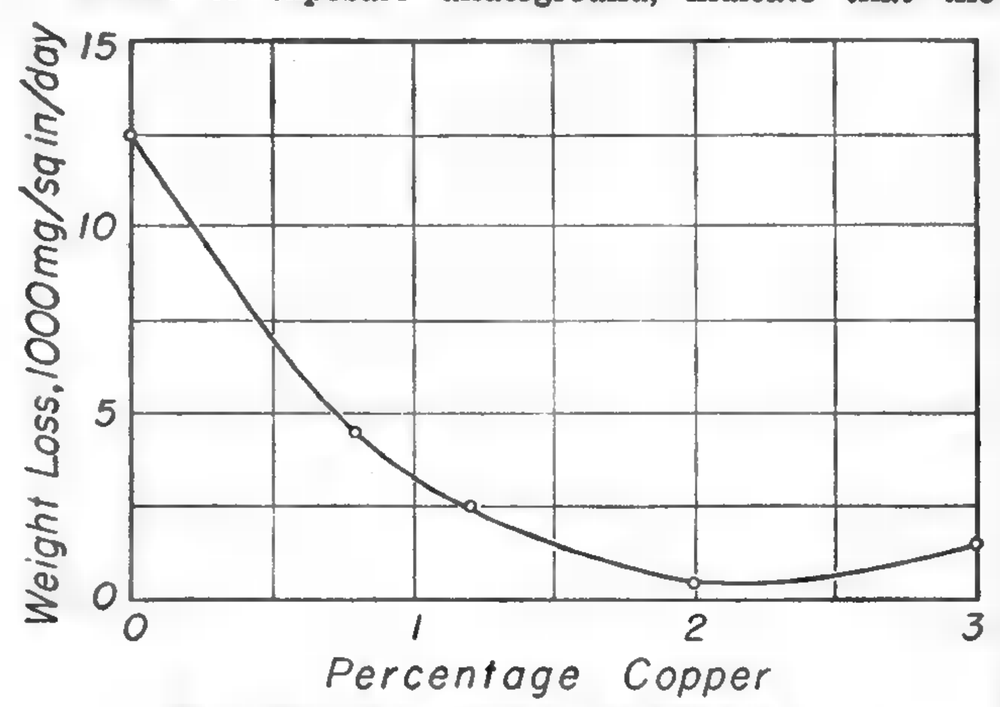

Fig. 8 Effect of copper on loss in weight of 18-8 stainless steel in boiling 10% sulfuric acid

effect of copper on submerged and underground corrosion, if at all noticeable, is not very pronounced.

There is some indication that paint adheres better to copper steel, and that zinc coatings on copper steel are more resistant than those on copper-free steel.

Copper is especially effective in increasing the corrosion resistance of steel in sulfuric acid. From 0.75 to 3.0% Cu in cast stainless steel containing 0.15% C, 18% Cr, and 8% Ni, decreased the corrosion rate in 10% boiling sulfuric acid enormously, as shown in Fig. 8. A copper addition to 18-8 stainless steel appears to have little effect on the corrosion rate in either nitric or acetic acid, nor does it seem to influence intergranular corrosion in any way. From 1 to 2% Cu is frequently added, however, to the highly-alloyed, corrosion-resisting steels of both the ferritic and austenitic types, in order to impart added corrosion resistance to certain mediums.

Low-Alloy, High-Strength Steels. Many low-alloy, high-strength steels have recently been developed to provide a relatively inexpensive structural material with about the same ductility and formability as ordinary structural steel, but with a decidedly higher yield strength. Nearly all these newer steels contain copper. (*See* the article on page 534 of this Handbook.) They are usually steels of complex alloy content, containing two or more alloying additions. Copper is used in almost every one of them to increase resistance to atmospheric corrosion. In some, more than 0.75% Cu is employed to raise the yield ratio and the tensile strength. It does not interfere with weldability. Steels containing 0.5% or more copper usually contain nickel in proportions of at least one-third the copper content, in order to improve rolling characteristics by reducing their tendency to crack, as well as to confer additional strength. For the same reason nickel is frequently used in forging steel containing 0.5% Cu or more.

Manganese in Steel

By C. E. Sims*

THIS article deals with the effect of manganese in pearlitic steels. The austenitic manganese steels are discussed in the article beginning on page 526.

The phase diagram of the C-Fe-Mn system (*see* pages 1252 and 1253) shows that manganese lowers the transformation temperature range of steel. Dilatometric tests indicate that manganese lowers the Ar_3 point more than the Ac_3 in binary iron-manganese alloys[2] (Fig. 2). The rates of heating and cooling in these tests were 18°F per min. At these heating and cooling rates, the Ac_3 and Ar_3 points occur at nearly the same temperature for pure iron. With a 1.1% Mn alloy, there is an apparent lag of 25 F; and with the 4.4% Mn alloy, the Ar_3 point lags about 450 F behind the Ac_3.

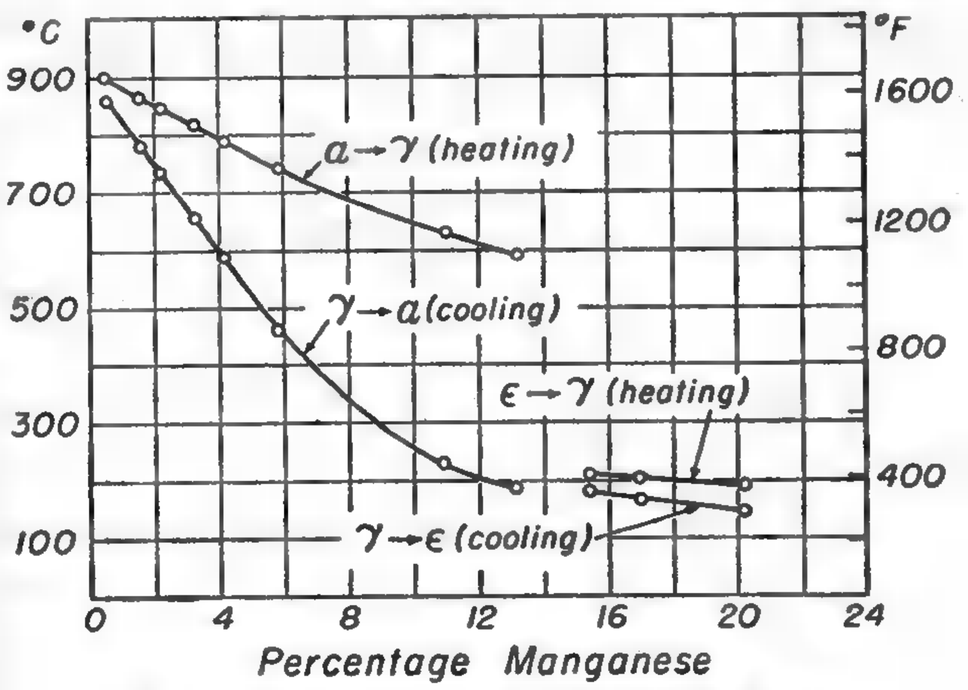

Fig. 1 Initial transformation temperatures for the gamma ⇄ alpha and gamma ⇄ epsilon transformations[1]

A summary of published results obtained in studies of pearlitic manganese steels[3] shows that the Ac_1 point is lowered approximately 11 F for each percentage of manganese; the Ac_3 point is lowered 116 F by the addition of 1% Mn, but further increase in manganese content has a much slighter effect. The Ar_3 point is lowered 125 F, and the Ar_1 point about 90 F for each 1% Mn in pearlitic steels.

Prepared for the Subcommittee on Alloying Elements in Steel

Effect of Manganese in Ferrite and Low-Carbon Iron Alloys. The effect of manganese as an alloying element in carbonless iron has been found to be very slight. Figure 4 shows the influence of manganese on carbonless iron alloys, containing as much as 1.4% Mn.[5] A straight-line relationship is indicated between the mechanical properties of the alloys and their manganese content in this range. The Brinell hardness number was raised from 70 for pure iron to 95 for a 1.4% Mn alloy. Tensile strength was increased from 42,000 to 54,000 psi, while the elongation and reduction of area remained unchanged. The influence of manganese on mechanical properties of carbonless

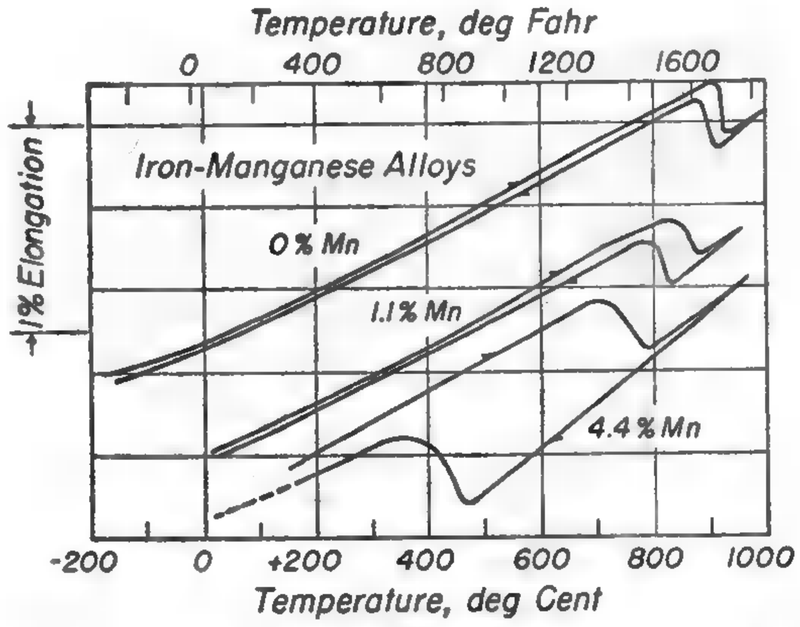

Fig. 2 Dilatometric tests on binary iron-manganese alloys[2]

and low-carbon iron in the higher range of manganese contents has not been investigated thoroughly. Bain has determined the most probable hardness values for carbon-free as well as for 0.1% C alloys,[6] (Fig. 5); the results are in agreement with values determined on the low-manganese alloys.[5] All data shown in Fig. 4 and 5 were obtained on annealed material.

Effect of Manganese on Medium-Carbon or High-Carbon Steels in the Pearlitic Condition. In pearlitic medium-carbon steels, manganese has a twofold function. It has a solution-hardening effect on the ferrite, and it influences the fineness of pearlite. Bain[6] shows the isolated solid-solution effect of manganese on a series of 0.55% C steels annealed to a uniform, lamellar structure in Fig. 6. In the

range from 0 to 7% Mn, the graph indicates an increase in strength, with a progressive loss in ductility. When the steels are compared on the basis of constant cooling rate, instead of on the basis of uniform structure, the properties are vastly more affected by manganese, because of the

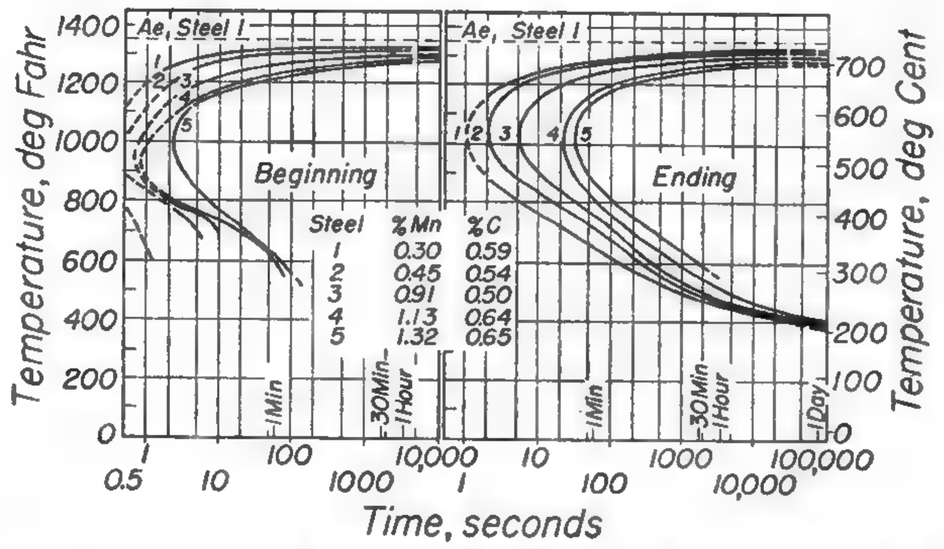

Fig. 3 Comparison chart showing influence of manganese on the isothermal transformation curve. *Left*, beginning; *right*, ending.[4]

refining influence on pearlite. This effect is shown in Fig. 7 taken from the same source.[6]

In the as-rolled condition, the mechanical properties of pearlitic manganese steels are determined largely by the fineness of the lamellar structure; and, as a general rule, a higher manganese content requires a correspondingly lower carbon content in order to provide the desired tensile

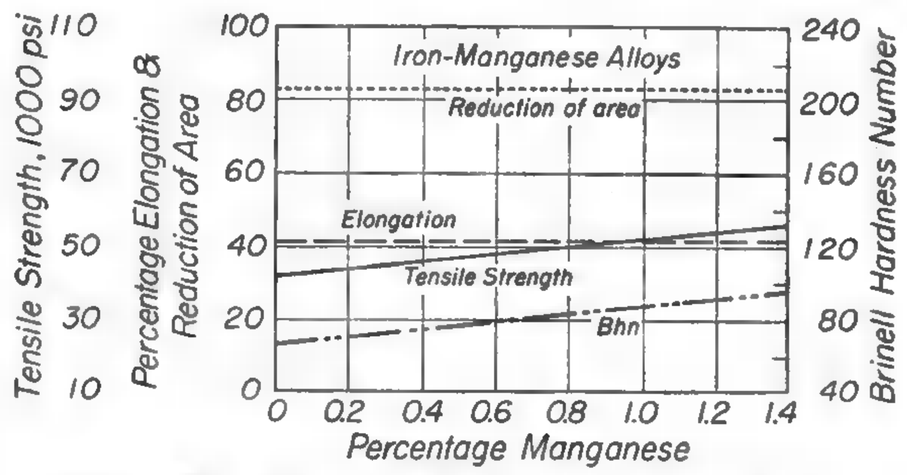

Fig. 4 Effect of manganese on mechanical properties of carbon-free iron-manganese alloy[5]

strength. Because it permits a lower carbon content for a required tensile strength, manganese is often employed as the principal alloying element in the manufacture of low-alloy, high-strength structural steels. With the use of manganese as an alloying element, either higher strength with equal ductility and impact properties, or better ductility and

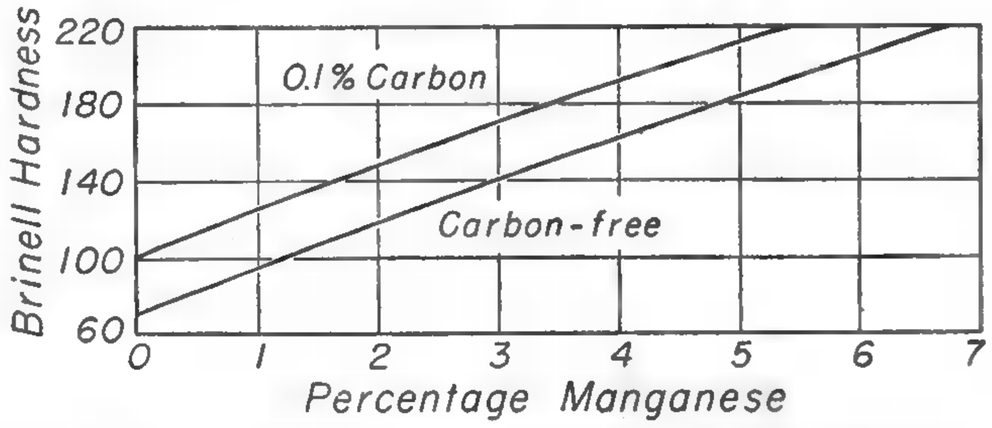

Fig. 5 Effect of manganese on hardness of carbon-free and low-carbon iron-manganese alloys[6]

impact properties with equal strength can be obtained than by the use of plain carbon steel.

Effect of Manganese on Behavior During Heating for Hardening or for Normalizing. Although manganese has generally been regarded as a carbide-forming element, because of its thermodynamic properties, no manganese carbide has been identified in steel, although such carbides have been observed in Mn-Fe-C alloys containing more than 50% Mn.[7] Manganese does occur in cementite of manganese steels. The rate of solution of cementite in the austenite of manganese steels during heating for hardening and for normalizing is similar to that in plain carbon steels. It is to be noted, however, that the minimum temperature for complete austenite formation shifts to lower

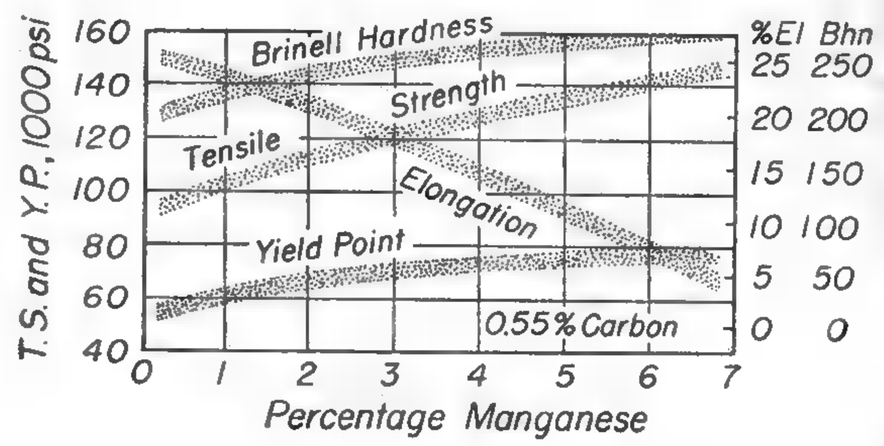

Fig. 6 Effect of manganese on mechanical properties of medium-carbon steel, heat treated to a uniform lamellar structure[6]

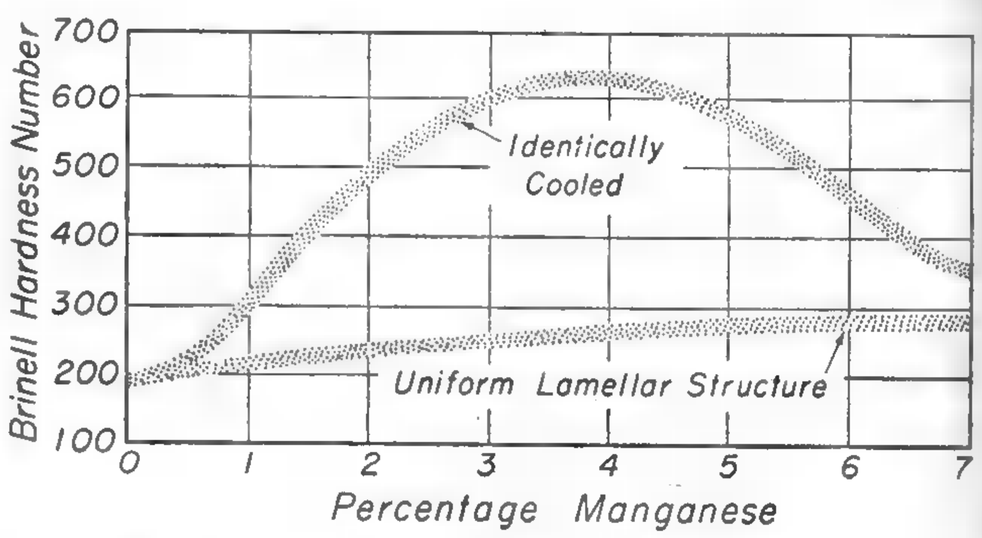

Fig. 7 Effect of manganese on hardness of medium-carbon steels[6]

temperatures, and that the eutectoid carbon content is appreciably lowered, with an increasing manganese content in the steel.[6] This condition is shown graphically in Fig. 8.

Effect of Manganese on Behavior During Cooling from the Austenitic State. As indicated by the transformation curves (Fig. 1 and 3), manganese retards transformation of

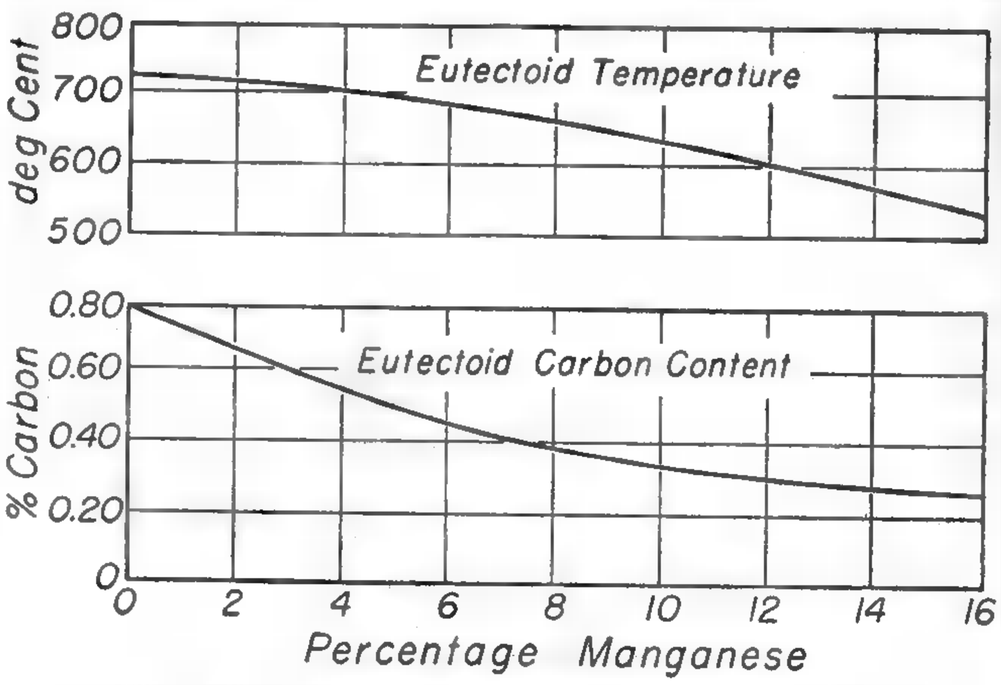

Fig. 8 Effect of manganese on eutectoid carbon content and eutectoid temperature of manganese steels[6]

austenite during cooling. The net result is a marked refinement of pearlite during air cooling, or a lower critical cooling rate for transformation into acicular products during quenching. The effect of manganese on the structures formed during cooling from the austenitic state is shown in Fig. 9 and 10. These structures were obtained by quenching thin specimens ½ in. sq in water from 1740 F (Fig. 9) and by cooling similar specimens in air from the same temperature (Fig. 10).

Of considerable importance in the industrial application of manganese steels is the fact that manganese decreases the rate of austenite transformation at subcritical temperatures[4] (Fig. 3). The familiar S-curve of isothermal transformation shifts to the right as the manganese content of the steel is increased.

The retarding effect of manganese on the rate of austenite transformation at subcritical temperatures is an important hardenability factor, because it reduces the cooling rate necessary to prevent transformation at the higher temperatures, where the products of transformation would be fine pearlite rather than martensite. Manganese is one of the most potent elements influencing hardenability, of those

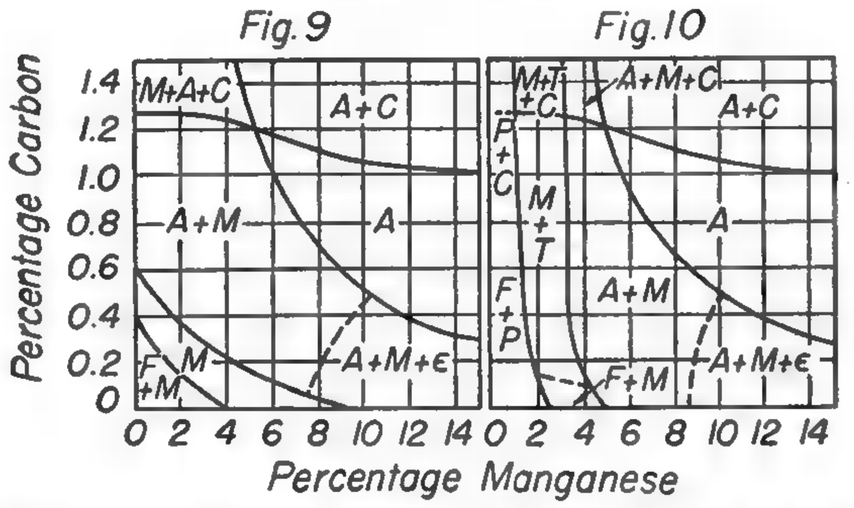

Fig. 9 Structural diagram showing the effect of manganese on structures of steel during water quenching from 1740 F[6]

Fig. 10 Structural diagram showing the effect of manganese on structures of steel during air cooling from 1740 F[6]

commonly employed in steelmaking.[8,9] The effect of manganese on hardenability is relatively greater above 1% than below 1%.[10]

With the exception of carbon, manganese lowers the martensite transformation temperatures more than any of the other alloying elements in steel. This is illustrated in

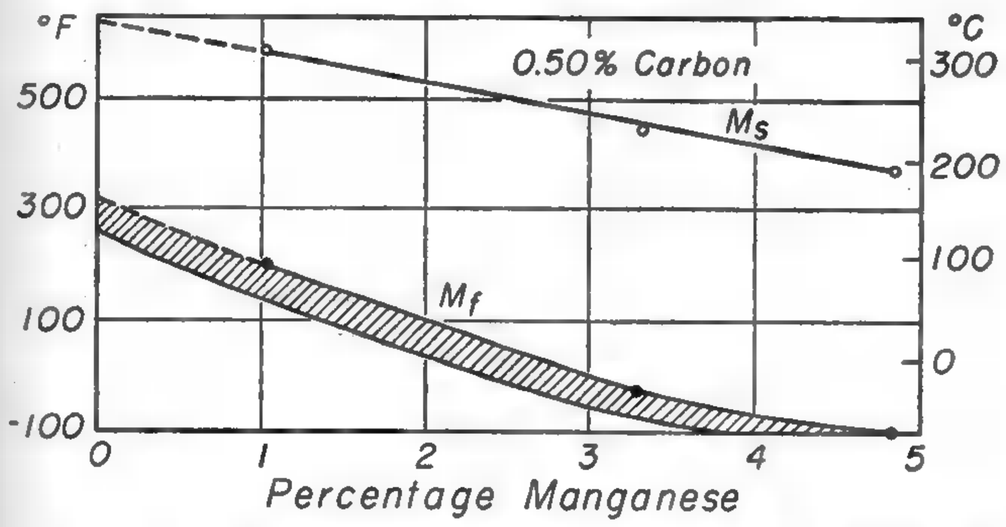

Fig. 11 Effect of manganese on the martensite transformation temperatures of a 0.50% C steel. Ms, starting point; M_f, finishing point[12]

Fig. 3 and 11. In high-carbon steels, manganese favors retention of austenite after quenching.[6]

Effect of Manganese on the Tempering of Quenched Steels. A comparison of the behavior during tempering of plain carbon and manganese steels is shown in Fig. 12, as given by Bain.[6] It is evident that, although the manganese steel had a higher level of hardness through the entire tempering temperature range, the two steels reacted similarly. For the same time and temperature of the tempering treatment, manganese steels show the same relative drop in hardness as do unalloyed carbon steels.

In high-carbon steels containing more than 1% Mn, appreciable quantities of austenite may be retained after oil quenching. However, no perceptible "secondary hardening" effects have been observed in manganese steels.[6]

Manganese steels show a pronounced tendency to temper-brittleness, often exhibiting a 50% loss in notch toughness after slow cooling from a temperature of 1100 F or higher. Quenching after tempering above 1100 F is, therefore, a recommended practice for these steels, particularly when the heat treated part has a fairly large cross section.

Characteristics of spheroidization and graphitization in manganese steels have not been satisfactorily evaluated, but circumstantial evidence points to the conclusion that manganese has a mild negative effect on both properties.

Special Effects of Manganese in Steel. *Effects of Manganese on Hot Shortness.* Among all the alloying elements employed in the manufacture of steel, manganese occupies a unique position. It is an indispensable ingredient in all commercial steels, and all efforts to make manganese-free steels have been in the nature of laboratory experiments.

Manganese reduces the "hot shortness" ("red shortness") resulting from the presence of sulfur, thereby enabling the metal to be hot worked. When manganese is absent, or very low, the predominant sulfide is FeS, which forms a eutectic with iron and has a tendency to form thin continuous films around the primary crystals during solidification of the steel. These films are liquid at the rolling temperature of steel and produce a condition of hot shortness. Manganese is outstanding in its power to combine with sulfur, and manganese sulfide has a much higher

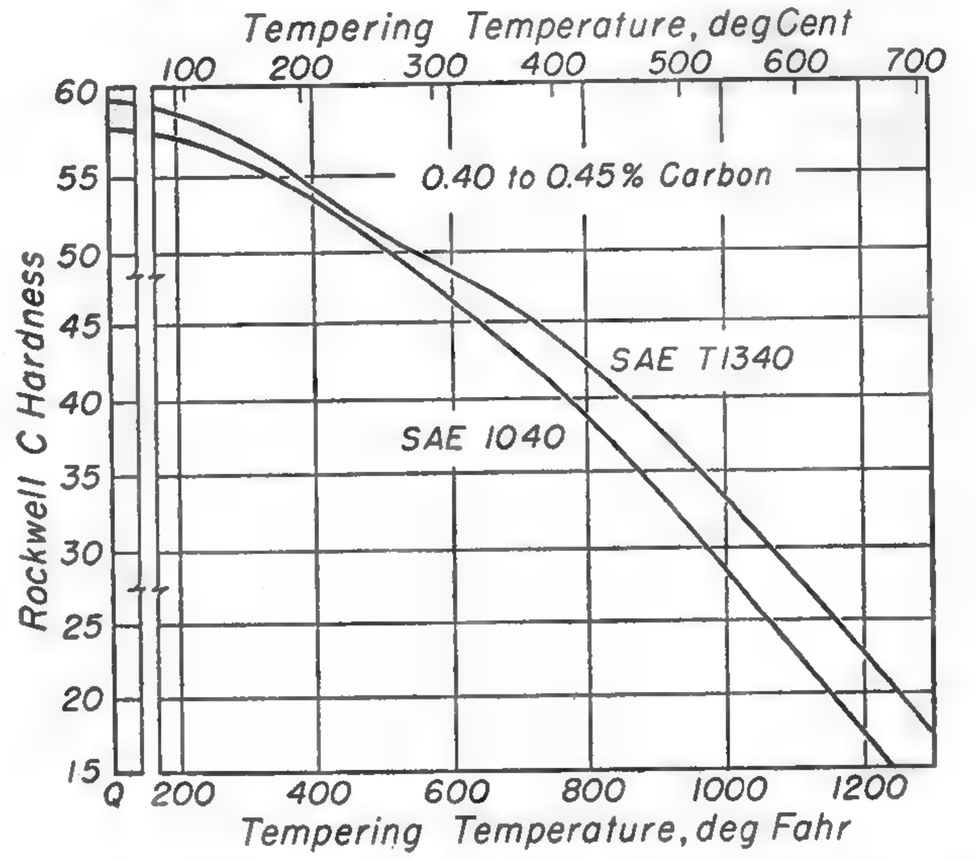

Fig. 12 Apparent effect of manganese on the behavior of steel during tempering.[6] Manganese content of SAE 1040 is 0.60 to 0.90%; that of SAE T1340 is 1.60 to 1.90%

melting point than the iron sulfide eutectic. It generally forms as separate globules, which remain solid at rolling temperature and have a less adverse effect on the hot working properties of steel. No other element seems to approach manganese in this property of preventing hot shortness. As a deoxidizer, manganese has an additive beneficial effect on the hot working characteristics of steel.

Effectiveness as an Alloying Element. Since manganese is present in all steels, there is no sharp dividing line between plain carbon steels and the so-called pearlitic manganese steels. Some authorities place the dividing line at 0.60% Mn, others at 0.80%, or even higher. Regardless of the arbitrary level at which manganese may be classified as an alloying element, it begins to function as an alloying element when present in amounts greater than about 0.60%, unless the sulfur content of the steel is unusually high.

Effect on Properties at Low Temperature. The transition zone from ductile to brittle fractures, as measured by notched-bar tests, is usually shifted to appreciably lower temperatures in both normalized, and quenched and tempered steels when the manganese content exceeds about 1%.[12] This is undoubtedly a secondary effect, stemming from the effect of manganese on the response to heat treatment.

Effect on Weldability. In common with most alloying elements which lower M_s and M_f temperatures, manganese increases the crack sensitivity of welded joints, particularly when this sensitivity is associated with higher carbon contents.*

* Unpublished results, Battelle Memorial Institute

Miscellaneous Effects. In pearlitic manganese steels, manganese does not appear to affect the resistance to oxidation, corrosion or abrasion one way or the other, nor does it appear to influence creep significantly at high temperatures.

Molybdenum in Steel

By A. J. Herzig*

THE principal contributions made by molybdenum when it serves as an alloying element in steel, may be summarized in a discussion of the effects of molybdenum on the hardening reaction, on the extent of temper brittleness and related phenomena, and on the properties of steel at elevated temperatures. Research into the fundamental processes by which molybdenum influences the properties of steel has led to studies of the effect of molybdenum on the lattice parameter of alpha iron,[1] the sharing of molybdenum by the solid solution and the carbide phases,[2,12] the role of molybdenum in the hardening of eutectoid steel,[3] the effect of molybdenum on the diffusion rate of carbon in steel,[4] and the rate at which molybdenum diffuses in austenite and in ferrite.[5]

These studies indicate that molybdenum is present in steel in the solid solution phase and in the carbide phase. In alpha solid solution, molybdenum expands the ferrite lattice. In the carbide phase, it may be dissolved in iron carbide, or it may enter a complex iron-molybdenum-carbon compound. The diffusion rate of molybdenum is exceedingly slow as compared with the diffusion rate of carbon.

Table I. Effect of Molybdenum Content on the Hardness of Annealed, Low-Carbon Steels

Carbon, per cent	Molybdenum, per cent	VPN, 10-kg load
0.02	0.004	67
0.03	0.11	76.5
0.03	0.54	92.5
0.04	1.50	99.5

Molybdenum slightly accelerates the rate of diffusion of carbon in austenite at temperatures higher than 2000 F, and slightly retards diffusion at temperatures lower than 2000 F. The slight effect of molybdenum on the rate at which carbon diffuses in austenite at subcritical temperatures can account for only a small part of the pronounced effect of molybdenum on the transformation of austenite. In an unpublished thesis,[6] there is evidence that 2% Mo raises the lowest temperature of recrystallization of iron by about 360 F.

Table II. Effect of Molybdenum Content on the Hardness and Tensile Properties of Annealed, Low-Carbon Steels

Carbon, per cent	0.08	0.08	0.09	0.10	0.09	0.08
Manganese, per cent	0.25	0.28	0.22	0.30	0.22	0.26
Silicon, per cent	0.10	0.10	0.06	0.06	0.05	0.03
Molybdenum, per cent	0.48	1.05	1.49	1.99	3.02	4.97
Tensile strength, psi	53,350	57,860	59,510	70,070	66,880	58,520
Yield strength, psi	25,300	26,125	28,140	35,750	32,100	24,750
Elongation, per cent in 2 in.	38.8	37.0	33.0	29.3	31.5	39.0
Reduction of area, per cent	65.0	63.8	64.0	60.8	62.8	79.4
Brinell hardness number	97	105	109	134	124	112

It may be concluded that the contributions of molybdenum to steel are derived both from the effect of the element in solid solution in ferrite, and the effect on the composition, mode of formation, and distribution of the carbide.

The Effect of Molybdenum in Ferrite and Low-Carbon Iron Alloys. The solid-solution hardening effect of molybdenum in annealed, low-carbon iron-molybdenum alloys, as reported by Austin,[7] is given in Table I.

The hardness and tensile properties of annealed, low-carbon molybdenum steels are given in Table II.*

Table III. Hardness of Quenched Iron-Molybdenum Alloys

Molybdenum, per cent	*Hardness As-Quenched from 2597 F* Brinell	Rockwell C
0	60	..
3	100	..
5	110	..
10	146	7
15	173	10
20	200	23
22	225	26

Iron-molybdenum alloys of more than 6% Mo contain the intermetallic compound Fe_3Mo_2 (epsilon phase), if equilibrium is attained at room temperature. Because of the presence of Fe_3Mo_2, the hardness of an annealed iron-molybdenum alloy that contains more than 6% Mo, is somewhat higher than the hardness of the alloy when it is a true solid solution. However, it is possible to retain as much as 22 to 30% Mo in solid solution in alpha iron, by quenching from temperatures of the order of 2550 F. The hardness of quenched iron-molybdenum alloys determined by Sykes[9] is given in Table III.

Table IV. Hardness of Quenched Fe-C-Mo Alloys

Molybdenum, per cent	Quenching Temperature, deg Fahr	*Hardness — VPN 10-kg load* As-Quenched	Reheated 25 hr at 1150 F
7.33	1900	186	189
10.33	2000	199	285
12.67	2000	210	360
17.55	2200	267	541
21.61	2350	338	812

The hardness of quenched Fe-C-Mo alloys containing 0.07 to 0.08% C, 0.27 to 0.31% Mn, and 0.05 to 0.07% Si, is given in Table IV.* In the as-quenched condition, the alloy consists of a solid solution of molybdenum in alpha iron and small quantities of iron-molybdenum carbide.

Prepared for the Subcommittee on Alloying Elements in Steel

* Climax Molybdenum Company, Laboratory Records

Age Hardening Alloys. Iron-molybdenum alloys that contain 6 to 30% Mo can be age hardened. Some of the hardness tests of iron-molybdenum age hardening alloys reported by Sykes[9] are given in Table V.

Table V. Hardness of Iron-Molybdenum Alloys

Molybdenum, per cent	Hardness, Rockwell C	
	As-Quenched from 2597 F	Reheated 20 hr at 1157 F
10	7	25
15	10	35
20	23	51
22	26	59
25	35	63
30	40	65

Hardness tests of age hardening Fe-C-Mo alloys containing 0.07 to 0.08% C, 0.27 to 0.31% Mn, and 0.05 to 0.07% Si are shown in Table IV.

The Effect of Molybdenum on Medium-Carbon or High-Carbon Steels in the Pearlitic Condition. Alteration by molybdenum of the pearlitic structure of medium-carbon and high-carbon steels is the result of the formation of molybdenum-bearing carbides and retardation of the rates of nucleation and growth of pearlite. The interlamellar spacing of pearlite formed at 1200 F is noticeably increased by the addition of 0.15% Mo.[10, 11] Higher concentrations of molybdenum further increase the interlamellar spacing until, at 0.75% Mo, the structure is considerably modified. (See reference 11 for micrographs.) Partially bainitic structures can be formed in 0.30% Mo steels transformed at temperatures as high as 1100 F. The amount of bainite in the structure is increased as the molybdenum content is raised. Bainite does not form in plain carbon steels at these high temperatures. In molybdenum steels, the formation of bainite at such temperatures is the direct result of retardation of the pearlite reaction by molybdenum. Because of the long time required to complete transformation in molybdenum steels at these temperatures, some spheroidization occurs before transformation is complete; plain carbon steels transform at the same temperatures to lamellar products, which are spheroidized less readily than bainite.

In hypoeutectoid steels, the addition of 0.30% Mo affects the relative rate of nucleation and rate of growth of ferrite so that, in the range between 950 and 1100 F, ferrite no longer outlines the austenite grains, as in plain carbon steels, but tends to precipitate as an intragranular acicular constituent. It is for this reason that the Widmanstätten type of structure is readily formed in the medium-carbon molybdenum steels.

The formation of proeutectoid carbide in high-carbon steels is modified by molybdenum so that the development of acicular carbides is promoted.

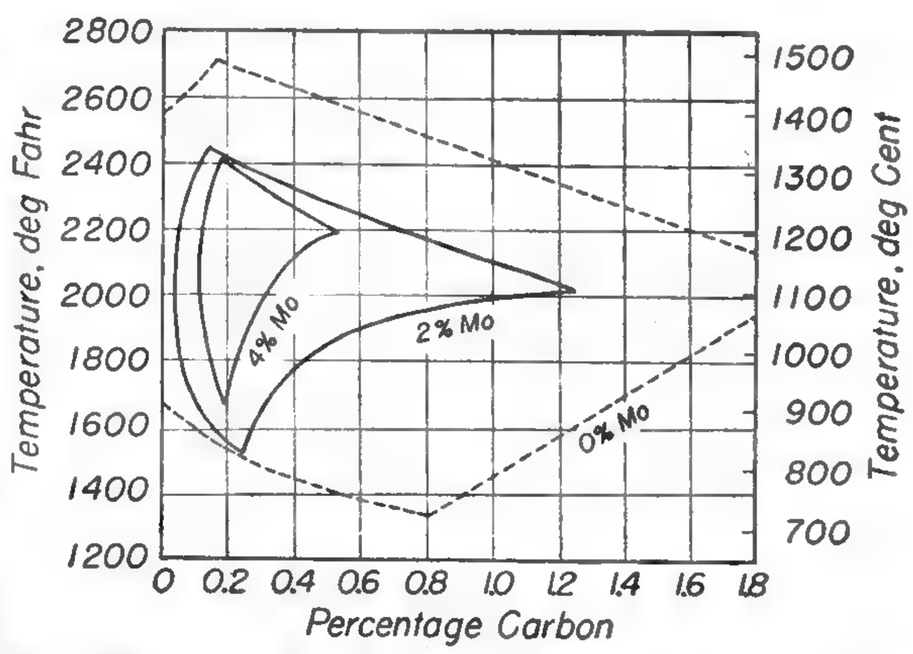

Fig. 1 Effect of molybdenum content on the temperature limits of the austenite phase field

The Effect of Molybdenum on Behavior During Heating for Hardening or for Normalizing. In heating a steel for hardening or for normalizing, the objective is to produce austenite free from ferrite. Residual free carbide in the austenite phase may or may not be desirable.

Figure 1 shows sections through the ternary Fe-C-Mo diagram, defining the composition and temperature limits of austenite free from ferrite and carbide.[12,16]

Figure 2 shows sections through the ternary diagram defining the composition and temperature limits for austenite free from ferrite but containing carbide as an equilibrium phase.[12,16] For the 2%, 4%, or 10% Mo regions of Fig. 2, compositions to the left of the Fe_3C solubility line, and within the area outlined, consist of austenite plus omega phase (Fe-Mo carbide), while compositions to the right of the solubility line consist of austenite plus omega plus Fe_3C.

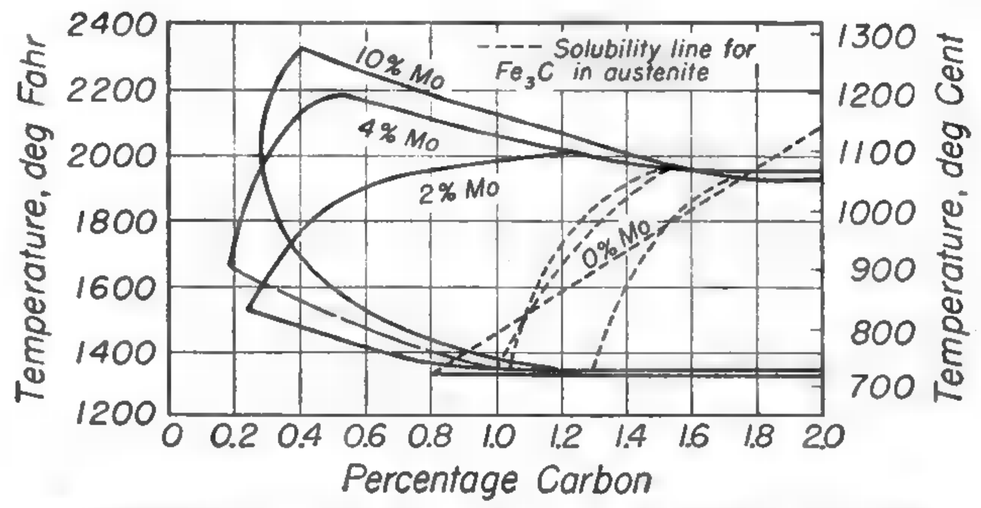

Fig. 2 Effect of molybdenum content on the temperature limits of the austenite-plus-carbide phase field

Bowman and Parke,[2, 3, 13] in a study of steels containing 0.38 to 0.83% C and as much as 1% Mo, showed that with molybdenum contents less than about 0.50%, some of the molybdenum was present in an orthorhombic carbide similar to cementite, Fe_3C, of the iron-carbon system, but that with molybdenum contents greater than about 0.50%, a face-centered cubic carbide $(Fe, Mo)_{23}C_6$ could be formed.

The rates of solution and the solubility limits of iron-molybdenum carbides in austenite have not been determined precisely. That molybdenum decreases the rate of solution of carbide in austenite is indicated in Table VI.*

In steel containing more than 0.50% Mo, it has been observed that solution of carbide is more difficult. For example, in a steel that contains 0.77% Mo, 0.78% C, more than 20 min would be required at a temperature of 2100 F to dissolve the carbides completely.

Table VI. Data on Solution of Carbide in Austenite

	Composition, percentage			
	Carbon	Manganese	Silicon	Molybdenum
Heat 1	0.73	0.69	0.17	0.017
Heat 2	0.74	0.70	0.18	0.29

Previous heat treatment of specimens: normalized at 1650 F, then annealed at 1450 F

Period in Furnace at 1410 F, minutes (Preheated to 1310 F)	Rc Hardness after Water Quenching		Microstructure after Water Quenching	
	Heat 1	Heat 2	Heat 1	Heat 2
3.5	30.6	29.6	M + P[a]	M + P
3.75	33.4	30.9	M + P	M + P
4.0	38.3	37.6	M + P	M + P
4.5	41.3	40.7	M + P	M + P
5.0	49.5	47.6	M + P	M + P
5.5	58.1	54.6	M + P	M + P
6.0	64.6	60.6[b]	M	M + P[b]

(a) M = martensite; P = pearlite
(b) Solution of carbide still incomplete. Development of peak hardness and fully martensitic structure in the steel that contains molybdenum would require longer time, higher temperature, or both.

The Effect of Molybdenum on Behavior During Cooling from the Austenitic State. Figures 3 to 14 show the effect of molybdenum on the structures formed during cooling from the austenitic state.[14] The specimens used in the investigation on which these charts are based were ¾ in. in diam by 1⅛ in. long, and had been normalized at 1800 F before the final heat treatment. Microstructures were observed at a point equidistant between the surface and center of the specimens.

In the Fe-C-Mo system, bainite is found in alloys containing about 0.70% C and 0.50% Mo or more, and air-cooled from higher than 1450 F. Water-quenched alloys contain bainite at lower concentrations of carbon and molybdenum.

The Effect of Molybdenum on the Tempering of Quenched Steels. At tempering temperatures of 450 F or less, a molybdenum content of 0.5% shows no important effect on the rate at which martensite decomposes in a eutectoid carbon steel.

At tempering temperatures higher than 500 F, molybdenum retards markedly the softening of martensite. Concentrations of molybdenum as low as 0.25% exert a significant effect on the hardness of martensitic medium-carbon and high-carbon steels when tempered within the range from 600 to 1200 F. In steels that contain 0.50% Mo, the retardation of softening is appreciably greater, and steels containing [illegible] to 5% Mo exhibit secondary hardening in the range from 750 to 1150 F.

Investigations of low-carbon (0.10 to 0.25%) steels have shown that molybdenum contents of 2 to 4% make the steels susceptible to secondary hardening effects. Secondary hardening is accomplished in both martensitic and non-martensitic prior structures, by tempering in the range from 1000 to 1150 F. This secondary hardening is accompanied by a loss of ductility as measured by notched-bar tests at room temperature. When the steels are tempered at higher temperatures, the hardness decreases fairly rapidly with rising temperature and ductility is restored.*

Molybdenum is a carbide-former and, at high tempering temperatures, it tends to segregate in the carbide phase. At 1300 F, tempering for long times may result in a high concentration of molybdenum in the orthorhombic cementite; or the face-centered cubic complex carbide $(Fe, Mo)_{23}C_6$ may be formed, if the molybdenum content is greater than 0.50%, as shown in Table VII.[2]

Table VII. Structure of Alloys Quenched and Tempered at 1300 F for 150 Hours

Carbon, per cent	0.82	0.78	0.74	0.83
Molybdenum, per cent	0.26	0.54	0.74	0.98
Molybdenum in ferrite, per cent	0.19	0.45	0.54	0.66
Molybdenum in carbide, per cent	0.73	1.29	2.23	2.81
Carbide Structure	Orthorhombic	Orthorhombic	Orthorhombic plus fcc	Fcc plus orthorhombic

Temper brittleness may be defined as the loss in notched-bar toughness that occurs in certain steels when they are exposed to temperatures in the range from 850 to 1100 F. The maximum rate of embrittlement occurs at about 950 F; the time required to lower notched-bar toughness a given amount at any temperature in the embrittling range varies with the composition of the steel.

Embrittlement may occur: (1) on tempering a susceptible steel in the range from 850 to 1100 F, (2) during slow cooling from a tempering temperature above 1100 F, or (3) on exposure to temperatures in the embrittling range after tempering at any temperature. Quenching after tempering at temperatures above 1100 F will minimize or eliminate temper brittleness by reducing the time the steel is subjected to temperatures in the embrittling range. If a steel is susceptible to temper brittleness, and if this steel must be tempered in the range from 850 to 1100 F to develop a desired hardness, embrittlement occurs during tempering. Quenching the steel after tempering in the embrittling range will not prevent or eliminate temper brittleness.

If embrittlement is fairly severe, the Izod and Charpy values at room temperature are appreciably lower when the steel is slowly cooled from tempering temperatures above 1100 F than when it is quenched from the same temperature. When a steel is only moderately embrittled, owing to low susceptibility or to short exposures to temperatures in the embrittling range, room-temperature Charpy and Izod values may not be significantly reduced, but the transition from a ductile to a brittle failure may occur at a higher temperature on the curve of Charpy value versus testing temperature.

Molybdenum minimizes temper brittleness in low-alloy steels. Molybdenum may retard the rate of embrittlement to such an extent that no loss of notched-bar toughness occurs under ordinary conditions of commercial heat treatment. Although chromium steels (0.75% Cr or more), chromium-nickel steels (with 0.75% Cr or more) and manganese steels are highly susceptible to temper brittleness, additions of molybdenum can reduce the susceptibility to a low order. When sufficient molybdenum is present, these steels may be tempered in the range from 850 to 1100 F, or they may be slowly cooled from tempering temperatures above 1100 F, without developing temper brittleness.

Special Effects of Molybdenum in Steel. *Properties at Elevated Temperature.* Molybdenum is the most effective alloying element that can be added to steel to increase the strength at elevated temperatures. Tests on vacuum-melted irons and iron-rich alloys of molybdenum and iron have shown that molybdenum in solid solution in ferrite increases the resistance to creep at 1000 F (*see* Table VIII).*

Table VIII

Effect of Molybdenum Content on the Creep Rate of Iron

Carbon, per cent	Molybdenum, per cent	Temperature, deg Fahr	Stress, psi	Creep Rate, per cent/1000 hr
0.012	0.0	1000	5,000	0.16
0.010	0.51	1000	7,500	0.032
0.009	1.01	1000	12,000	0.078

The magnitude of the effect in these 0.01% C alloys suggests that the contribution of molybdenum to the increased creep strength in steel does not depend on the presence of carbon. Molybdenum retards graphitization in steels intended for service at high temperature, although it is seldom used in percentages high enough to insure against graphitization for many years of such service.

The creep strength of carbon-molybdenum steels has been extensively investigated. An authoritative comparison with plain carbon steel is given in Table IX.[13]

The elevated-temperature hardness of the steels, compared in Table IX, is shown in Fig. 15.[13]

Table IX. Effect of 0.53% Mo on the Creep Strength of Steel

Composition, percentage					Temperature, deg Fahr	Stress, psi	
[illegible]	Mn	Si	S	P	Mo		Creep rate, 0.1%/1000 hr	Creep rate, 0.01%/1000 hr
0.35	0.55	0.19	0.03	0.016	...	850	7,600	3,400
0.16	0.66	0.24	0.027	0.015	0.53	850	28,500	20,000
0.16	0.66	0.24	0.027	0.015	0.53	1000	15,000	5,200

The same effectiveness in increasing the strength at high temperatures carries over to the use of molybdenum in the austenitic steels for applications at high temperature.

High Speed Steel. Compositions of high speed steel in which molybdenum is the principal alloying element have been widely used commercially. Molybdenum substitutes for tungsten in the function of imparting hardness at elevated temperatures ("red hardness") on the basis of one part of molybdenum to two parts of tungsten by weight. In commercial compositions, the substitution of molybdenum for tungsten is usually made only in part, since the steels often retain 1 to 6% W. The similarity in the hardness at elevated temperatures for a standard tungsten high speed steel and a 6% Mo, 6% W high speed steel is shown in Fig.

* Climax Molybdenum Company, Laboratory Records

16.[15] The greater susceptibility of molybdenum high speed steels to surface decarburization when heated in oxidizing atmospheres has been a major factor in retarding the more widespread use of such steels. Decarburization is overcome

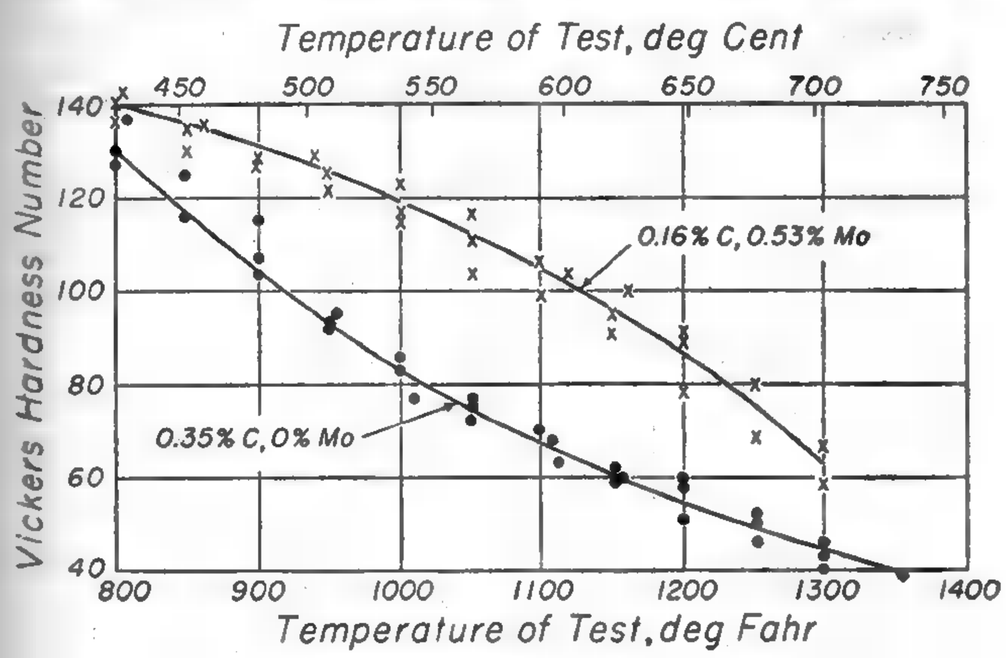

Fig. 15 Hardness of carbon steel and molybdenum steel at elevated temperatures

in commercial operations by the use of salt baths, borax coatings or controlled furnace atmospheres.

Resistance to Oxidation and Corrosion. Molybdenum steels, when exposed to oxidizing atmospheres, do not generate a tightly adherent protective scale.[8] Therefore molybdenum does not contribute toward resistance to oxidation, but the free-scaling characteristics of steels that contain molybdenum have been recognized as an advantage. In some forging operations, scale that does not free itself from the entire surface of the steel, sometimes has a serious effect on the accuracy of the forging. In cleaning operations, such as pickling and sandblasting, free-scaling characteristics are desirable. The detrimental effect of an adherent insulating scale during the hardening operation is widely recognized.

In some applications, marked improvement in resistance to corrosion is obtained by the addition of molybdenum to steel. In low-carbon steels that contain copper, experience indicates that molybdenum retards the rate of atmospheric corrosion. It has also been observed quite generally that a small addition of molybdenum to steel definitely increases the resistance to attack by 50% HCl; for example, in macro-etching. In stainless steels of the 18% Cr—8% Ni type, the use of molybdenum to enhance the resistance to certain types of corrosive mediums is also well established. The addition of 3% Mo to 18-8 steel contributes resistance to sulfite, sulfate, acetic acid, and acetate solutions. The same steels are less subject to pitting during corrosion in sea water. "Contact corrosion" or "differential aeration",

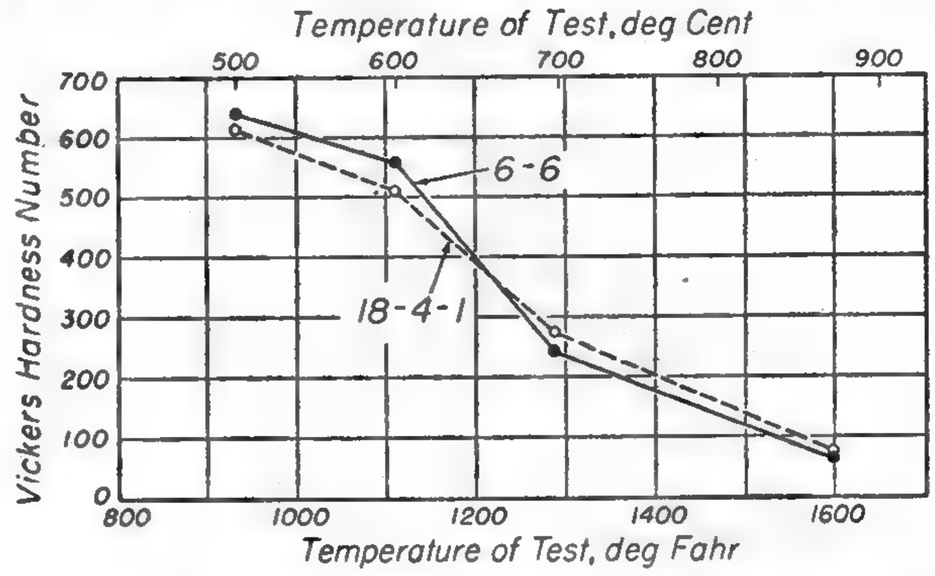

Fig. 16 Hardness of 18-4-1 and 6-6 high speed steels at elevated temperatures

resulting from the presence of foreign matter in corrosive mediums to which 18-8 steel is subjected, can be greatly minimized by the addition of molybdenum.

Nickel in Steel

By J. W. Sands*

NICKEL is unique among the elements added to steel, in that it forms with iron a continuous series of solid solutions and has no demonstrated tendency to form compounds. Because of the effectiveness of nickel in depressing the temperature of the gamma-to-alpha transformation in iron, these solid solutions are wholly austenitic at room temperature, under any conditions of cooling, when the nickel content exceeds about 30%. Many of these austenitic alloys possess unusual magnetic, expansion and thermoelastic properties that make them of great value to industry. Although frequently referred to as "high-nickel steels", they are more properly iron-nickel alloys and, as such, are described in other sections of this Handbook.

Excluding the austenitic alloys, the major contributions of nickel to steel result from (1) the effects of nickel on ferrite, (2) the effects of nickel on the hardening reactions, (3) the effects of nickel on transformation temperature ranges, and (4) the effects of nickel on resistance to embrittlement at low temperature.

* Development and Research Division, The International Nickel Company, Inc., New York

Prepared for the Subcommittee on Alloying Elements in Steel

Nickel is ordinarily found only in the solid solution phase. Nickel is not a carbide-former. Apparently it does not greatly affect the diffusion rate of carbon in austenite, although the diffusion rate of nickel itself, which is very much slower than that of carbon, is affected markedly by variation in carbon content.[1] Nickel influences the rate of transformation of austenite more in the bainite temperature range than in the pearlite region. The effects of nickel may therefore be attributed, in the main, to the influence of nickel in ferrite and in the manner of formation and distribution of the carbide phase.

The Effect of Nickel in Ferrite and Low-Carbon Iron Alloys. When nickel is introduced in amounts up to approximately 5%, the effect of it in carbonless iron is to increase strength and hardness without inducing a comparable reduction in ductility. With contents beyond about

5% Ni, even slowly cooled alloys begin to assume a martensite-like nature, and strength and hardness increase more rapidly. With contents between about 15 and 20% Ni, slowly cooled alloys appear to consist almost entirely of such a martensitic structure[2, 3] and the maximum hardness of the system (about 300 Brinell) is attained. When the percentage of nickel is further increased, stable austenite appears

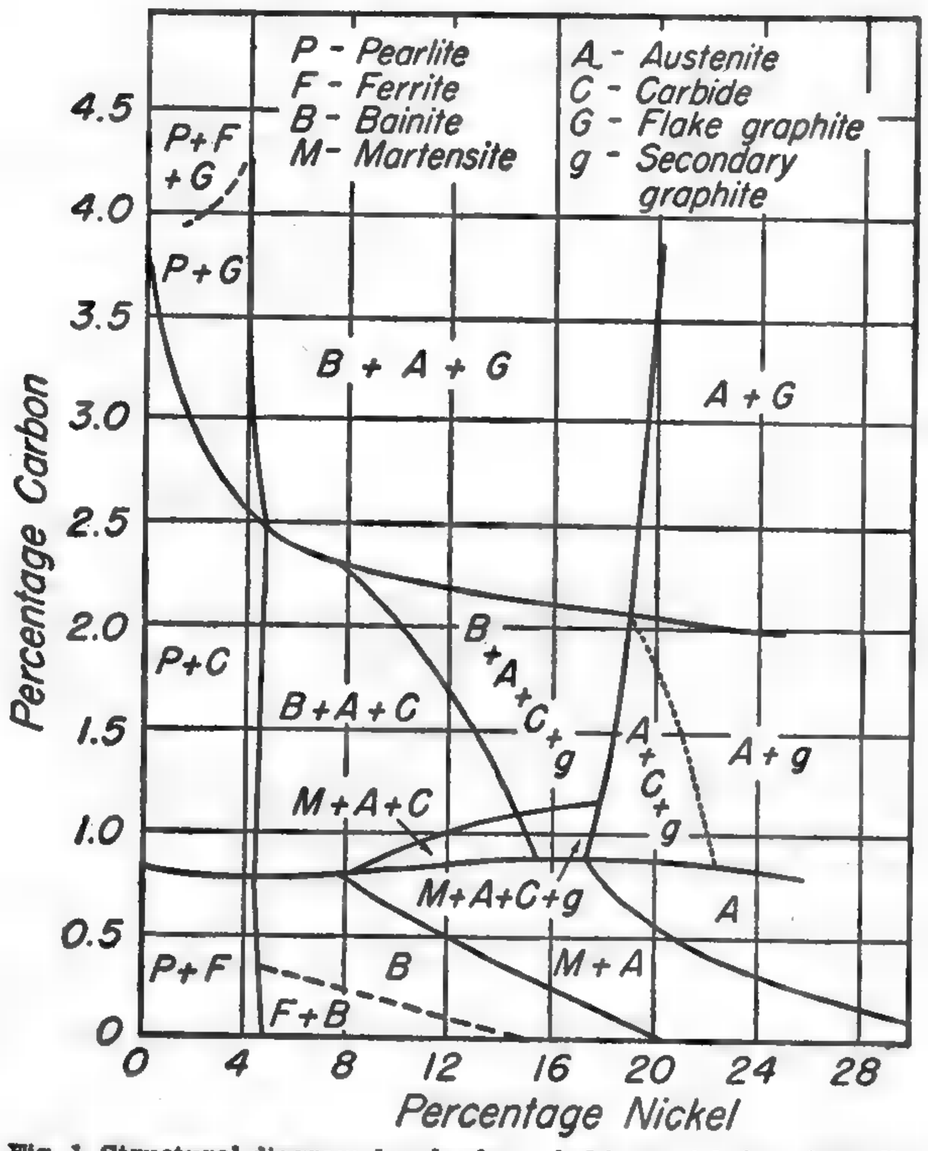

Fig. 1 Structural diagram for slowly cooled iron-nickel-carbon alloys. Specimens 1.2 in. in diam were cast into dry sand molds and cooled in the molds (Eash and Pilling)

in increasing quantities, with consequent decrease in hardness. Beyond about 35% Ni, the carbonless alloys are ordinarily wholly austenitic, not only at room temperature but at all subatmospheric temperatures. These changes are indicated by the zero carbon level in the Fe-Ni-C structural diagram shown in Fig. 1.

The transformation between the α and γ phases in the iron-nickel alloys containing less than 35% Ni, is so sluggish that there is a large hysteresis between the transformation temperature ranges during heating and cooling at ordinary slow rates. A region of two-phase equilibrium exists between α and γ, as indicated by the phase diagram of the iron-nickel system, page 1211 in this Handbook. The ranges of transformation temperature actually observed during slow cooling and slow heating are usually of more practical interest than the equilibrium lines. These ranges are shown in Fig. 2.*

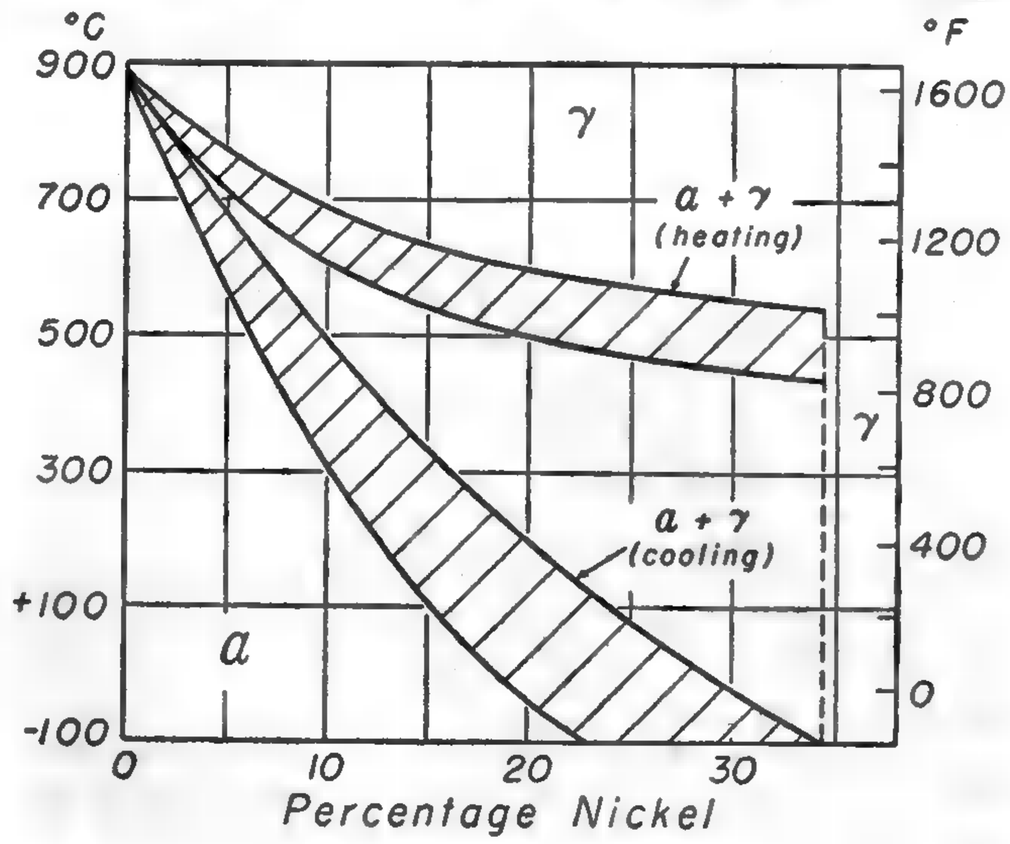

Fig. 2 Transformation temperature ranges of iron-nickel alloys during slow cooling and slow heating (Merica's selection of data)

In the ferritic alpha range it appears fairly well established that strength is increased about 4200 psi and hardness about 16 Brinell numbers for each 1% Ni. The relation is not strictly linear, however, as indicated by Fig. 3.

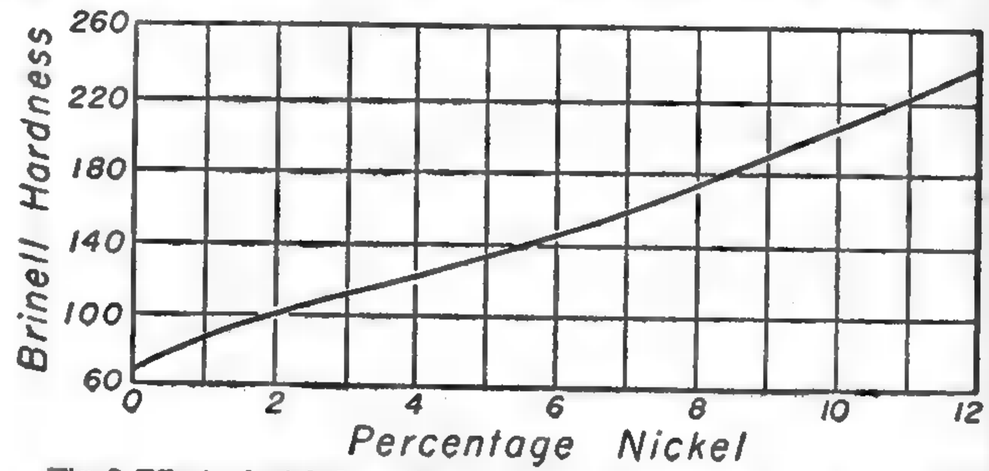

Fig. 3 Effect of nickel on the hardness of annealed pure iron. (Author's selection of the most probable values, based on references 2, 3, 4, 5, 6, 7, 8 and unpublished data)

Since nickel in steel has no affinity for carbon, the effect of nickel in low-carbon iron alloys is to superimpose this degree of strengthening and hardening upon the increases resulting from the additions of carbon. The effect of nickel on the tensile properties of annealed iron-carbon alloys that contain approximately 0.05% C is shown in Fig. 4.

The degree of strengthening imparted to iron by nickel, although less than the effect of carbon, is sufficient to be very useful when improved elastic properties are desired without deleterious effects on weldability, forming characteristics, or other factors adversely influenced by carbon. This is one of the major reasons for the extensive use of

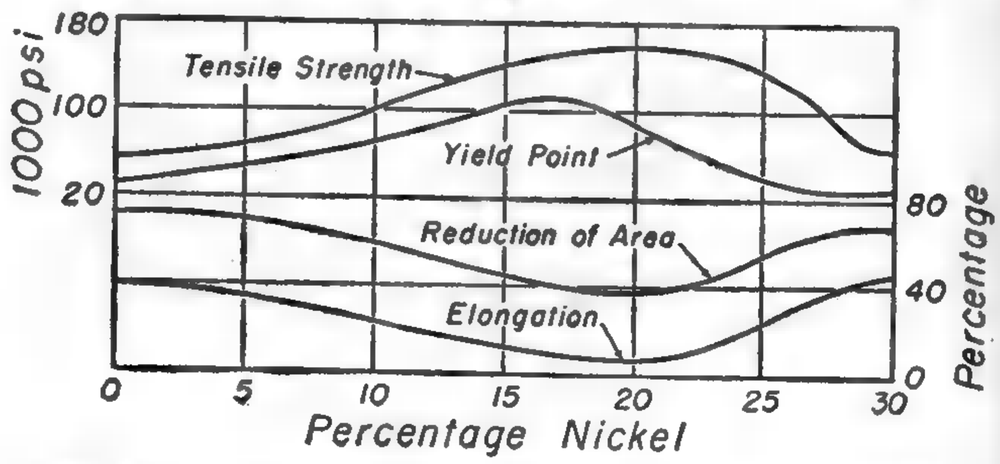

Fig. 4 Effect of nickel on the tensile properties of annealed low-carbon (0.05% C) steels. (Author's selection of the most probable values based on references 4, 5, 7, 8 and unpublished data)

nickel in the group of readily weldable, higher-strength structural steels currently in favor.

The Effect of Nickel on Medium-Carbon or High-Carbon Steels in the Pearlitic Condition. Pearlite in nickel steels is finer and therefore stronger and tougher than the pearlite of carbon steels, because it forms in a lower temperature range. Furthermore, nickel, in common with the other usual alloying elements, reduces the eutectoid carbon ratio; the reduction is approximately 0.04% C for each 1% Ni. Hence the structure of unhardened nickel steels contains a higher percentage of pearlite than plain carbon steels of similar carbon contents comparably treated. These two factors, particularly the fineness of pearlite, together with the strengthening of the ferrite, permit a given strength and hardness to be obtained in normalized nickel steels with considerably lowered carbon contents, thereby markedly increasing toughness and plasticity. Other advantages include improved resistance to fatigue. The following data

* P. D. Merica, 1939 Metals Handbook

are illustrative.[9] Both steels were normalized and tempered in the form of solid forgings 6 in. in diam.

Composition, per cent C	Mn	Ni	Tensile Strength, psi	Yield Point, psi	Izod Impact, ft-lb	Fatigue Limit, psi	Fatigue Ratio, per cent
0.46	0.62	...	86,200	51,300	17	40,000	46
0.24	0.94	2.70	86,300	63,000	105	54,000	■

The Effect of Nickel on Behavior During Heating for Hardening or for Normalizing. Since nickel is confined to the solid solution phase, it has no tendency to promote the formation of any complex carbides that might be difficultly soluble. Therefore, no special precautions are necessary in heating nickel steels for austenitizing. In fact, this operation is somewhat simplified by the fact that nickel lowers the transformation temperatures.

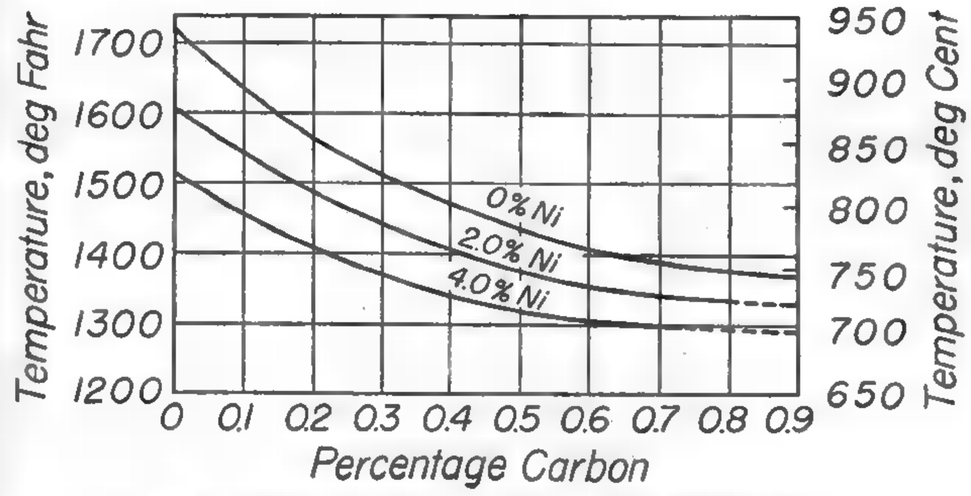

Fig. 5 Effect of nickel on the A_3 transformation during heating (Scott)

Nickel and manganese are the only two of the usual alloying elements that lower the eutectoid temperature,[10] and nickel is the more effective. Nickel steels thus allow lower heat treating temperatures, resulting in less scaling, warping and cracking, lowered fuel costs, and less wear on heat treating equipment. The degree to which nickel lowers the temperature of the A_3 range on heating, according to Scott,[11] is shown in Fig. 5.

Effect of Nickel on Behavior During Cooling from the Austenitic State. Nickel retards both pearlite and bainite transformations while steel is cooling from the austenitic state; the bainite is influenced more markedly than the pearlite. English investigators have reported that the high-temperature intermediate products formed by the decomposition of austenite in nickel steels at temperatures just lower than the pearlite range, appear to show less deterioration in mechanical properties, as compared with tempered martensite, than do steels that contain no nickel.[12] Thus nickel tends to minimize the deleterious effects of "slack" quenching.

The diagram presented as Fig. 1 shows the structures that result when Fe-Ni-C alloys are cast into dry sand molds in the form of arbitration bars, 1.2 in. in diam, and are cooled in the molds.[3] The diagram indicates what may be expected to result from commercial slow cooling; but it should be emphasized that the boundaries shown as lines do not represent sharp steps from one phase or group of phases to another. Instead these lines represent narrow transition zones where the constituents coexist. For contents lower than approximately 0.80% C, the diagram is relatively simple and reflects the strong austenitizing effect of nickel in conjunction with carbon.

Effect of Nickel on the Tempering of Quenched Steels. Nickel has no unusual effects on the tempering of martensite. No secondary hardening occurs in plain nickel steels and, consequently, there is no exceptional resistance to softening. With more carbon than the carburizing grades, the nickel steels exhibit the usual minimum in the curve of impact resistance versus tempering temperature, at about 500 F, because of decomposition of austenite retained after the quench.[13]

When quenched nickel steels are tempered for long periods of time, as is often necessary in treating heavy sections, care should be taken not to exceed the true Ac_1 temperature, which recent investigations have shown to be considerably lower than the apparent Ac_1 temperature indicated by *conventional* tests made under conditions of continuous heating.[14] This precaution is unnecessary when tempering periods do not exceed an hour or two; but longer holding at temperatures slightly higher than the true Ac_1 may result in the formation of enough austenite to produce a hardening of the steel during subsequent cooling, thereby necessitating a second tempering operation to break down the transformation products so formed. The Ac_1 temperature for 3½% Ni steel (2340, for example) is generally given as about 1280 F, but the safe upper limit for tempering temperature is actually only 1225 F. Safe upper limits for some other steels that contain nickel, together with the Ac_1 temperatures heretofore generally accepted, are given in Table I.

Table I. Apparent Ac_1 Temperatures and Maximum Tempering Temperatures for Steels Containing Nickel

Steel	Apparent Ac_1 Temperature, deg Fahr	Maximum Tempering Temperature, deg Fahr
2350	1280	1200
3140	1355	1275
3141	1350	1275
3250	1340	1275
3350	1290	1225
3440	1290	1225
4340	1350	1275
4640	1320	1250

Nickel appears to exert no curative effects when added to steel that is subject to temper brittleness, nor does it seem to induce or intensify this phenomenon.

Nickel will not induce graphitization in steels during the tempering operation, even if the steels are held within the tempering range during the extended periods necessary for tempering heavy sections.*

Special Effects of Nickel in Steel. *Carburizing Steels.* Nickel steels are particularly suitable for the case hardening process, as demonstrated by their popularity for the most exacting applications, such as aircraft engine gears and roller bearings of all sizes. Nickel steels provide strong tough cases, resistant to wear and fatigue, together with good core properties. The lower transformation temperature ranges and the smaller difference between transformation temperatures of case and core are conducive to simplified hardening treatments and lessened distortion. Nickel reduces slightly the rate of penetration of carbon into steel that is being carburized. Therefore the carburizing steels of higher nickel contents may require a somewhat longer carburizing period than carbon steels in order to obtain a given depth of case.

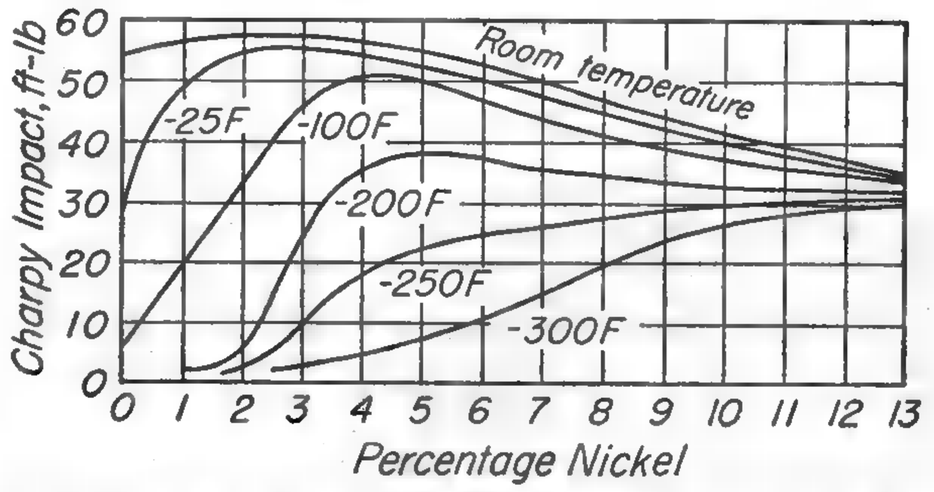

Fig. 6 Influence of nickel on the impact strength of normalized low-carbon (0.10 to 0.20% C) steels at low temperatures (Keyhole notch)

Resistance to Embrittlement at Low Temperature. As discussed in the article on page 204 in this Handbook, at reduced temperatures all ferritic steels suffer a deterioration in toughness that is most easily detected by the notched-bar impact test. This tendency to embrittlement

* Unpublished data from the International Nickel Company Research Laboratory

becomes important in connection with apparatus exposed to low atmospheric temperature or subatmospheric temperature artificially produced. Nickel is widely accepted as a specific for this difficulty and generous amounts appear indispensable for the very lowest temperatures.[15] Nickel is particularly effective in applications where quenching is not feasible and where normalized or normalized and tempered steels must be used. The effect of nickel on the impact resistance of normalized low-carbon steels at low temperature is indicated in Fig. 6.

Resistance to Corrosion. Nickel, in amounts ordinarily used in ferritic steels, is effective in imparting improved resistance to atmospheric corrosion, especially in industrial and marine atmospheres, as illustrated by the data plotted in Fig. 7.[16] In other environments no detrimental effects are observed, and in particular mediums, such as alkalies, there is a beneficial effect roughly proportional to the nickel content.

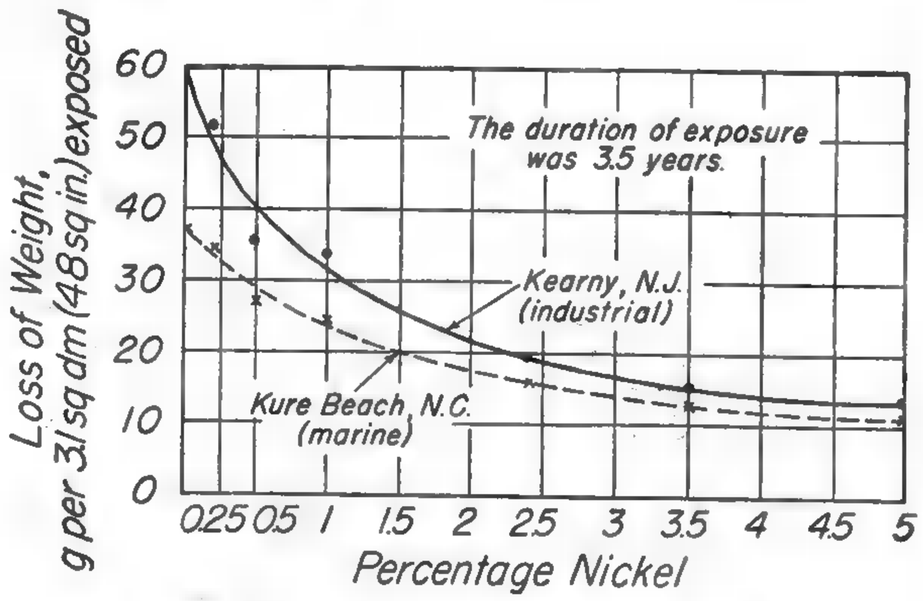

Fig. 7 Effect of increasing nickel content on corrosion in marine and industrial atmospheres (Larrabee)

Although few ferritic steels are used primarily for resistance to corrosion, this characteristic is obviously desirable, particularly when weight is reduced by the use of thinner sections of higher-strength steels. Many of the high-strength structural steels contain several alloying elements, and in these complex nickel steels, the beneficial effects of the individual elements on resistance to corrosion are mutually intensified.

In some steels improvement is essential both in resistance to corrosion and in strength. In the oil production field, for example, advantages are recognized in the use of nickel steels to provide a marked increase in resistance to corrosion fatigue in sucker rods, operating in contact with oil-well brines.

There are also applications in which it is economically preferable to use nickel steels, even when improved mechanical properties are not required. An illustration is the extensive use of nickel steels to resist attack by alkalies in chemical plants, petroleum refineries and pulp mills.

Precipitation Hardening. Nickel alone does not impart age hardening characteristics to steel, but it will do so in combination with certain elements, notably aluminum. This fact becomes an advantage in nitriding steels that carry aluminum as an essential constituent. By a fortuitous circumstance the optimum aging temperature coincides with the customary nitriding temperature. This allows an automatic hardening of the core during the nitriding operation, after fabricating operations have been carried out in the soft condition. Table II illustrates this effect in 3½% Ni nitralloy.

Table II. Core Properties of G and N Nitralloy[a]

	Nitralloy G Before and After Nitriding	Nitralloy N (with 3½% Ni)	
		Before Nitriding	After Nitriding

Silicon in Steel

By Earl S. Greiner*

WHEN silicon is alloyed with iron under equilibrium conditions, the A_3 transformation is raised and the A_4 transformation is lowered. This results in a closed gamma "loop", having a gamma phase limit at 2.2% Si and 1170 C (2140 F).[1] Silicon forms a solid solution with the alpha phase and contracts the lattice.[2] The alpha phase solid solubility limit in the binary alloys varies from 15.2% Si at 600 C (1110 F) to 20.4% Si at 1030 C (1885 F).[3] The addition of carbon to iron-silicon alloys increases the solid solubility limit of the gamma phase to approximately 8% Si, at 0.5% C and 1160 C (2120 F).[4] The alpha can dissolve about 0.25% C in the alloy containing 10% Si at 1160 C (2120 F).[4] Silicon promotes graphitization in Fe-C-Si alloys.[5]

The Effect of Silicon in Iron and Low-Carbon Iron Alloys. According to data by Yensen,[6] the ductility of annealed iron-silicon alloys of high purity, containing from 0 to about 2.5% Si, is substantially the same as that of iron. The ductility decreases markedly, however, for alloys containing more than 2.5% Si. In general, the tensile and yield strengths of these annealed iron-silicon alloys increase with silicon contents to 4.5%, but decrease in the range from 4.5 to 6.5%.

The mechanical characteristics of four low-carbon steels (0.05 to 0.07% C) containing from 0.39 to 2.39% Si have been reported by A. Pomp[7] and are given in Table I. These steels were in the as-rolled condition, and the silicon was probably present in solution in alpha iron (ferrite). The increase of the Brinell hardness of these alloys with increasing silicon content is caused by silicon hardening the ferrite. The data in Table I also show that the addition of 2.39% Si, or less, to low-carbon alloys increases the tensile and yield strengths and decreases the reduction of area and impact values.

Prepared for the Subcommittee on Alloying Elements in Steel

Table I. Mechanical Properties of Low-Carbon Structural Silicon Steel As-Rolled (Pomp[7])

Per Cent					Brinell Hardness	Tensile Strength, psi	Yield Strength, psi	Elongation in Approximately 3 in.,[a] per cent	Reduction of Area, per cent	Charpy Impact Value,[b] m-kg per sq cm
C	Si	Mn	P	S						
0.05	0.39	0.25	0.014	0.049	117	58,000	40,500	29.5	72	6.5
0.07	1.17	0.32	0.013	0.034	130	67,500	47,500	29.5	71.5	3.1
0.05	1.73	0.35	0.014	0.030	140	72,500	54,500	29.5	64	3.4
0.06	2.39	0.16	0.010	0.016	181	76,500	53,500	24.5	53.5	0.9

[a] Elongation in 70 mm determined [b] 10 by 11-mm cross section

The mechanical properties of as-rolled structural shapes of low-carbon, open hearth silicon steel have been reported by Meiser.[8] The averaged values of these properties for six steels that contained 0.15 to 0.19% C, 0.85 to 1.10% Si, 0.90 to 1.10% Mn, 0.030 to 0.035% P, and 0.030 to 0.040% S are as follows:

Tensile strength	77,800 psi
Yield strength (drop of beam)	56,500 psi
Elongation in approximately 8 in.	24.2%
Reduction of area	54.2%

The addition of silicon to iron promotes grain growth and increases the electrical resistivity. Yensen[9] reported the resistivity of iron-silicon alloys to be as follows:

Silicon, per cent	0	1	2	4	6
Resistivity, microhm-cm at 20 C (68 F)	9.6	23.0	34.2	56.5	78.7

The Effect of Silicon on Medium-Carbon or High-Carbon Steels in the Pearlitic Condition. Various investigators[10] have observed that silicon decreases the carbon content of the eutectoid. Bain[11] places the eutectoid in Fe-C-Si alloys containing 8% Si, at 0.33% C and 1120 C (2050 F).

According to Bain,[5] "the carbide is little modified by nickel, silicon or aluminum, except that graphitization is accelerated in their presence if little or no carbide-forming elements are present".

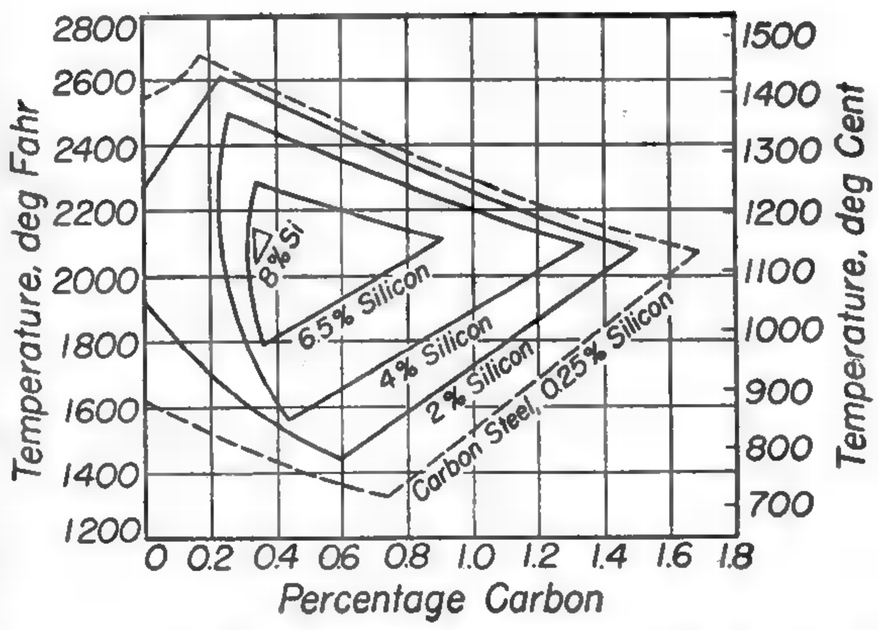

Fig. 1 Effect of several uniform silicon contents on the carbon limitations for pure austenite at elevated temperatures (after data of Satô; Bain[12])

The Effect of Silicon on Behavior During Heating for Hardening or for Normalizing. In connection with the heat treatment of steels for hardening or normalizing, it is necessary to heat the materials so as to transform the ferrite to austenite. The "triangles" in sections through the ternary Fe-C-Si equilibrium space model, according to the data of Satô,[12] define the composition and temperature limits for producing pure austenite in these alloys (Fig. 1). Compositions lying progressively to the left of the "triangles" in Fig. 1 will consist largely of austenite, but with increasing amounts of ferrite (α or δ iron). Those compositions lying progressively to the right of the triangles, at temperatures below the vertices at the right, will consist largely of austenite, but with increasing amounts of carbide or graphite, or both for some high-silicon alloys. In general, the sections in Fig. 1 show that silicon steels require higher austenitizing temperatures than plain carbon steels.

The Effect of Silicon on Behavior During Cooling from the Austenitic State. Kramer, Hafner, and Toleman[13] have shown that silicon promotes the hardenability of steels. For numerical data, see the article on page 494.

The Effect of Silicon on the Tempering of Quenched Steels. The curves in Fig. 2, from Bain,[14] show that increasing the amount of silicon in 0.50 to 0.55% C steels that have already been quenched, results in increasing the hardness after tempering at corresponding temperatures. This increase in the hardness of quenched and tempered medium-carbon silicon steels is probably caused by silicon strengthening the ferrite, which contains the carbide particles.

When some hardened alloy steels are tempered and slowly cooled from the tempering temperature, they are susceptible to a phenomenon known as temper brittleness. If this brittleness develops, the impact resistance of the steel decreases. The effect of silicon on the susceptibility of steels to temper brittleness is not well established. Experiments by Burns[15] on silicon-manganese steels containing 0.4 to 0.5% C indicate, however, that the susceptibility to temper brittleness increases with the silicon content, but it is mainly influenced by the manganese. Temper brittleness in silicon-manganese steels containing 1% Mn, does not become serious until the silicon approaches 1.5 to 2%. If the steels contain less than 0.6% Mn, as much as 3% Si may be present without serious susceptibility to temper brittleness.

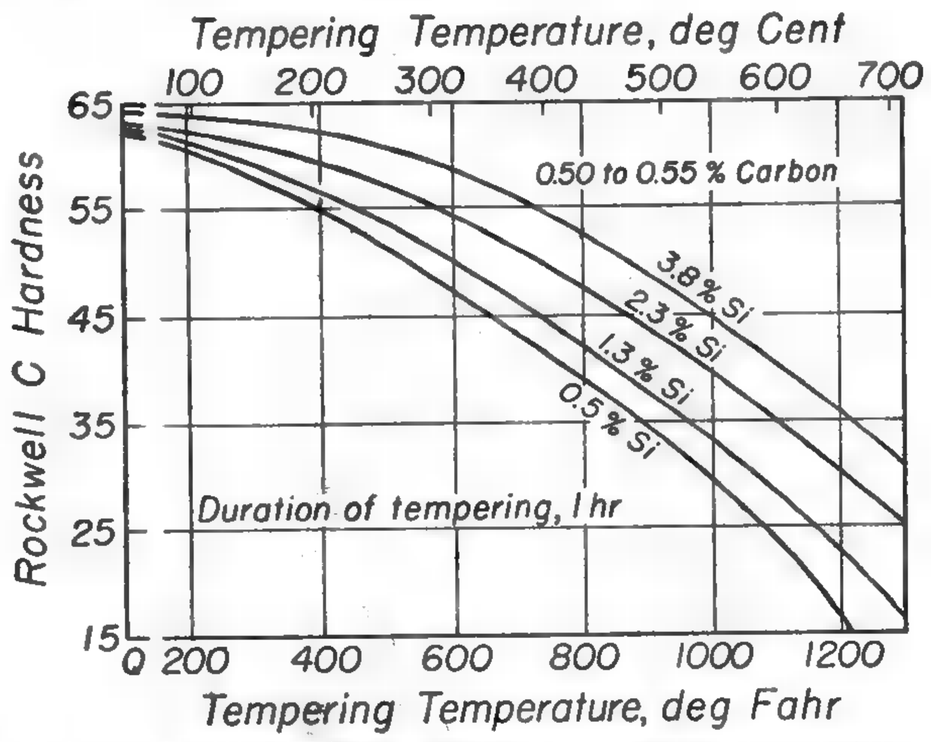

Fig. 2 The softening with increasing tempering temperature, of quenched 0.50 to 0.55% C steel as influenced by silicon content (Bain[14])

Special Effects of Silicon in Steel. *Resistance to Oxidation and Corrosion; Decarburization.* Silicon is added to chromium, chromium-tungsten and chromium-nickel steels to increase the resistance to high-temperature oxidation. This characteristic makes some of these materials useful for such applications as exhaust valves in internal combustion engines.[16] Tests by Mathews[17] indicate that the addition of about 2% Si, or less, to the 18% Cr, 8% Ni (18-8) stainless steel, increases the resistance to scaling at 980 C (1800 F). One of the commercially produced types of the 18-8 stainless steel contains from 2 to 3% Si.

According to Houdremont and Bennek,[18] silicon-manganese steels exhibit greater resistance to scaling and greater decarburization of the surface than similarly treated manganese steels. Comparative data on the scaling and de-

carburization of these materials after heating at 850 C (1560 F) for 10 hr are as follows:

Composition, per cent C	Si	Mn	Weight Loss Through Scaling, mg per hr per sq m	Decarburization mm	in.
0.47	1.54	0.56	38.4	0.51	0.0201
0.53	1.54	0.61	41.5	0.55	0.0216
0.35	0.32	1.75	76.0	0.00	0.00
0.60	0.37	1.73	75.8	0.00	0.00

For materials requiring resistance to corrosion by certain inorganic acids and other chemicals, the 14 to 16% Si cast irons, containing 1% C or less, have a wide field of application.[19] These alloys are not machinable, except by limited turning with tungsten carbide tools; hence castings must be finished by grinding. These materials are also used for apparatus requiring resistance to erosion as well as to corrosion.

Magnetic Characteristics. Alloys of iron and 0.5 to about 5% Si have lower hysteresis and eddy current losses than iron in alternating magnetic fields. Furthermore, the magnetic permeability in direct-current fields is satisfactory for many applications. Because of these features silicon steel is extensively used for electrical equipment.

Table II

Typical Uses and Magnetic Core Losses of Silicon Steels[20]

Grade	Typical Uses	Silicon, (nominal) per cent	Total Core Loss,[a] 60 Cycles, 10,000 Gausses No. 29 Gage (0.014 in.) Sheet, watts per pound

[a] Guaranteed maximum

Silicon steel sheets and strip for electrical purposes are prepared commercially by a number of organizations. Some of the grades are listed in Table II, along with typical uses, nominal silicon contents, and maximum total core losses (hysteresis plus eddy current losses) for 0.014-in. sheet materials made by one commercial supplier.[20]

Among the deleterious impurities, carbon, sulfur and oxygen are considered to be the most harmful to the magnetic properties of silicon steel, and should therefore be eliminated or maintained in as small quantities as possible for such applications.

Silicon steel sheets are prepared either by hot rolling[21] or by hot rolling prior to cold rolling.[22]

The annealing of silicon steel sheet or strip for magnetic applications is important, and a number of practices are used, depending on the quality desired. These heat treatments remove the mechanical strains and improve the magnetic characteristics. One method[23] for annealing consists of heating the material, protected against oxidation, at 800 to 1000 C (1470 to 1830 F) or higher, and then cooling it slowly. Another treatment[22] for silicon steel, initially hot rolled and finally cold rolled by a special process, consists of coating the sheets with a refractory powder and then annealing them in flat packs at 1200 C (2200 F) for 60 hr in purified hydrogen. The material produced by the latter method has a high degree of preferred orientation of the crystals, which affects the magnetic properties.

Laminations from this silicon steel sheet are frequently annealed again after punching, in order to remove the harmful effects of the cold work on the magnetic and mechanical properties. One recommended treatment for improving the characteristics of silicon steel laminations[20] after stamping, consists of heating to 760 to 790 C (1400 to 1450 F) for 2 hr, under nonoxidizing conditions, and then slowly cooling. For additional information on magnetically soft materials, see the article on page 587.

Titanium in Steel

By G. F. Comstock* and S. F. Urban*

UNTIL recently, titanium was used in the steel industry almost exclusively for deoxidation, leaving negligible residual amounts of titanium in the solid steel.[1] The earliest use of titanium as an alloying element was in austenitic stainless steel, where titanium contents greater than a critical minimum were found to prevent intergranular corrosion and embrittlement by stabilizing the carbon as titanium carbide.[2] Titanium has been used also for stabilizing the carbon in plain chromium steels, to prevent hardening during rapid cooling in air.[3] At present such applications of titanium are being extended to plain carbon[4] and other low-alloy steels.[5] To qualify as an alloying element in steel, titanium should be present in amounts of 0.025% or more; smaller titanium contents are typical of steels that have been deoxidized by titanium, in which the effect of the element as an alloy addition is not attained.

Titanium is discussed here as an alloying element in steel, exclusive of stainless and high-alloy types.

The Effect of Titanium on the Strength of Ferrite. In steel of very low carbon content or in ingot iron, which is not hardenable by heat treatment, titanium increases the hardness and strength by entering into solid solution in the ferrite. Titanium has been reported[6] to have a greater effect in this respect, per weight percentage in the ferrite, than any of the usual alloying elements except silicon and beryllium. The relative effects of the various alloying

* The Titanium Alloy Manufacturing Company, Niagara Falls, N. Y.
Prepared for the Subcommittee on Alloying Elements in Steel

elements on the strength of ferrite are indicated by Fig. 1.[6] Since hardness is known to be closely related to tensile strength, these same relations may safely be assumed to apply with reasonable accuracy to the effects of the elements on hardness of ferrite, regardless of heat treatment.

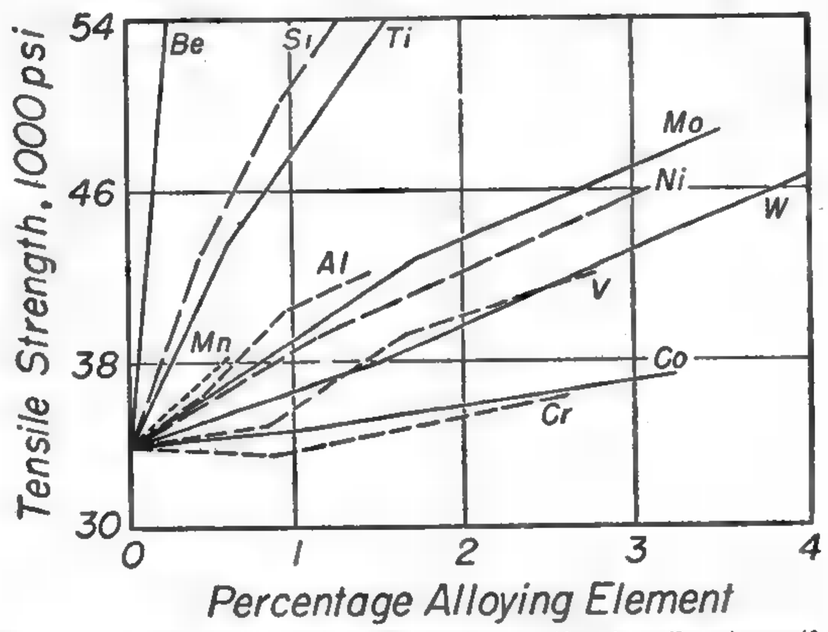

Fig. 1 Influence of alloying elements on the tensile strength of ferrite (Lacy and Gensamer[6])

Titanium in Age Hardening Reactions. The phase diagram of the iron-titanium system indicates a decrease in solubility of the compound Fe_2Ti in ferrite with decreasing temperature, so alloys that contain about 2.5 to 7% Ti can be temper hardened or age hardened by appropriate heat treatment. The effects of titanium content and aging or tempering temperature are shown in Fig. 2.[8]

Similar effects are obtained in medium-carbon and high-carbon steels, though perhaps through a more complicated set of reactions, since titanium does not form double carbides as do most alloying elements. Alloys that contain appreciable quantities of carbon can be age hardened if the quench before aging is from a temperature high enough to dissolve the titanium carbide. The minimum temperature required for accomplishing this end varies with the carbon and titanium contents and can be understood best from a study of the Fe-Ti-C system, discussed on page 1256 in this Handbook and in other technical publications.[10,11] One specific illustration of age hardening in 0.21 to 0.24% C steels is shown in Fig. 3.[11]

Elevation of Grain-Coarsening Temperature by Titanium. When used in sufficiently large amounts in steel, titanium produces a finer grain size. In this respect its action is similar to that of vanadium or aluminum. However, when titanium is added along with aluminum, the fine grain size is kept from coarsening at higher temperatures than when aluminum is used alone, even in abnormally large amounts. A comparison of the ASTM austenitic grain sizes in a titanium steel and a plain carbon steel not treated with aluminum, after normalizing at various temperatures, is given in Table I,[12] and the effects on

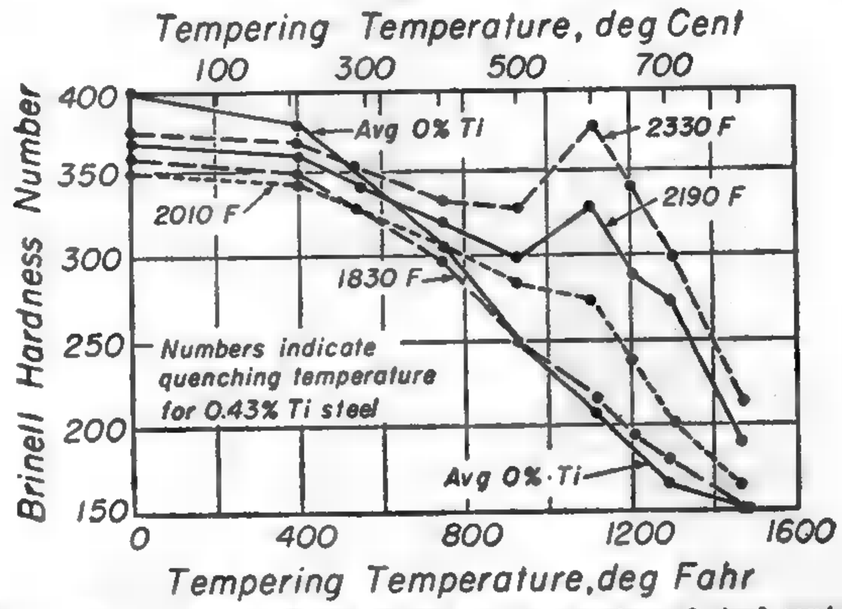

Fig. 3 Changes in hardness during the tempering of steel containing 0.21 to 0.24% C (Houdremont, Naumann and Schrader[11])
The numbered curves apply to 0.43% Ti steel after water quenching from different temperatures, and the other curve applies to plain carbon steel quenched from 1650 to 2330 F (900 to 1280 C).

(a) Total aluminum contents were as follows: 0.13% for No. 149, 0.11% for No. 159, 0.10% for No. 158, and 0.05% for No. 162.

the grain-coarsening temperature when various amounts of titanium are present with aluminum, are illustrated in Table II.[13]

The results obtained from heat No. 149 in Table II show that the use of a larger amount of aluminum for deoxidation does not necessarily raise the grain-coarsening temperature. Increasing the titanium content, however, was effective in that direction. All the steels that contained more than 0.2% Ti had grain-coarsening temperatures at least as high as 1950 F, while one steel containing no more than 0.12% Ti did not coarsen at the temperature that produced coarsening in the aluminum-deoxidized or zirconium-deoxidized steels without titanium.

Effect of Titanium on Strain Aging and Embrittlement. One method of measuring the tendency toward strain aging is the "work brittleness" test.[14] A comparison of titanium steels with those deoxidized by aluminum is shown in Fig. 4. In this figure there is no comparison with semikilled steels, which are much more susceptible to "work brittleness" than either the titanium steels or those deoxidized with aluminum.[15] Another method for measuring the strain aging tendency is by the character of the stress-strain curve, or the knee of the stress-strain curve, for low-carbon steels.

Low-carbon steel containing more than enough titanium to combine with all the carbon, is extremely resistant to all kinds of strain aging, including the type revealed by the return of a definite yield point in sheets that are aged after cold rolling.* The effect of titanium on the yield point is illustrated by Fig. 5.[16] With more than 4.5 times as much titanium as carbon, steel has no definite yield point, but gives stress-strain curves like those characteristic of nonferrous alloys,[17] whether normalized, annealed, or aged after straining. Such steel, therefore, does not develop stretcher strains when deep drawn.

Tensile properties of titanium steel of this type, in the form of sheets produced by commercial methods from basic open hearth heats, are reported in Table III.[18] The test specimens were about 0.073 in. thick, 1.5 in. wide, and slightly more than 8 in. long between shoulders. The aging procedure consisted of holding the metal for three weeks at room temperature and for one hour at 450 F. The strength of this steel is shown generally to decrease slightly

on aging, with an improvement in ductility; whereas ordinary sheet steel, or even the so-called "nonaging" aluminum-killed steel, normally increases as much as 25% in yield strength during aging at 450 F after as much as 5% strain, and may lose half of its ductility.[18]

Titanium Enameling Iron. There are numerous references in technical publications to the possibility that "reboiling", in enameling, is related to liberation of hydrogen from the steel during the fusion of the cover coat on the ground coat. None of these references suggest the possible formation of hydrogen as a product of the reaction of water vapor with the carbides of steel. This water vapor may be in the atmosphere of the enameling furnace or may result from the combined water present in the enamel slip applied to the iron surface. Another hypothesis that associates carbides with reboiling, assumes that a reaction occurs between these carbides and oxides from the enamel; the union is presumed to result from diffusion at the enameling temperature and to produce carbonaceous gases. In any event, laboratory and commercial tests have indicated that low-carbon steel containing enough titanium to fix all the carbon, is always immune to reboiling,[19] by virtue of the

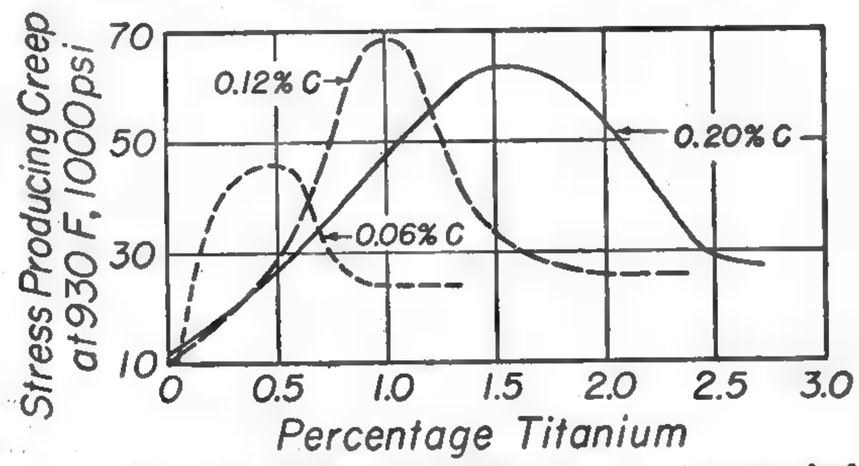

Fig. 6 Effect of titanium in low-carbon steels, water quenched from 2190 F (1200 C) and tempered at 1110 F (600 C), on the stress producing creep of 0.001% per hr between the 25th and 35th hr, under load at 930 F (500 C) and not more than 0.2% permanent set in 45 hr (Bardenheuer and Fischer[20])

extremely low reaction rate of titanium carbide with water vapor or oxides at the enameling temperature, compared with any other known carbide. This refers specifically to reboiling phenomena; another technical article[19] deals with such problems as adherence.

Strength at Elevated Temperature. The normalizing of titanium steels at temperatures higher than 2000 F develops rather high resistance to creep. This is probably a result of the precipitation hardening that occurs during tempering after the high-temperature heating. Figure 6 shows how the creep resistance varies with the titanium content in three different carbon steels heat treated as indicated.[20] Here it is evident that titanium-carbon ratios of 7 to 9 give the highest values. At the quenching temperature used (2190 F) this titanium-carbon ratio coincides approximately with the limit of the single-phase gamma field in each steel. Thus it appears that the creep strength rises with the titanium content of the gamma phase as long as no alpha is present, but drops when, because of still higher titanium content, the alloys also contain some alpha at the temperature used for the solution heat treatment.

The presence of other alloying elements with titanium in the steel improves the creep strength, as compared with the value obtainable from a single alloying element.[20,21]

Titanium steels have a high resistance to attack by hydrogen-hydrocarbon mixtures. "Resistance" in this connection means that decarburization and loss of ductility are low. The comparison between the stability of titanium steels in the presence of hot hydrogen and that of steels containing other elements is approximately proportional to the stability of the respective carbides.[9] Figure 7 presents a comparison, in this respect, of most of the common alloying elements in steel. As indicated in Fig. 7, titanium steels are of no special value for resisting hydrogen unless they contain at least four times as much titanium as carbon, so that no iron carbide occurs in them.

To illustrate more explicitly the effect of titanium on the loss of carbon and of ductility in steels exposed to hot

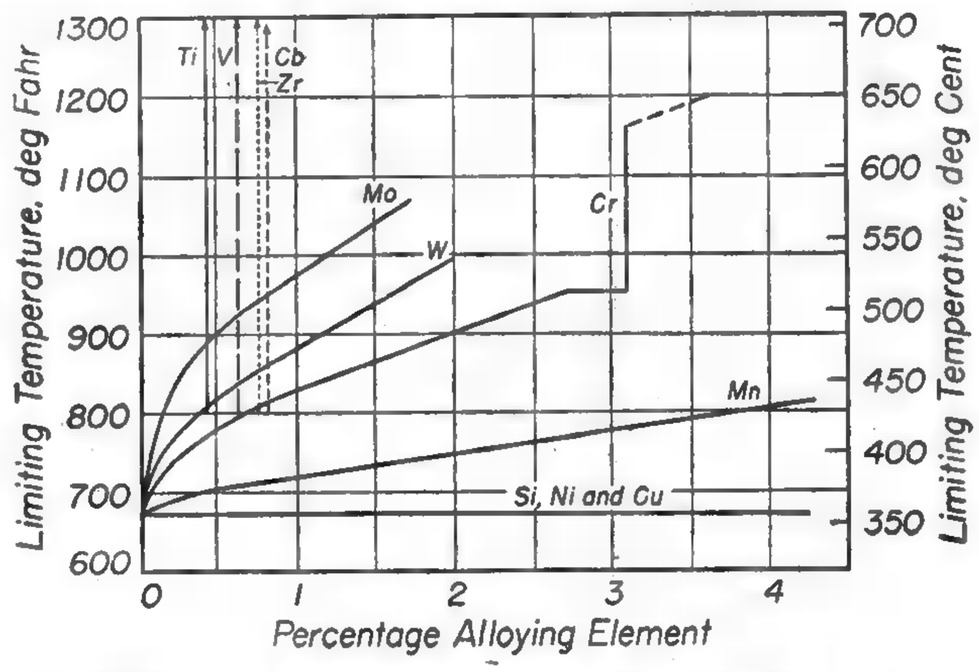

Fig. 7 Influence of alloying elements on resistance of 0.1% C steels to hydrogen at 4267 psi for 100 hr (Naumann[9])

hydrogen, the data in Table IV[9] are presented. These results from 100-hr experiments have been confirmed by recent American tests of thousands of hours duration and at various pressures and temperatures.[18] The results indicate that in all instances where all the carbon was stabilized by more than four times as much titanium, the steels have retained their normal ductility and other mechanical properties, provided nitrogen was not involved in the exposure.

Properties of Titanium Steels at Room Temperature. The variation in the properties of a 0.37% C steel with titanium contents in the range from 0 to 0.94% is illustrated in Fig. 8. These steels were all melted in large electric-arc furnaces and were deoxidized with aluminum for controlled grain size. The titanium steels came from the same heat but low-carbon ferrotitanium had been added to the ingot molds in different amounts. The steel that contained no titanium was made at a different mill. The compositions are reported in Table V.

Table IV. Influence of Titanium on the Carbon Content and Ductility of Steels Exposed to Hydrogen for 100 Hours Under 4267 psi Pressure at the Temperatures Noted[9]

0.80	3.70	4.6	0.80	0.80	0	0

The ingots were rolled to bars 1.5 in. in diam and were forged to bars ⅞ in. in diam before heat treatment. The mechanical properties are compared in four conditions of heat treatment, as indicated in Fig. 8. The strength of the titanium steel is shown to be greatly increased by normalizing at 2150 F, as compared with 1750 F, but the ductility is correspondingly reduced. The impact values of the titanium steels are very low after high-temperature normalizing, even though the grain size is not coarsened as much as that of the carbon steel. Thus it is evidently the solution of titanium or titanium carbide in the ferrite at high temperature that promotes notch sensitivity, rather than mere increase in grain size.

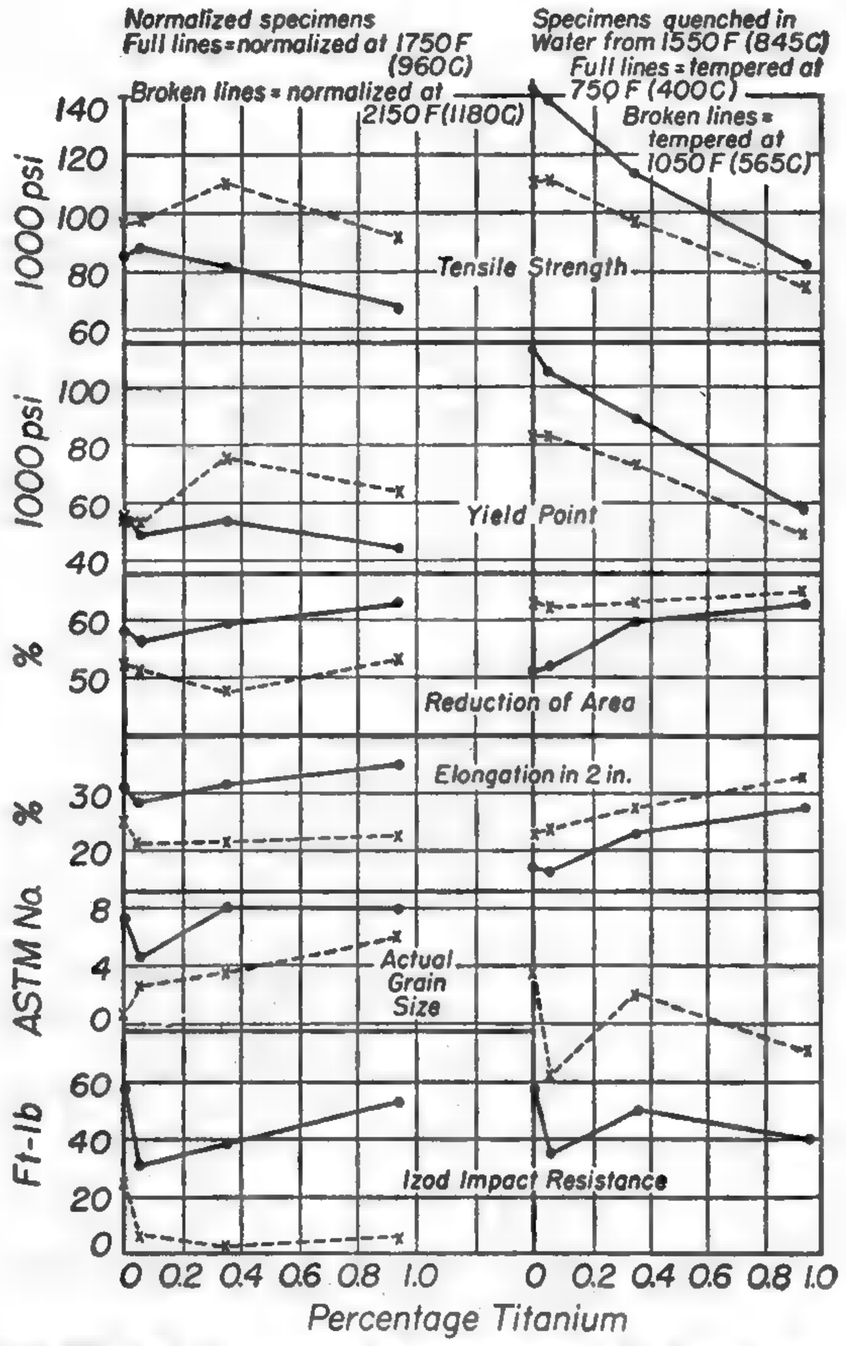

Fig. 8 Effect of titanium on the properties of forged and heat treated aluminum-deoxidized 0.37% C steel. (*See* Table V for chemical compositions.)

Table V. Compositions of Steels Referred to in Fig. 8

Steel	C	Mn	Si	Al	Titanium
Carbon	0.35	0.72	0.27	Present	None
Titanium	0.37	0.63	0.26	0.21	0.05
				0.26	0.35
				0.09	0.94

The Effect of Titanium on Hardenability. As indicated in one of the preceding sections, titanium raises the grain-coarsening temperature of steel. Because of this, hardenability is decreased by reason of a decrease in grain size. Thus the effect of titanium on hardenability is evident only when very high quenching temperatures are employed—high enough to dissolve the carbides. These temperatures are considerably higher than any normal heat treating range.

Tungsten in Steel

By J. Y. Riedel*

TUNGSTEN was the first alloying element used in tool steels. Mushet steel, containing about 12% W, was the first commercial alloy tool steel. Great prominence was given tungsten alloy tool steels by the discovery of Taylor and White, in 1898, that high-temperature heat treatment of tungsten steels develops superior cutting ability. Thereafter, tungsten steels that had been given this special treatment were known as "high speed steels".

Tungsten alloys with iron in all proportions and combines with carbon to form complex carbides in steel. There are two principal ways in which tungsten produces useful properties in steel: (1) by enabling the steel to resist the effects of elevated temperatures and (2) by forming an extremely hard, abrasion-resisting carbide. The combination of these two effects produces the characteristics found in high speed steels. It should be noted that tungsten not only enables steels to maintain their strength at elevated temperature, but also tends to decrease the extent of softening that normally occurs during tempering.

Tungsten steels are used only where the properties produced by the tungsten addition are unique. No standard SAE or AISI alloy steels contain tungsten, because the properties desired in these steels can be more readily obtained by the use of less costly alloying elements. For many alloying purposes, tungsten is considered only one-half as effective, weight for weight, as molybdenum, the element which it most closely resembles in its effects on steel. Since for a number of years the price of tungsten has been twice that of molybdenum, it is obvious that marked advantages must be obtained from tungsten-bearing steels, compared with molybdenum-bearing steels, in order to justify their use. High speed steels containing 18% W are the most widely used tungsten steels. In European practice there has been some tendency to use Ni-Cr-W steels instead of the Ni-Cr-Mo steels commonly used in this country. However, this is undoubtedly because of the scarcity of molybdenum and the relative abundance of tungsten in Europe.

* Bethlehem Steel Company, Bethlehem, Pa.
Prepared for the Subcommittee on Alloying Elements in Steel

The Effect of Tungsten in Ferrite and Low-Carbon Iron Alloys. The solid-solution strengthening effect of tungsten in annealed low-carbon iron-tungsten alloys, as reported by Lacy and Gensamer,[1] is given below. On the basis of the data shown as weight percentage, tungsten appears to be a mild ferrite-strengthener by comparison with some other elements. However, if a comparison is made on the basis of atomic percentage, it is found that tungsten is surpassed only by titanium and beryllium.

Tungsten, weight %	0	1.44	3.05	3.99
Tensile strength, psi	33,900	37,750	43,550	46,300
Tungsten, atomic %	0	0.44	0.95	1.25

The following tabulation, from information reported by Bain,[3] shows the same effect when measured in terms of Brinell hardness numbers. It should be noted, however, that these data are estimates rather than actual test data. On the basis of weight percentage, tungsten is about one-half as effective as molybdenum in strengthening ferrite; but as indicated above, tungsten is more effective when comparing on a basis of atom for atom instead of weight for weight.

Tungsten, %	0	2	4	6	10	14	18	23
Bhn	70	80	90	100	115	130	145	160

In carbon-free alloys the maximum solid solubility of tungsten is 33% in ferrite at 2800 F (1538 C). This solubility decreases to about 4.2% at room temperature, so that the possibility of precipitation-hardening alloys in this range of composition is indicated. Actually, carbon-free iron-tungsten alloys from 10% to 50% W show marked precipitation hardening, because of precipitation of iron tungstide, Fe_3W_2. A Brinell hardness of approximately 500 can be developed in alloys of 30 to 40% W by water-quenching from 1500 C (2732 F) and aging at 700 C (1292 F), according to Sykes.[3]

The Effect of Tungsten on Medium-Carbon or High-Carbon Steels in the Pearlitic Condition. Tungsten additions to medium- or high-carbon steels tend to suppress the formation of definitely lamellar pearlite when these steels are cooled from above the transformation range, as, for example, after rolling or normalizing. Fairly rapid air-cooling produces structures of the Widmanstätten type. In these structures the ferrite is dispersed, showing little tendency to outline the original austenitic grains. Retarding the cooling rate produces little change except that the carbide is converted to a spheroidal form.

There are very few data on the properties of pearlitic tungsten steels, probably because tungsten is rarely used alone in an alloy steel. In general, tungsten increases the hardness and strength of normalized and annealed steels. Table I shows typical data illustrating this point.[4]

The Effect of Tungsten on Behavior During Heating for Hardening. The addition of tungsten to steel narrows the range where stable austenite can exist, and in turn, enlarges the range of stable ferrite. The iron-tungsten diagram exhibits a typical gamma loop, showing that no austenite can exist above 6% W. Tungsten is therefore classed as a ferrite-forming element in steel, as well as a carbide-forming element. The presence of 0.1% C enlarges the gamma loop to 10% W, while 0.3% C allows some austenite to exist in the presence of 20% W.

Some tungsten-bearing compositions show an unexpectedly low hardness after quenching. This is because at the quenching temperature the alloy is in a region of mixed austenite and ferrite. The inability to obtain complete austenitization results in low hardness. As an example of this, Gill and others[7] cite an instance where 18% W, 4% Cr, and 2% V steel with less than 0.50% C shows a low hardness after quenching; while with half this alloy content and the same carbon content and heat treatment a hardness of Rockwell C 60 can be attained.

Tungsten is considered one of the strongest carbide-forming metals. In steel, tungsten forms a complex carbide of varying composition, usually assumed to be Fe_4W_2C or Fe_3W_3C. Under some conditions, this complex carbide may decompose to form a simple tungsten carbide, WC.

Tungsten has a pronounced effect on the eutectoid temperature and the eutectoid composition of Fe-W-C alloys, as illustrated in Fig. 1 from Bain.[3] In common with other alpha-forming elements, tungsten raises the temperature of the eutectoid reaction, thereby requiring an increase in the heating temperature that is necessary for hardening. Increased tungsten content also lowers markedly the carbon content of the eutectoid. This fact, in addition to the abrasion-resisting character of the carbides, is important in explaining the great wear resistance of tungsten steels, since the lower the carbon content of the eutectoid, the greater the amount of free carbide in a steel of a given carbon content.

Although there are no quantitative data, it is known that the carbides in tungsten steels are dissolved in austenite only with great difficulty, and that extremely long times are required to approach conditions of equilibrium in an austenitizing treatment. This fact is believed to be responsible for the reputation of tungsten steels for exhibiting fine grain size. The relatively insoluble carbides

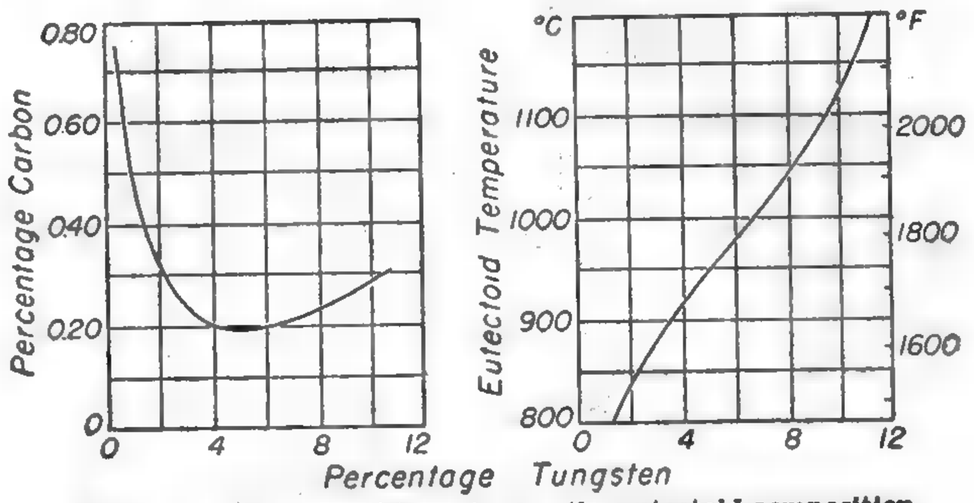

Fig. 1 The influence of tungsten on the eutectoid composition and eutectoid temperature

are so effective in restricting grain growth that in tungsten finishing steel it is possible to obtain a finer grain size than in any other type of steel.

The difficulty of dissolving the carbides in tungsten steels is probably also responsible for the confusion that exists in the literature concerning the effect of tungsten on hardenability. It is a recognized fact that at relatively low quenching temperatures, where very fine grain size is attained, a tungsten steel shows a more shallow depth of hardening than does a carbon steel of the same carbon content. On the other hand, high quenching temperatures combined with long holding times result in complete carbide solution, and the depth of hardening is considerably greater than in a carbon steel of the same carbon content, treated in the same manner. However, there are no quantitative data that measure the exact contribution of tungsten to hardenability, such as the Grossmann multiplying factors available for other elements.

The Effect of Tungsten on Behavior During Cooling from the Austenitic State. No reliable data are available to show the precise effect of tungsten on the behavior of steels during cooling from the austenitic state. In a general way it is known that when tungsten is in solution, transformation of austenite is very sluggish. This means that the upper portion, or "nose", of the "S-curve" is displaced to the right, resulting in a tendency towards air-hardening. When tungsten is not in solution, its effect on transformation of austenite is almost negligible. This has been shown by S-curves published by Payson and Klein,[5] where it will be noted that the curve for 1.14% C tool steel is almost identical with the curve for tungsten finishing steel.

Although tungsten is usually considered a strong carbide-forming element, there are circumstances where the complex carbide decomposes during annealing or slow cooling. Gregg[6] quotes several instances where tungsten carbide, WC, was formed in annealing 6% W steel, while Gill and others[7] cite instances where graphite was formed in the same type of steel.

The Effect of Tungsten on the Tempering of Quenched Steels. It is a widely known fact that tungsten enables steels to resist the softening that takes place during the tempering after quenching. Data from Bain,[8] shown in Fig. 2, illustrate this effect. The fact should be emphasized that, in order to produce this effect, the tungsten must be in solution. Tungsten present in undissolved carbides is totally ineffective in resisting the effects of tem-

Table I. Strength and Hardness of Tungsten Steels[4]

% C	% W	Tensile Strength, psi	Bhn
0.12	0.41	58,500	97
0.11	0.94	60,000	97
0.11	1.75	69,500	109
0.13	4.96	90,000	153
0.17	11.89	123,200	223
0.86	0.40	147,000	241
0.85	0.95	160,900	241
0.80	2.75	177,000	302
0.83	4.68	180,000	302
0.81	9.99	191,700	293

pering. It is believed that the temper resistance of tungsten steels results from the extreme reluctance of the complex tungsten carbide to precipitate and coalesce.

Many tungsten steels show a secondary hardening effect similar to that obtained in tempering high speed steels. Since virtually all the commercial tungsten steels contain other alloying elements in addition to tungsten, the contribution of tungsten in this respect is difficult to measure accurately, though it is undoubtedly considerable.

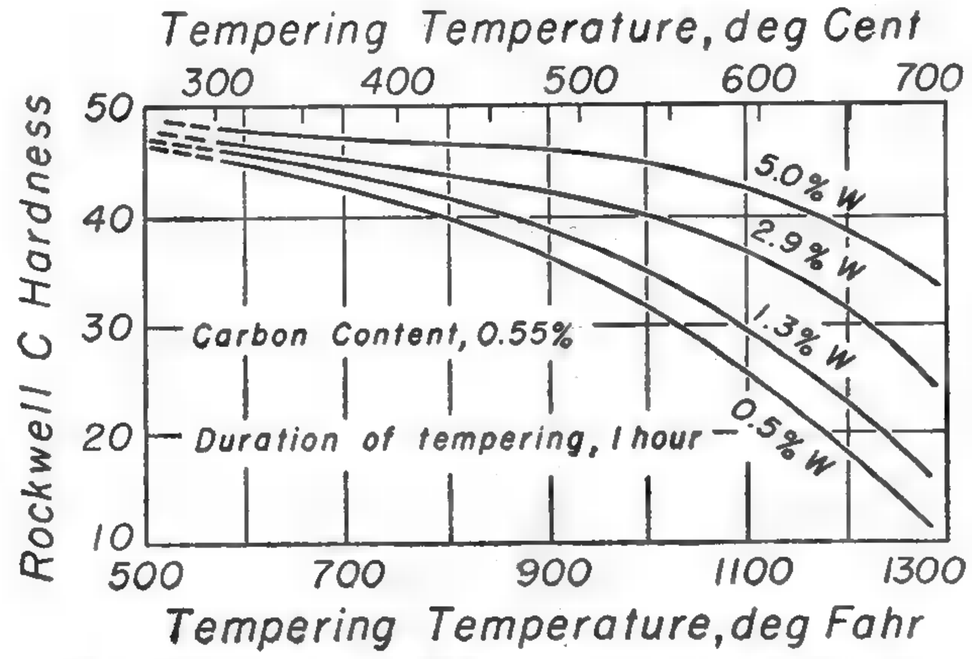

Fig. 2 The effect of tempering temperature on the hardness of quenched 0.55% C steels containing various amounts of tungsten

The superior resistance to tempering is responsible for two advantages of tungsten steels as compared with other steels; namely, greater strength at elevated temperatures and greater toughness at the same hardness. The ability to cut or deform materials depends on the hardness and strength of the tools at the operating temperatures of the working surfaces. Thus, greater strength at high temperatures makes tungsten steels suitable for cutting-tool and hot die applications. The greater toughness of tungsten steels is accounted for by the relief of residual stress previously developed in the quenching operation. High tempering temperatures are more effective than low temperatures in relieving stress; and if the stress can be relieved with no additional loss of hardness, the tool will have greater ability to withstand service stresses.

The effect of tungsten on temper brittleness is not accurately known. Some investigators report that tungsten does not affect the temper brittleness of a given steel; others report that it resembles molybdenum in that it reduces the susceptibility. However, it is known that tungsten is less effective than molybdenum in reducing the susceptibility to temper brittleness; therefore molybdenum is always chosen for this purpose in modern steels.

Special Effects of Tungsten in Steel. *High Speed Steels.* The outstanding application of tungsten is in high speed steel (typical composition, 18% W, 4% Cr, 1% V, 0.70% C). Although it is possible to make high speed steels without tungsten, it is generally agreed that some tungsten is necessary to produce a tool of highest cutting efficiency. The fact has already been mentioned that the characteristics of high speed steel depend on the combination of the resistance of the matrix to tempering and the wear resistance of the free carbides.

Hot Work Steels. The resistance of tungsten steels to tempering is obviously a useful property for a hot work steel (typical composition, 10% W, 3% Cr, 0.30% V, 0.35% C). In addition to this, tungsten steels are useful in hot work operations even where the surface working temperatures exceed the tempering temperature. This is because of the very slow rate of additional loss of hardness that occurs in service under these conditions.

Finishing Steels. The usefulness of the finishing steels (approximately 3.50% W, 1.35% C) for maintaining a keen cutting edge is obviously associated with the wear resistance of the free carbides. However, this type of steel also develops a peculiar slippery glazed surface during service. This phenomenon, which has not been scientifically evaluated, may be associated with the coefficient of friction and undoubtedly contributes to the wear resistance of this type of steel.

Creep-Resisting Steels. Tungsten might be expected to increase the creep strength of steel in the same manner as molybdenum. Two low-alloy, creep-resisting steels are commercially recognized in specification ASTM A 193-46T. Compositions of these steels are as follows:

Grade	C	Mn	Si	Cr	Mo	W	V
B11	0.42/0.49	0.25/0.40	0.20/0.35	1.00/1.50	....	1.70/2.30	0.20/0.30
B13	0.38/0.45	0.75/1.00	0.20/0.35	0.50/0.70	0.45/0.65	0.85/1.35	....

Recently a tungsten modification of a stainless steel has been found useful in resisting creep at temperatures as high as 1100 F. The approximate composition of this alloy is 0.12% C, 12.0% Cr, 2.0% Ni and 3.0% W.

Oxidation-Resisting, High-Temperature High-Strength Alloys. Various attempts have been made to improve the high-temperature strength of austenitic nickel-chromium steels by the use of tungsten. At present there are no standard AISI stainless steels containing tungsten, but one of the most widely used exhaust-valve steels is a modified austenitic stainless steel. The approximate composition of this steel is 0.45% C, 14.0% Cr, 14.0% Ni and 2.5% W.

It has been reported that during the past five years considerable research work has been started to develop alloys with high-temperature strength combined with oxidation resistance, primarily for use in gas-turbine parts. Although this work is far from complete, considerable progress has been made. The most promising alloys already developed (1946) are modified austenitic cobalt-nickel-chromium alloys, containing any or all of the following elements: tungsten, molybdenum, titanium and columbium. The tungsten content usually ranges from 1 to 4%. (*See also* pages 566 to 569 in this Handbook.)

Magnetic Properties. Tungsten has been added to steel for producing permanent magnets since the period between 1880 and 1890. One of the most widely used magnet steels was a 0.70% C, 5.5% W steel, and tungsten was also added to cobalt magnet steels in quantities of 3 to 9%. However, magnet steels containing tungsten have now been made virtually obsolete by cast or powdered metal alloys, such as the Fe-Ni-Al or Fe-Ni-Al-Co types.

Density. Because of its high density, tungsten increases the density of steels to which it is added. The weight of a given volume of 18-4-1 type high speed steel is calculated on the basis that the density is 10% greater than the density of ordinary steels. Although high density is often considered a disadvantage, it is because of the high density that the 18-4-1 type of high speed steel has been used for counterweights.

Vanadium in Steel

By Jerome Strauss* and F. F. Franklin*

VANADIUM is used in steels because of two principal functions that sometimes appear to be not entirely distinct. These functions are (1) the refinement of the grain structure, and (2) the behavior of the vanadium carbide, principally its stability at elevated temperatures, and its solution in, and separation from, the metallic matrix of the steel.

Vanadium is soluble in ferrite; however, the tendency of vanadium to form carbide is so strong that except when an excess of vanadium is present, it is found mainly in the carbide phase. In addition to forming carbides, vanadium also forms oxides and nitrides, but the behavior of vanadium with oxygen and nitrogen in steels has been studied much less than the reactions of vanadium with carbon.

It has been demonstrated[1] that these carbides influence the characteristics of grain refinement in vanadium steels, although how much of the grain refinement may result from the properties of oxides and nitrides that may be formed, is among the facts not yet established. Nevertheless, it is well known that these fine structures are produced by vanadium in primary crystallization from the melt, as well as in phase transformations during heat treatment. Quite apart from the control of grain size in cast and wrought steels is the use of vanadium to produce fine carbide structures in hypereutectoid steels, thereby influencing the distribution of free carbide after hot working. Furthermore, the presence of carbide widens the hardening range of low-alloy steels that contain vanadium. In this respect there is some similarity between vanadium and the aluminum used in aluminum-treated steels, but with distinct differences that will be discussed later.

Differences of opinion exist concerning the relative deoxidizing power of vanadium when compared with other oxide-forming elements. However, in view of the fact that vanadium is too expensive to use as a commercial deoxidizer, it is sufficient to indicate that vanadium is far from being the strongest of these agents. It is much less active than aluminum, for example.

In the solid state vanadium and nitrogen form stable nitrides that have been utilized in the development of special steels for nitriding. In the molten steel bath, the procedure by which vanadium nitrides are formed and their subsequent reactions in the solid state have not yet been studied in detail, although a few facts have been established as indicated hereafter.

The Effect of Vanadium in Ferrite and Low-Carbon Iron Alloys. Vanadium and alpha iron are mutually soluble in all proportions in the solid state at temperatures higher than 1234 C, and are likewise soluble at temperatures lower than this, except in the range of composition in which the intermediate phase FeV exists. However, this range of vanadium content is beyond any thus far used in steels or other finished alloys; it is wholly in the composition range of the ferro-alloys that are used to introduce vanadium into liquid steel.

In working with binary alloys in which, though not determined, the carbon was asserted to be less than 0.01% and the other impurities correspondingly low, Lacy and Gensamer[2] found that vanadium increased the tensile strength of ferrite in the proportion of about 4000 psi for 1% V. Table I gives the tensile properties of the three iron-vanadium alloys, along with those of the iron of lowest manganese content, as a basis for comparison.

Edwards, Phillips and Jones[3] determined the properties of 0.025% C annealed alloy steels containing 0.26, 0.55 and 0.69% V. Their results are shown in Table II, along with the properties of a steel that has a very low aluminum content. This low-aluminum steel is the only one that contained no vanadium, in this series.

Investigating the effects of vanadium on annealed steels that contain slightly more carbon (0.10% C), Hougardy[4] found that the hardness is first raised to a maximum value at about 0.5% V, then is rapidly reduced, and is gradually increased thereafter by additional amounts of vanadium. Table III is an abstract of this work.

Although Vogel and Martin[5] stated that vanadium increased the solubility of carbon in ferrite to a considerable degree, subsequent work[6] has shown that such an increase is slight and that the solubility values of carbon in ferrite that contains vanadium, are very close to those of carbon in pure alpha iron.

Age Hardening. Although age hardening alloys probably exist in the iron-vanadium system (*see* page 1219 in this Handbook) the compositions that might be affected have not been studied from this standpoint. The influence of vanadium on the age hardening of carbon and rimming steels is not simply an effect of vanadium on ferrite and is described later in this article.

The Carbide Phase. The common form of vanadium carbide is V_4C_3. Another form, VC, is presumed to exist but specific information about it is lacking.

Table I. Tensile Properties of Annealed Iron-Vanadium Alloys

Elongation, %	31.8	28.1	27.1	23.9

In affinity for carbon, vanadium stands between chromium and manganese on the one side, and titanium and columbium on the other. Likewise, vanadium carbide is less soluble in austenite than are carbides containing chromium and manganese, but vanadium carbide dissolves to a greater extent than titanium carbide.[1]

Table III. Hardness of Annealed 0.10% C Steel

Vanadium, %	0.0	0.5	0.7	1.6	2.7	4.7
Hardness R_B	61	72	65	65½	66	68

Apparently vanadium carbide is slightly soluble in ferrite; it dissolves to a considerably greater degree in austenite but the rate of solution is low and the individual particles that remain undissolved are a major cause of the restraint of grain growth.

Vanadium carbide is only slightly soluble in iron carbide. The double carbide formerly presumed to exist is an ex-

tremely fine mechanical mixture of vanadium carbide and iron carbide.[5]

Effect of Vanadium on Medium-Carbon and High-Carbon Steels in the Pearlitic Condition. The effects on mechanical properties of steel when vanadium is used as the principal alloying agent are illustrated in Table IV, which lists the properties of plain carbon and carbon-vanadium steels identical in carbon contents, after these steels have been quenched and tempered to a given tensile strength, normalized and tempered, and annealed.

Vanadium is used in steel castings, especially in the production of certain alloy grades, to prevent the formation of hard spots caused by localized martensite, with consequent improvement in machinability. In welded steels, vanadium serves a similar purpose by preventing hardening and embrittlement of the zone affected by heating during the welding operation. This elimination of hard spots and the resistance to hardening in welding operations are probably caused by the influence of vanadium on phase transformations, which is discussed in a later section.

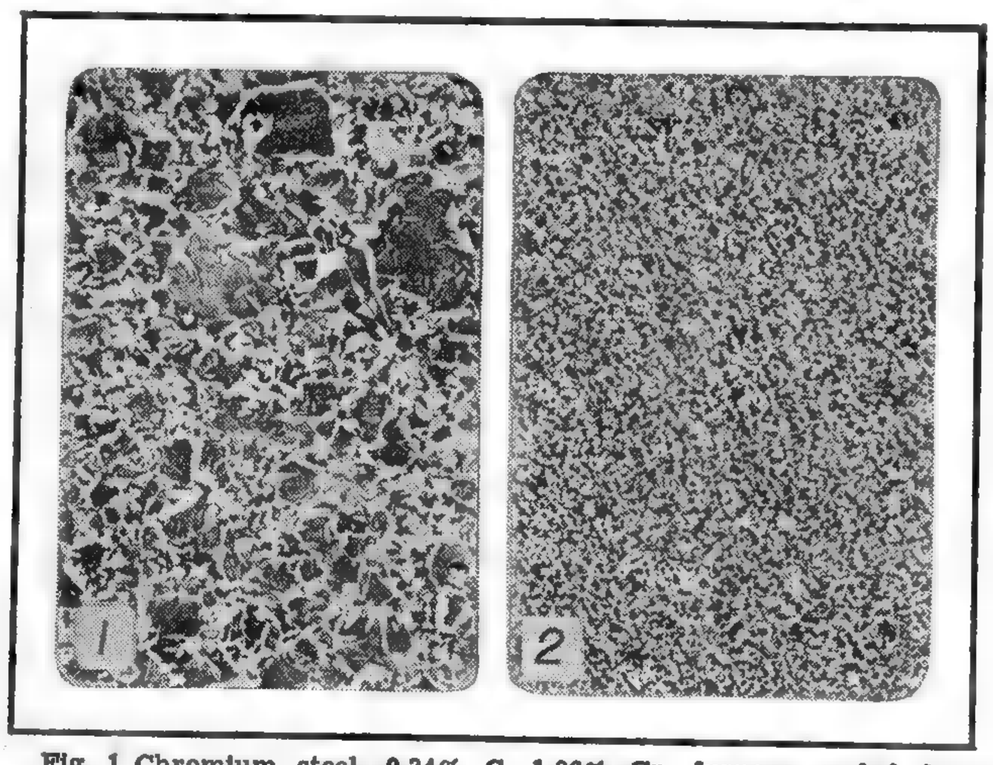

Fig. 1 Chromium steel, 0.34% C, 1.06% Cr, furnace cooled from 1550 F

Fig. 2 Chromium-vanadium steel, 0.34% C, 1.09% Cr, 0.26% V, furnace cooled from 1550 F

The effects of vanadium on the properties of a steel when more than one principal alloying element is present are indicated in Table V, which shows the effects of vanadium on a chromium steel when annealed, and when quenched and tempered.

Figures 1 to 4 show the effects of vanadium on the microstructure of chromium steels that have identical carbon contents, when furnace cooled from 1550 F and 1850 F.

The Effect of Vanadium on Behavior During Heating for Hardening or for Normalizing. Vanadium raises the A_3 point and lowers the A_4 point progressively to close the gamma loop. The solubility of vanadium in carbon-free gamma iron is limited to about 1%. Carbon increases the extent of the gamma field, but this increase may be offset by the addition of vanadium in approximately the ratio of vanadium to carbon in V_4C_3.

The rate at which vanadium carbides dissolve during austenitizing depends on their amount, size and dispersion in the matrix. Zimmerman, Aborn and Bain[9] found, in heating ■ 0.27% V, 0.87% C steel, that these carbides were only partly dissolved at 1700 F and that it was necessary to increase the temperature to 2000 F for effective solution. Table VI gives a comparison of the rates of solution of carbides in plain carbon and vanadium steels of eutectoid composition, when heated within and above the transformation range.

The fine austenitic grain sizes inherent in vanadium steels have been attributed by some investigators to nucleation effects of vanadium carbides, and by others to vanadium nitrides or oxides, or both. It now seems that any one or more of these phases may be responsible, providing they are properly dispersed in the matrix.

cellent ductility and impact resistance during the development of high tensile strength and yield strength. Vanadium increases the hardening range of pearlitic steels. Aluminum is the only other element commercially capable of producing and stabilizing grain refinement to a similar extent. In vanadium steels, however, the hardening range, although widened, remains consistently within well-defined values,

Table VI. Effect of Vanadium on the Solubility of Carbide in Austenite

and the upper limit is not so high as to create difficulty in grain coarsening preparatory to machining, by normalizing at moderate temperatures with subsequent recovery of fine grain structure by customary heat treatment. In carburizing operations at the usual temperatures, vanadium steels retain their fine grain size and develop high strength without loss of ductility and impact resistance, when quenched directly from the carburizing box.

The effects of vanadium on grain size are observed in quenched steels and in steel cooled more slowly from the austenitizing temperature, as shown in Fig. 1 to 4.

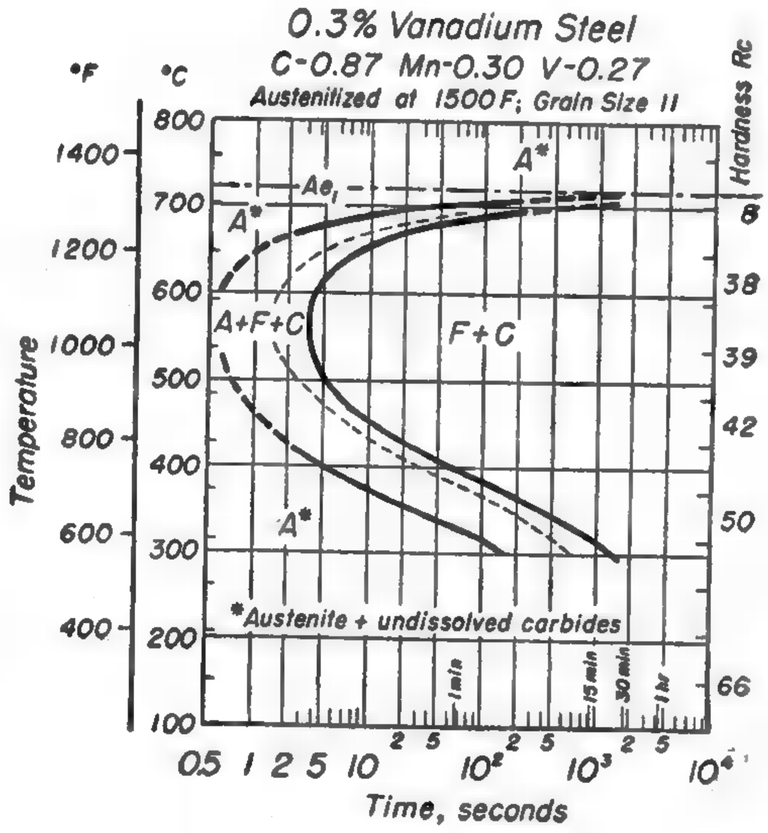

Fig. 5 Isothermal transformation diagram for a vanadium steel, austenitized at 815 C (1500 F) (U. S. Steel Corporation Research Laboratory)

The Effect of Vanadium on Behavior During Cooling from the Austenitic State. Vanadium held in solution in austenite retards the transformation of austenite during rapid cooling. Undissolved vanadium, dispersed throughout the austenite as particles of carbide or other compounds, acts as nucleating material which tends to prevent supercooling, and in this manner increases the rate of austenite transformation. Furthermore, since the undissolved carbides contain both vanadium and carbon, the matrix is impoverished in these elements and the rate of austenite transformation is correspondingly greater for this reason than the rate for austenite that contains all the vanadium and carbon in solution. Figures 5 and 6 illustrate the effects of these factors on the rate of transformation of austenite.

The Effect of Vanadium on the Tempering of Quenched Steels. Vanadium retards softening during the tempering of martensitic structures. This effect is seen in steels containing several alloying elements, as well as in those where vanadium is the principal alloying constituent. Figure 7 shows the effects of vanadium on the properties of quenched and tempered nickel steel.[7]

Secondary hardening may be observed within the tempering range from 900 to 1150 F, and has been attributed to precipitation. In certain compositions, for example in tool steels, hardness of the steel is actually increased, but in most commercial operations involving low-alloy steels, a retardation is observed in the loss of strength with increasing tempering temperatures.

According to Crafts and Lamont,[8] vanadium is more effective than any other element in retarding the softening of a steel during the tempering operation. Their investigation indicated that 0.03% V would retard softening of 0.30%

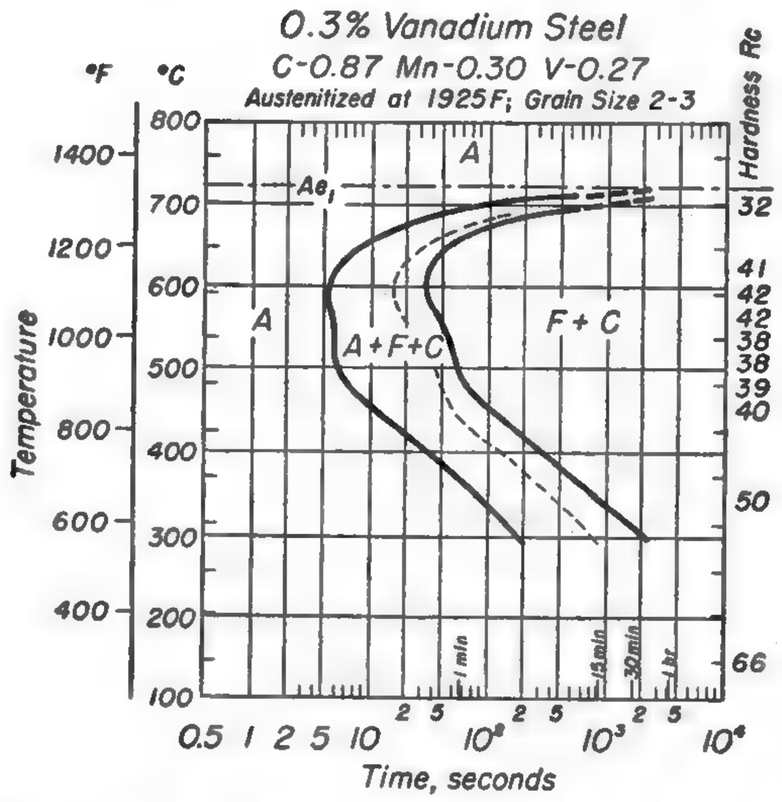

Fig. 6 Isothermal transformation diagram for a vanadium steel, austenitized at 1050 C (1925 F) (U. S. Steel Corporation Research Laboratory)

C steel by one Rockwell C unit after two hours at tempering temperatures of 1100 and 1200 F.

The retardation of the rate of softening, according to Zimmerman, Aborn and Bain,[9] is caused by the precipitation of vanadium-rich carbide, which has low diffusivity, wide dispersion and slow coalescence. This retarding effect has been ascribed also to the increase in solubility of carbon in ferrite, caused by the presence of vanadium, and subsequent precipitation during tempering within this range. Carbon-free iron-vanadium alloys of low vanadium content do not undergo secondary hardening.

It must be pointed out that only the vanadium that is held in solution is effective in retarding softening during tempering, and that this effect will not be developed to a substantial degree unless proper precautions have been taken during the austenitizing operation to dissolve an adequate amount of vanadium carbide.

The ability of vanadium steels to retain their hardness at elevated temperatures reflects the influence of vanadium in tempering.

Special Effects of Vanadium in Steel. *Properties at Elevated Temperatures.* The effect of vanadium on hardness at elevated temperatures has been noted previously. Table VII shows the creep rate at 850 F of a plain carbon steel in comparison with that of a vanadium steel.[10]

This retention of strength and hardness is responsible for the extensive use of vanadium steels for springs operating at elevated temperatures, such as exhaust-valve springs in internal-combustion engines and locomotives.

Tool Steels. Vanadium is added to tool steels to improve their serviceability and to refine the carbide structure,

which is otherwise extremely difficult to break up during the hot working of the steel. Small amounts of vanadium are sufficient to refine the carbide structure, but greater additions are used to obtain hardness at elevated tempera-

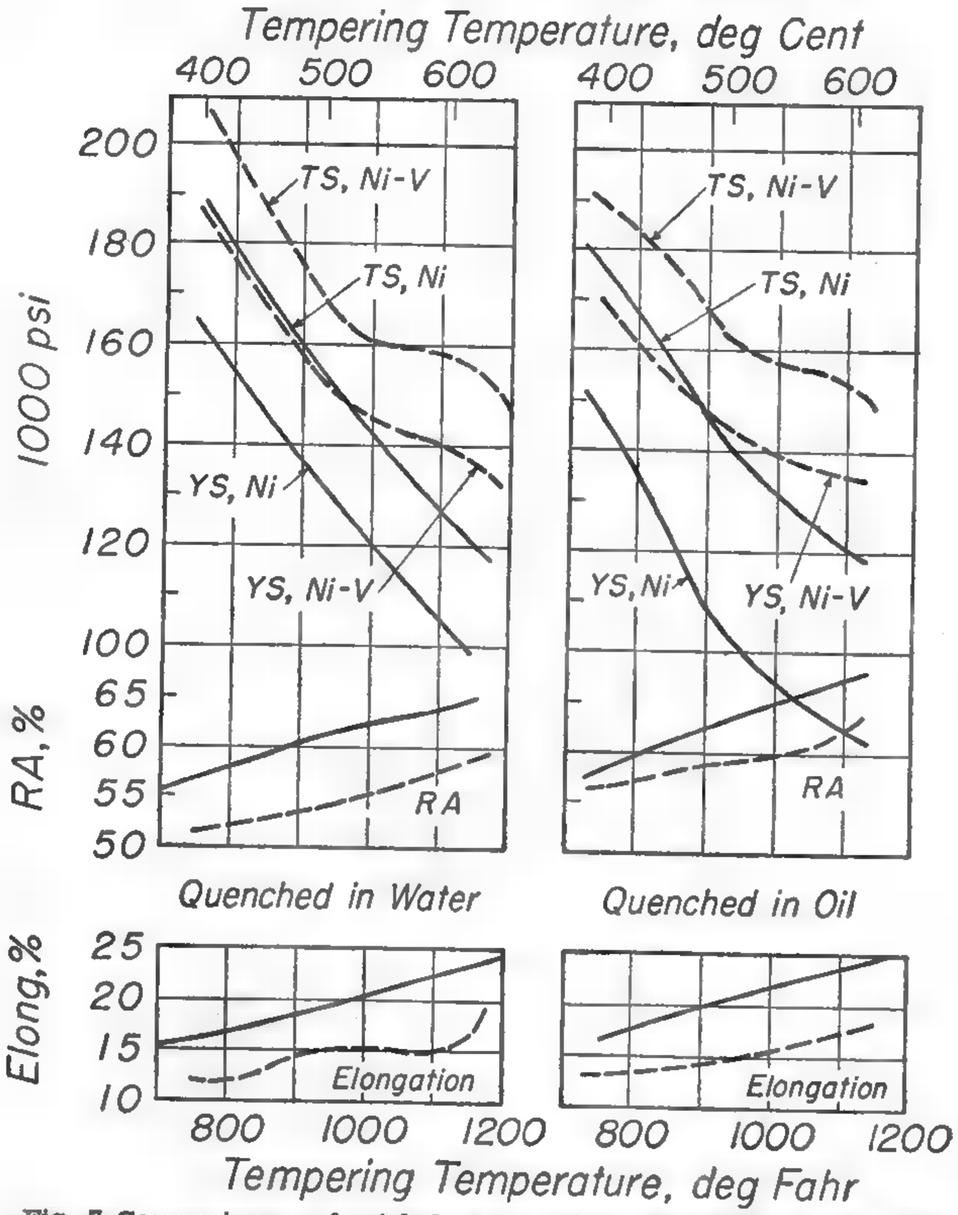

Fig. 7 Comparisons of nickel and nickel-vanadium steels, water quenched and oil quenched. Solid lines, SAE 2330, 0.30% C, 0.65% Mn, 3.50% Ni, quenched from 1450 F. Dashed lines, 0.29% C, 0.45% Mn, 3.41% Ni, 0.20% V, quenched from 1600 F, then from 1520 F ("Nickel Alloy Steels", and Bullens[7]).

tures ("red hardness") as well as resistance to wear at both low and high operating temperatures.

The effects of 1 and 2% V on the hardness of high speed steels at elevated temperatures, as described by Harder and Grove,[11] may be seen in Table VIII.

A tungsten high speed steel recently developed, containing 12 to 14% W, 5% V, 5% Co, 1.5% C, has exceptionally high Brinell hardnesses of 677 at 1000 F and 462 at 1200 F.

Endurance Limit. Vanadium raises the endurance limit and the ratio of endurance limit to tensile strength not only in very low-carbon steels but also in medium carbon and moderately high-carbon constructional steels. Many steels do not have high endurance properties unless quenched and tempered, but carbon-vanadium steels possess endurance ratios of about 50% when normalized and

Table VII. Creep Rate of Vanadium Steel

Composition, percentage C	Mn	Si	V	Load, psi	Rate of Deformation at 500 Hours, % per hour	Average Total Deformation after 500 Hours, per cent
0.35	0.55	0.19	...	10,000	0.00058	0.5231
0.37	0.70	0.16	0.18	10,000	0.00006	0.120

tempered and medium-carbon manganese-vanadium steel, specially designed for use in large sections, after being normalized and tempered, has an endurance ratio of 55 to more than 60%.

The characteristic uniformity of structure and composition of vanadium steels contributes significantly to these uniformly high endurance values.

Resistance to Oxidation. Vanadium slightly retards oxidation at high temperatures, but not sufficiently to be of commercial importance. On the other hand, the scale that is formed on the surface of vanadium steels is well defined and very easily removed, a fact that is of commercial importance in hot working by rolling and forging.

Resistance to Corrosion. Like titanium and columbium, vanadium, if used in the proper proportions, will increase the resistance of austenitic stainless steels against inter-

Table VIII

Hardness of High Speed Steels at Elevated Temperatures

By Mutual Indentation (Brinell)

Type of Steel	1110 F	1200 F	1290 F
18-4-1	480	320	160
18-4-1	470	304	220
14-4-2	435	338	250
18-4-2	445	346	260

granular corrosion, by stabilization of the carbides. Payson[12] has reported, however, that vanadium also lowers somewhat the general corrosion resistance of these steels.

In low-alloy steels, vanadium seems to have a slight retarding effect on corrosion but not enough to be of commercial importance.

Age Hardening. Vanadium is used to prevent age hardening in low-carbon rimmed steels. Epstein[13] showed that vanadium-treated, low-carbon rimmed steel possesses nonaging properties equal to those of fully killed aluminum steels, and yet retains the essential characteristics and manufacturing advantages of rimmed steels.

Table IX. Nonaging Vanadium Steel

	As Skin-Passed	As Aged at 212 F for 24 hours
Yield strength, psi	30,000	30,300
Elongation at yield point, %	0	0
Rockwell B hardness	46	46

After adding 0.05% V to a heat of this type of steel, Epstein found 0.032% V in the final product. The tensile strength of 44,900 psi at room temperature was reduced to 38,600 psi at 400 F, and sheets of this steel, skin-passed to about 1% elongation, showed no significant increase in yield strength after aging at 212 F for 24 hours, as shown in Table IX. Epstein's findings have been confirmed by the production experience in numerous plants.

Methods and Application of Hardenability Testing

BY THE SUBCOMMITTEE ON HARDENABILITY

THE capacity of steel to harden, when cooled from above the transformation range, is known as "hardenability" and is generally evaluated from the hardness produced by different cooling rates in a given piece. For purposes of measurement, the factors affecting the cooling rates must be controlled, such as the composition, temperature and velocity of the quenching medium, and the type and thickness of scale.

In general, the hardenability of steel depends on the composition and grain size of the transforming austenite; the hardenability of the SAE and AISI grades of alloy steels can be calculated approximately by the methods discussed in the article on page 494 of this Handbook. Because of factors which are not taken into account in the calculations and which may cause erroneous results, the current practice among steelmakers and users of steel is to determine experimentally the hardenability of steels subject to specifications for hardenability.

Steels subject to hardenability specifications include the extremely shallow water-hardening tool steels, the medium-carbon steels, the oil-hardening automotive and constructional alloy steels of the SAE and AISI grades, and alloy tool steels. The grades of tool steels that harden deeply in air and that are used for die blocks, cold forming tools with large sections, and extrusion tools such as rams, mandrels, and dummy blocks, have only recently been the subject of hardenability studies. Several methods for measuring the hardenability of steel are in use at the present time; in general, each of these methods is designed primarily to amplify differences in the hardenability of a single type of steel. A test designed primarily for the oil-hardening grades of steel will not be sensitive when applied to the shallow-hardening grades or to steels that harden deeply in air. Likewise, other tests devised especially for shallow-hardening or for air-hardening steels will not be useful if applied to other steels.

Methods of Test

Jominy End-Cooled Test for Medium-Hardening Steels. Medium-hardening or common alloy steels are usually tested for hardenability by the end-cooled method,[1] which involves heating a test bar 1 in. in diam to the proper austenitizing temperature and then cooling only the end face with water. The hardness is then measured at intervals of 1/16 in. from the water-cooled end to determine how far from this end the increased hardness extends.

The standard test that is specified both by the ASTM (Tentative Method A255–46T) and SAE (1947 SAE Handbook, page 303) consists briefly of using either of the test specimens shown in Fig. 1 and 2. The test specimen is normalized at about 150 °F above the Ac_3 point, then machined to remove any decarburization and to obtain the correct dimensions. Following this, the specimen is heated to about 75 °F above the Ac_3 point in a closed container that has a layer of cast-iron chips in the bottom. The specimen is held at this temperature 30 min and is cooled immediately thereafter on the hardenability fixture. The time spent in transferring to the fixture should not be more than 5 sec. This fixture is constructed so that the test specimen is held 1/2 in. above the water opening, in order that a column of water may be directed against the bottom of the piece. The water opening is 1/2 in. in diam and adjustment is made so that before the specimen is placed over it, a column of water 2½ in. high

comes from the opening. The water temperature is kept at 75 F plus or minus 5 °F and a condition of still air is maintained around the specimen during cooling. The piece is permitted to remain on the fixture until cold, or at least for 10 min, and is then quenched in cold water.

After cooling, two parallel flats, 180 deg apart and 0.015 in. deep, are ground along the entire length of the bar, and hardness measurements are taken at intervals of 1/16 in. for the first inch, then usually at intervals of 1/8 in. for the second inch, and 1/4 in. for the remainder of the bar. These hardnesses may be plotted to give a standard hardenability curve. (*See, for instance,* Fig. 3.) Care must be taken to avoid tempering when the parallel flats are ground. After grinding, it is good practice to etch the flats with 5% nital or other suitable etchant, to determine whether grinding has caused any tempering.

The standard test bar (1 in. in diam) should be used whenever possible, but other sizes may be used to make comparisons of hardenability. Bar diameters as low as 1/2 in. can be used with the standard water-cooling equipment. Sizes as small as 1/4 in. may be used by inserting a nozzle with an opening 1/8 in. in diam instead of the standard 1/2-in. nozzle. These bars, of course, will not be comparable with the standard 1-in. specimen, but can be compared with one another.

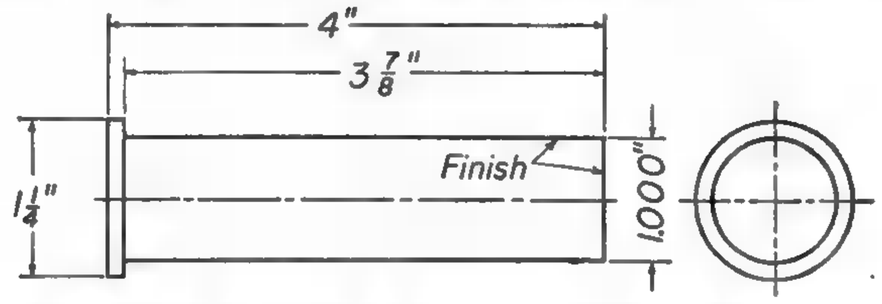

Fig. 1 Preferred specimen for Jominy end-cooled hardenability test

If it is desirable to obtain a result comparable with the standard specimen, 1 in. in diam, a smaller specimen may be machined to the dimensions shown in Fig. 4 and inserted into a standard 1-in. bar that has been properly drilled. About 0.2 grams of low-melting alloy is placed in the bottom of this hole and the bar is heated to about 212 F. The smaller specimen is then inserted into the hole, a small piece of asbestos is placed on top of the insert, and the tong-hold piece is screwed down fairly tight. The entire assembly is then heated to the austenitizing temperature and cooled in the standard manner. After the insert has been removed by heating to about 212 F, hardness measurements are taken as they would be for any standard bar.

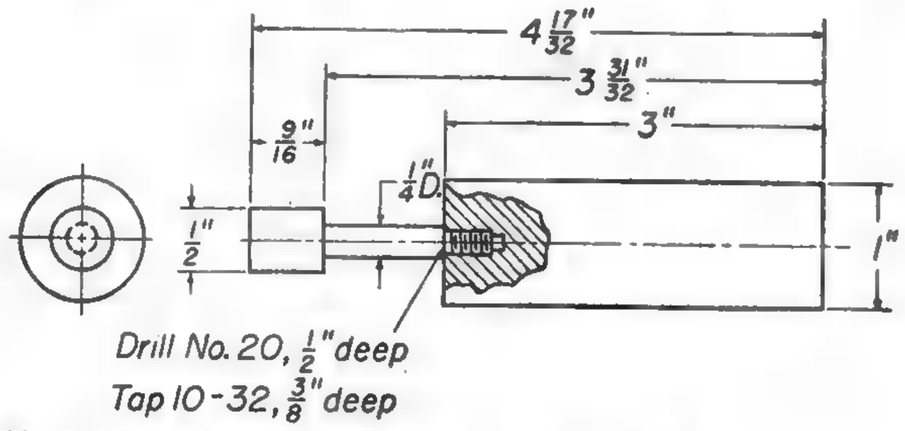

Fig. 2 Optional specimen for Jominy end-cooled hardenability test

The Society of Automotive Engineers and the American Society for Testing Materials have written hardenability specifications for the end-cooled test that are alike in the main. They do not correspond in a few details, which might make a difference with some steels. The SAE requires that samples taken from larger bars or billets be forged to 1¼ in. in diam; whereas the ASTM does not require this. The SAE specifies heating the test specimens on a piece of graphite; the ASTM, on cast-iron chips. The forging operation is difficult for many consumer plants, since frequently such plants have no forge shop. For very large pieces, however, the forged bars give more reproducible results. Heating on graphite will result in a temperature higher than that of the furnace, if the furnace atmosphere is air.

Segregation of carbon, manganese and other chemical elements occurs in the ingot, and the hardenability of the steel in these segregated portions will differ from that in the remainder of the steel. In general, specimens taken from the top of the ingot will have higher hardenability than the steel from the middle, and specimens from the bottom of the ingot will have lower hardenability than steel from the middle.

It is possible with cast test specimens to obtain results that will indicate the hardenability of the steel in the as-forged condition. In the cast test bar to be used for such purposes, grain size, which is important, is controlled by the thickness of the mold and the size of the hot top. A mold successfully used was made of cast iron,

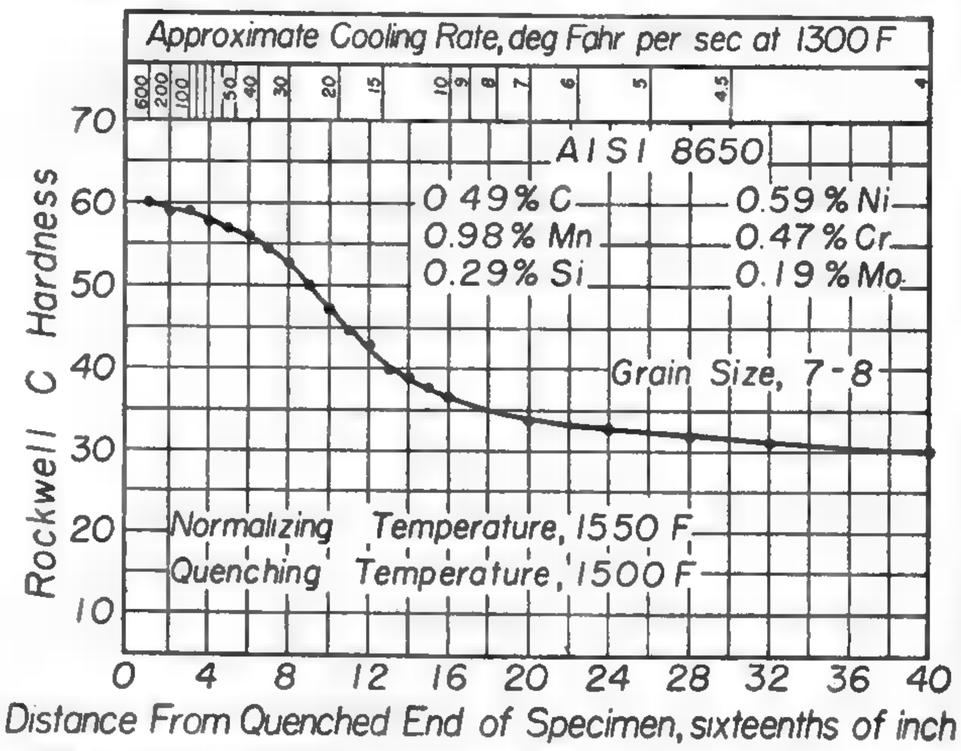

Fig. 3 Typical end-quench hardenability curve for AISI 8650 steel

as shown in Fig. 5. Hardenability tests made on pieces cast in this mold gave results consistently in good agreement with those obtained from the bars rolled from the heat of steel. It is common practice to perform a Jominy test on billets or rolled bars made of a particular grade of steel, using the recommended austenitizing temperatures (AMS, SAE or AISI) for this particular grade. The heat treatment of the cast specimens is changed, if necessary, to make the resulting hardness curves of both cast and forged specimens the same.

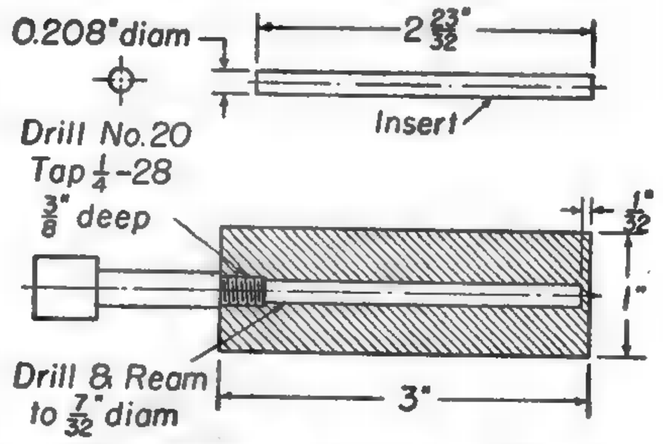

Fig. 4 Insert-type specimen for Jominy end-cooled hardenability test of steel available only in small sizes

Shallow-Hardening Steels. ***The Rockwell-Inch Test.*** The Rockwell-inch test has been used considerably for discriminating among the characteristics of the simple carbon steels ranging from 0.30 to 0.60% C, both in coarse-grained and fine-grained types. Following is a brief description of how the test is made and applied:

A prolongation is forged from the full section of a bar or billet to produce about a 10-in. length, 1⅛ in. in diam. After normalizing, the round is turned to 1 in. in diam plus or minus 0.003 in. and is smoothed with No. 3 emery cloth. A 4-in. length of this bar 1 in. in diam is then used as the specimen.

The specimen is heated to 1550 F plus or minus 10° in an ordinary atmosphere, then quenched and equalized in agitated water held between 65 and 95 F.

The untempered specimen is then cut transversely with

an abrasive wheel; precautions are used to avoid localized tempering. Overheating can be detected by employing a 5% nital etchant on the cut surface.

The cut end and the opposite end should be parallel. The specimen is then probed with a Rockwell C hardness penetrator across at least two diameters at 90 deg to each other. A surface reading is made on the lightly polished outside diameter. One half of the surface reading and of the reading at the center are added to the seven intermediate readings and the total figure is divided by eight. This gives a Rockwell-inch reading that actually

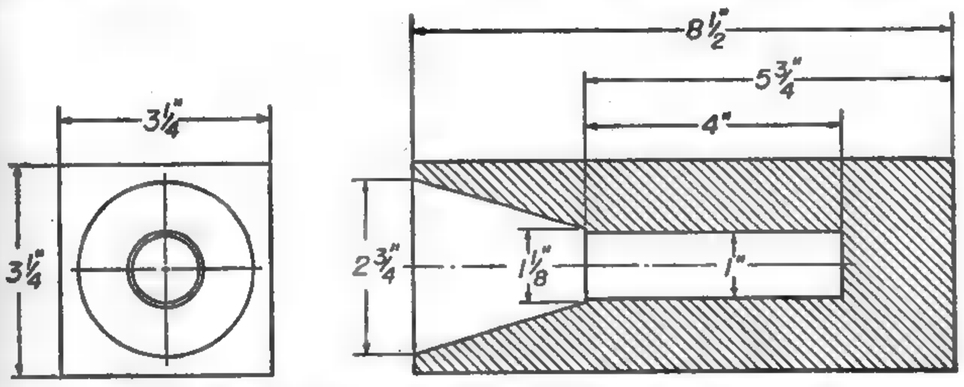

Fig. 5 Mold for casting hardenability test specimens

represents the area under the hardenability curve and usually gives a figure from 32 to 60 for carbon steel containing 0.30 to 0.60% C.

When duplicate tests are conducted on the same bar or billet, they will usually check within less than one Rockwell-inch. Checks made by different laboratories on the same billets will usually agree within less than two Rockwell-inches. On the other hand, two mill heats of almost identical composition, except for the cumulative

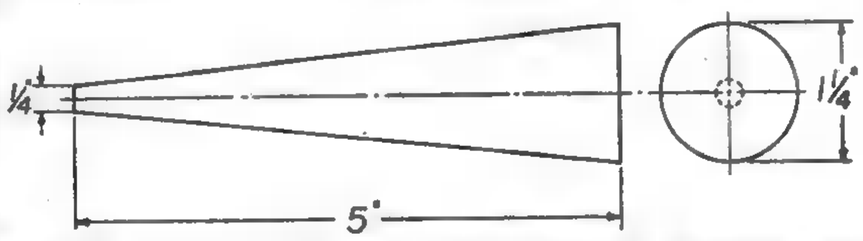

Fig. 6 Specimen for cone test (Post, Green and Fenstermacher)

total of permissible residual elements, may check as far apart as 8 Rockwell-inches.

A mill heat of 42 Rockwell-inches in hardenability might harden successfully to the surface intensity and depth required without cracking in a 3/4-in. section; whereas a mill heat of similar composition, but having variables as mentioned above, would crack if a piece of the same size were quenched in water. Quench cracking is not always related to a particular hardenability, but experience indicates that beyond a certain hardenability, the hazard of quench cracking is intolerable.

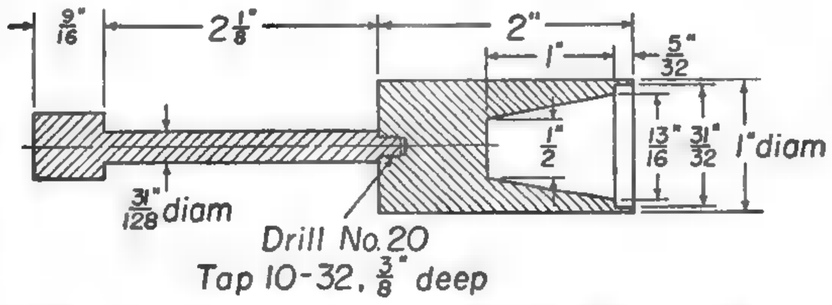

Fig. 7 Type L specimen for end-cooled hardenability test

The Cone Test of Green and Post.[3] The cone test was developed to measure the hardenability of shallow-hardening steels of the 1.10% C type. It consists in quenching a cone 5 in. long by ¼ in. in diam at the small end and 1¼ in. in diam at the large end into a brine flush (Fig. 6). The cone is then split longitudinally and the Rockwell C hardness is determined along the longitudinal axis. It is important for the specimen not to be tempered in these cutting and grinding operations.

The hardness penetration can be measured by etching with a light acid. An electromagnetic testing device[4] has been used to determine the hardenability of the hardened cones without slicing or grinding the cones. Rates of cooling past 1300 F have been determined for all points along the axis of the cone test specimen. These data make it possible to specify the cooling velocity that will yield a given Rockwell hardness in the steel specimen.

The duration of heating the cone and the temperature used should correspond with those to be used in production operations. It is customary to heat steels of the 0.60 to 1.30% C grades to 1450 F during a total heating period of about 30 min, including a 10-min soak at temperature. Steels of the 1.10% C type are generally pretreated by oil quenching from 1600 F.

The brine flush used consists of a standard 3-in. flushing pipe with about a 1-in. overflow of brine. The brine solution contains 10% NaCl by weight and is at room temperature. Cones are flushed with the small end down.

The L-Bar of Jominy.[5] This test was designed to measure the hardenability of the more shallow-hardening plain carbon steels. The standard Jominy specimen that has a flat end is used. This specimen, which has had a tapered hole drilled in the water-cooled end, is hardened on the regular end-quench test equipment. The dimensions for such a test bar are shown in Fig. 7. In order to use this bar on the regular end-quench cooling equipment, a longer adapter is necessary, as shown in the figure. The

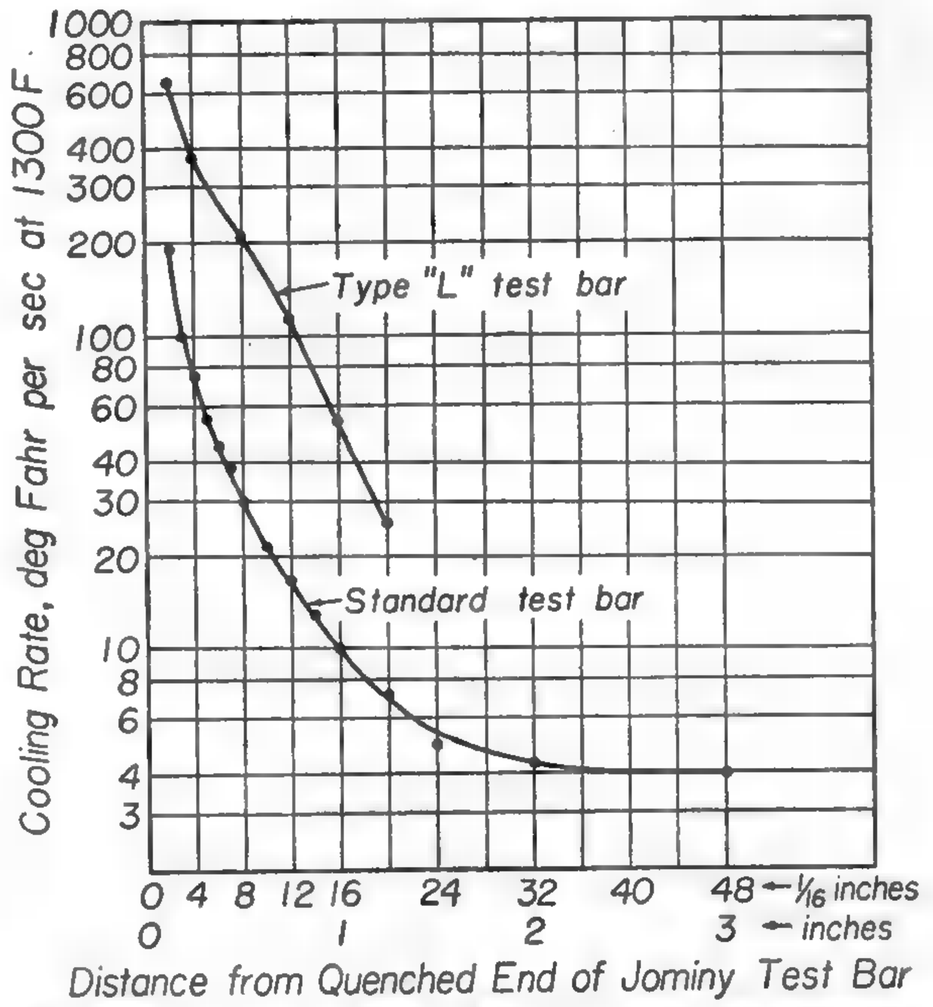

Fig. 8 Cooling rates at different distances from the quenched end of the Type L and the standard test bars

important feature of this specimen is the shape of the hole cut in the end. This hole produces a wall thickness of 3/32 in. at the extreme end to 1/4 in. at the top of the hole. The specimen is heated to whatever austenitizing temperature is desired, and is then hung vertically in the fixture on the hardenability equipment while water at 75 F plus or minus 5° is sprayed into the hole on the end. It is recommended that the height of the water column be increased to 4 in. before making a test with this type of bar. The time of heating and the temperature used should correspond to those to be used in production operations. The structure of the steel to be tested should correspond to the structure that will be present in the steel in production immediately before hardening.

After hardening, parallel flat surfaces 0.015 in. deep are ground on the surface of the outside layer of the test bar, and Rockwell C hardnesses are determined. The Rockwell C hardnesses are then plotted in a convenient manner to show the distance of each from the water-cooled end. As in the cone test described above, the cooling velocity necessary to yield a Rockwell C hardness from the specimen of steel can be determined from these measurements.

Figure 8 shows the cooling rates obtained with the type L test specimen and with the standard test specimen.

Shepherd Disk Hardenability Test. The hardenability of shallow-hardening steels is determined by quenching slabs of various thicknesses in a special spray of brine. After hardening, these slabs are sectioned with a thin grinding wheel and etched to show depth of hardening. The hardenability is reported as the number of thirty-seconds of an inch thickness of the thinnest slab that shows a soft core 5/64 in. wide or larger.

(*a*) *Prehardening Treatment.* Slabs are heated 40 min at 1600 F, and oil-quenched. Scale is removed from slabs.

(*b*) *Hardening Operation.* A final hardening consists of quenching slabs from 1420 F in brine. Slabs are austenitized in a gas-heated lead pot containing a thermocouple and using a 20-min heating cycle.

The Shepherd Penetration-Fracture (P-F) Test.[6] This test consists of hardening in brine four samples machined to 3/4 in. in diam by 3 in. long. One specimen each is quenched from 1450, 1500, 1550 and 1600 F. Each specimen is notched in the middle and fractured by impact. One half of each is examined for grain size of the case as compared with a standard set of Shepherd fracture standards. Penetration tests are made on the other half of each specimen by grinding and polishing the fractured face, then etching 3 min in a 50% HCl solution at 180 F. The hardness penetration is measured in 1/64 in.

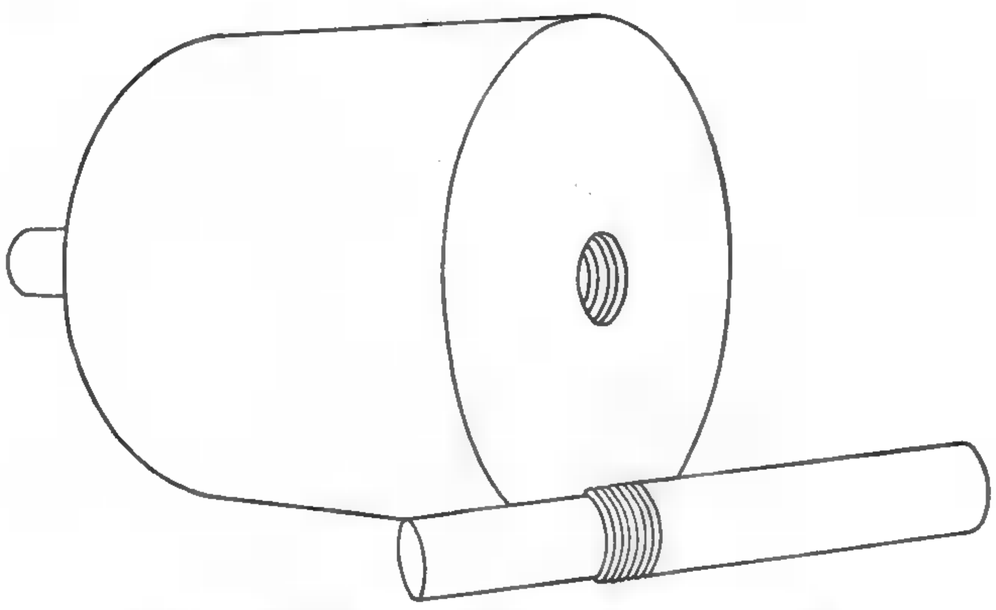

Fig. 9 Specimen for gradient-cooling air hardenability test

For determining the penetration-fracture values of 1.10% C tool steels, the specimens are generally pretreated by oil quenching from 1600 F after soaking for 40 min at temperature. The steel is then hardened after a heating cycle of 25 min for each austenitizing temperature.

Deep-Hardening Alloy Steels. The air hardenability test developed for deep-hardening steels, consists of taking a slug of 32% Ni-Fe alloy, 6 in. in diam by 6 in. long, drilling a hole 0.058 in. in diam through its center, and tapping about 1 in. at each end. The hardenability specimen itself is 7 in. long by 1 in. in diam; 4 in. of this length extends from the end of the 6-in. slug and the remaining 3 in. (0.856 in. diam) reaches into the center of the slug (Fig. 9). Two specimens are inserted into the 6-in. diam slug, one at each end; the assembly is then heated to the hardening temperature, soaked, removed from the furnace, placed on an elevated wire screen and air cooled. The specimens are then unscrewed, ground flat on two opposite sides, and hardnesses are taken at locations corresponding to definite cooling rates past 1000 F.

Cooling rates have been determined along the surface of the specimen. As with the other tests described above, a determination of the Rockwell hardness along the length of the hardenability specimen, permits a statement of the cooling rate that will yield the required Rockwell hardness for that particular steel specimen. Unlike the shallow-hardening grades and more deeply oil-hardening grades of steel, the air-hardening types are relatively insensitive to slight changes in chemical composition, as far as the resulting hardenability is concerned. In air-hardening steels, it is necessary only to determine the air hardenability of a given type composition. Air hardenabilities for several types of air-hardening steels are listed in Table I in terms of S/V, where S is surface area and V is volume.

Correlation. A number of tests have been made on the medium-hardening steels to correlate the results from the end-cooled specimen with results obtained by quenching cylinders and making a hardness traverse of the cross section of the cylinder.[8] For purposes of comparison, Fig. 10 shows the relationship between distance on the

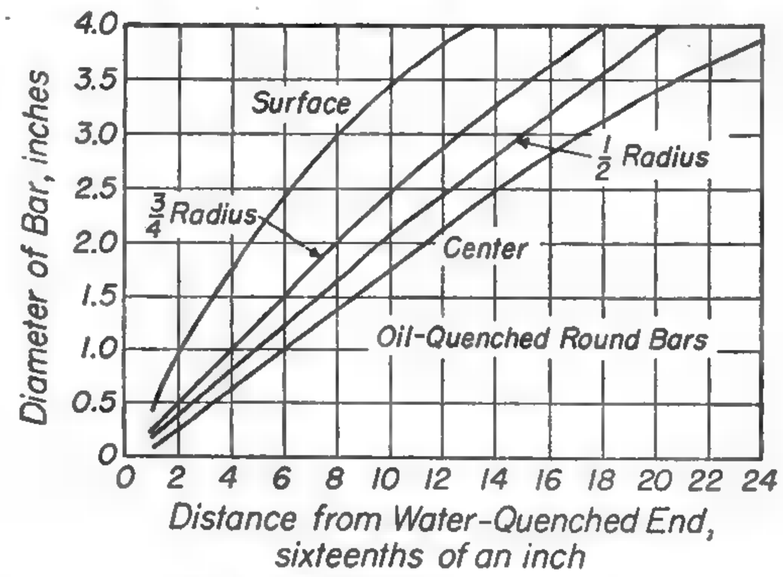

Fig. 10 Relationship between distance on the Jominy bar and points at the surface, ¾ radius, ½ radius and center of round bars quenched in still oil

Jominy bar and points at the surface, ¾ radius, ½ radius and center of round bars quenched in still oil; Fig. 11 shows corresponding relations for bars quenched in still water. A theoretical method has been developed[9] to calculate the hardenability curve on the end-cooled bar from a knowledge of the critical diameter of the steel. This information is discussed in the article on page 494.

The experimental correlation of the cone test, the Jominy L-bar, the Shepherd P-F and the Shepherd disk tests are given in Table II.

Application of Test Data

In the selection of steel for any part that requires heat treatment, the hardenability of the steel becomes a first consideration. The design of the part usually determines whether water quenching or oil quenching is preferable, and the design and size of the part determine the rate of cooling at any point in the part.

The choice of steels[10] is limited to those that will harden at the required rate of cooling and often the steel selected

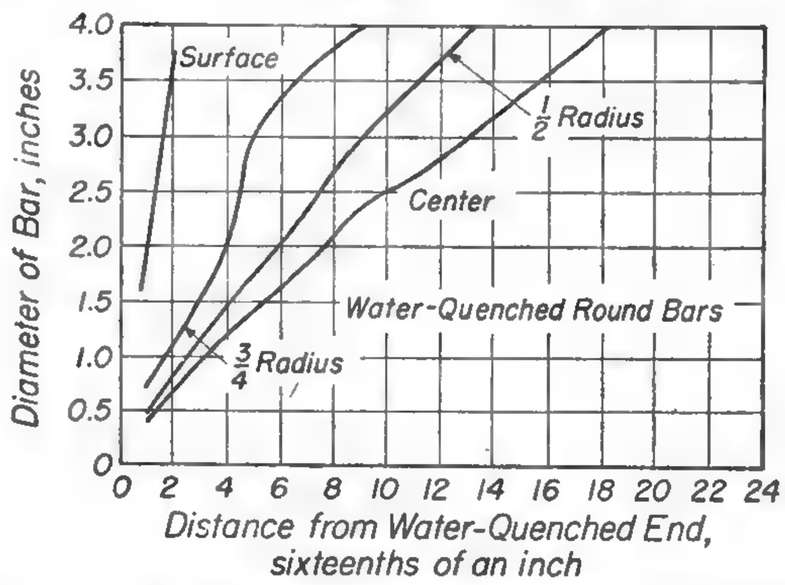

Fig. 11 Relationship between distance on the Jominy bar and points at the surface, ¾ radius, ½ radius and center of round bars quenched in still water

is the least expensive one that will harden at the necessary rate. Unfortunately few available data give the cooling rates of various parts. The rate of cooling of some of the common sizes of bars has been determined at the surface and center and at various points between surface and center.[11,12,13] For convenience, Table III has been prepared, giving the rate of cooling of several common sizes of specimen computed from Scott's work.[12]

(a) Carburized at 1650 F, 8 hr; hardness taken 0.015 in. below surface at about 0.90% C.

When parts are very near the size and shape of one of these specimens, the rate of cooling may be approximated. In Fig. 8 the rate of cooling is given for various points on the end-cooled bar, and it is possible, by reference to this figure, to determine on the end-cooled bar the location that corresponds to any desired cooling rate.

By obtaining the hardenability curve of various steels by means of the end-cooled bar, it is possible to select a steel that hardens satisfactorily with the desired cooling rate. From the standpoint of hardenability such a steel will be satisfactory for the intended part. If the part is to be water-quenched, it is likely that one of the shallow-hardening specimens will be used in determining the correct cooling rate.

Another method of applying hardenability data, as described by Boegehold,[14] is to make an experimental part from a steel for which the end-cooled hardenability curve has been determined. A hardness traverse is made from the surface to the center of this part and the hardnesses so obtained are compared with those obtained on the end-cooled bar. It may be assumed that points of equal hardness will have the same cooling rate, and the cooling rate can thus be determined at the various points from the surface to the center of the part.

The following is an example of the application of hardenability data: An axle shaft, 5 in. in diam and 3½ ft long, is required in a machine. The engineering analysis indicates that the torsion requirements will approach a maximum of 30,000 psi and that the bending stresses will reach a maximum of 100,000 psi. What must be the hardenability pattern of the steel used in this part?

Since the shear stress in torsion is about one-half that in bending, the latter will be the primary consideration. In bending, stresses approach zero in the neutral axis; therefore the steel need not be hardened completely to the center. This is helpful because distribution of stress in quenching will favor bringing the part out whole and, after tempering, should leave the exterior layers in compression.

In order to withstand a fatigue load of 100,000 psi in bending, a minimum Rockwell C hardness of 44 is required. This hardness should be obtained by tempering ■ structure as quenched, containing not less than 95% martensite which, it is believed, should be present to at least the half-radius position in the shaft. In a steel containing 0.45% C this means an as-quenched hardness of Rockwell C 55.

Reference to published charts (SAE and AISI) will show that in order to harden a bar 5 in. in diam to half-radius, a composition will be required that will harden

Table II. Chart for Correlation of Shallow Hardenability Locations of Equal Hardenability

Cooling Velocity, °F per sec at 1300 F	Cone Test, mm	L Bar, 1/32 in.	Shepherd P-F, 1/64 in.	Shepherd Disk Test, 1/32 in.
250 to 280	34 to 40	9 to 10	7 to 9	10
225 to 250	40 to 45	11 to 12	9 to 11	11
190 to 220	47 to 53	13 to 14	11 to 14	12
170 to 190	55 to 61	15 to 16	14 to 18	13
140 to 160	65 to 72	17 to 18	Through	14
100 to 130	75 to 90	20 to 22	Through	15
90 to 115	83 to 95	22 to 26	Through	16

with ■ cooling rate of 7° per sec at 1300 F. Translated in terms of a standard end-quenched specimen (Jominy bar), this means a minimum of Rockwell C 55 at 20 sixteenths.

Therefore, the choice of steel is narrowed to a composition equivalent in hardenability to SAE 4345. Special surface hardening of a lower-alloy steel might be an alternate approach.

The rates of cooling at surface and center of a block of steel are governed by the surface per unit volume (S/V) factor for the shape in question. The rates of cooling blocks past 1300 F and 1000 F as a function of S/V has been determined for S/V ratios from 1.0 (represented by a specimen 6 in. in diam by 6 in. long) to 4 (represented by a long bar 1 in. in diam). It has also been

Table III. Rates of Cooling of Common Sizes of Bars

shown that the high-alloy steels of the air-hardening type are fairly insensitive to slight variations in chemical composition, at least in regard to the hardness developed in any size of block after air hardening. This makes it possible to write down the hardenability of various air-hardening types in terms of the expected hardness to be developed in any size block of known S/V ratio. Such data are shown in Table I.

Table IV. Rockwell C Hardness for Various Carbon Contents and Percentages of Martensite

Percentage Carbon	Percentage Martensite				
	50	80	90	95	99.9
	Rockwell C Hardness				
0.18	31	35	37.5	39	43

0.28	36.5	40.5	43	44.5	49
0.33	39	43.5	46.5	48.5	52
0.38	42	46	49	51	54
0.43	44	48	51	53.5	57
0.48	46.5	52	54	57	60

Hardenability Specifications. Hardenability specifications may be developed so that a given hardness is required within a range of cooling rates or distances on the end-cooled bar, or so that a minimum hardness will be obtained at not less than a given distance on the end-cooled bar.

For instance, an aircraft specification on SAE 8740 steel requires a hardness of not less than Rockwell C 50 for a minimum distance of 7/16 in. from the cooled end of the Jominy specimen, when the steel has been normalized at 1700 F and subsequently quenched from 1525 F. This is expressed by stating that the hardenability shall be J50=7 minimum when determined by the standard end-quench test. In Fig. 3 showing the hardenability of AISI 8650 steel, J55=6.

An aircraft specification of an SAE 3312 steel states that the hardenability shall be J41 max and J32=6. Steel purchased under this specification will never harden to more than Rockwell C 41 and will have a hardness of not less than Rockwell C 32 at the center of a bar 1 in. in diam quenched in still oil.

Table IV[15] may be used as a guide in choosing the hardness for reference points in steels of different carbon contents. Such data are of interest in the formulation of specifications for hardenability.

As part of the steel specification, hardenability specifications are growing in popularity, since they insure better control of the hardening process.

The Calculation of Hardenability

By John M. Hodge*

THIS article discusses the calculation of hardenability from chemical composition and grain size. The method to be described was developed in 1942. It is based on the principle that each chemical element in the composition has a multiplying effect on the hardenability.

This method has been found to work very well on plain carbon and low-alloy steels. However, irregularities, still unexplained, have been observed in steels of high hardenability and in steels containing less than 0.20% C. Following is a detailed discussion of some of the factors, such as uncertainties in the measurement of hardenability values, particularly those of the pure iron-carbon alloys, and the possibility of incomplete solution of carbides, which are involved in these irregularities. These factors are of such a nature that one investigator, working with one set of conditions, may derive a factor apparently different from that derived by another investigator working with another set of conditions, particularly in work with the more highly alloyed steels. It is not yet known, however, whether these irregularities actually reflect a departure from the principle of multiplying factors.

The Factors Affecting Hardenability. The principal factors affecting hardenability are as follows:

1 The composition of the austenite
2 The grain size of the austenite
3 The homogeneity of the austenite

It is obvious that, if the individual and cumulative effects of these factors on hardenability can be evaluated quantitatively, it would be possible to calculate or predict hardenability from a knowledge of these factors alone.

* Research and Technology Dept., Carnegie-Illinois Steel Corporation, Pittsburgh. Prepared for the Subcommittee on Hardenability.

The Evaluation of Hardenability Effects. The individual effects of any of the factors enumerated above may be evaluated by studying the manner in which hardenability changes with changes in a single variable. This involves the measurement of hardenability in a series of steels in which all the variables (carbon content, alloying elements and grain size) are held constant except one. The effect of this single variable on hardenability is then expressed as the quotient of the hardenability value at a given value of the single variable, and the hardenability value at zero percentage (or at a fixed value of the variable). This quotient thus becomes a multiplying factor that serves as a numerical expression of the hardenability effect of the single variable studied.

As an illustration of this method, the hardenability values of two series of steels in which the phosphorus content is the single variable are shown in Fig. 1. It will be noted that the hardenability increases regularly as the phosphorus content increases. Furthermore, the rate of increase of hardenability with increasing phosphorus content is greater in the steel having the higher base hardenability. This is necessarily true if the hardenability effect of phosphorus is to be represented by a single series of multiplying factors.

The multiplying factors for phosphorus, which express the manner in which hardenability changes with changes in the phosphorus content, are shown in Fig. 2. These have been derived by dividing the hardenability values at the various percentages of phosphorus by the base hardenability at zero phosphorus in each series of steels.

In order for this method of evaluation of hardenability effects to be valid it is necessary that the hardenability values be measured and expressed in terms of fundamental

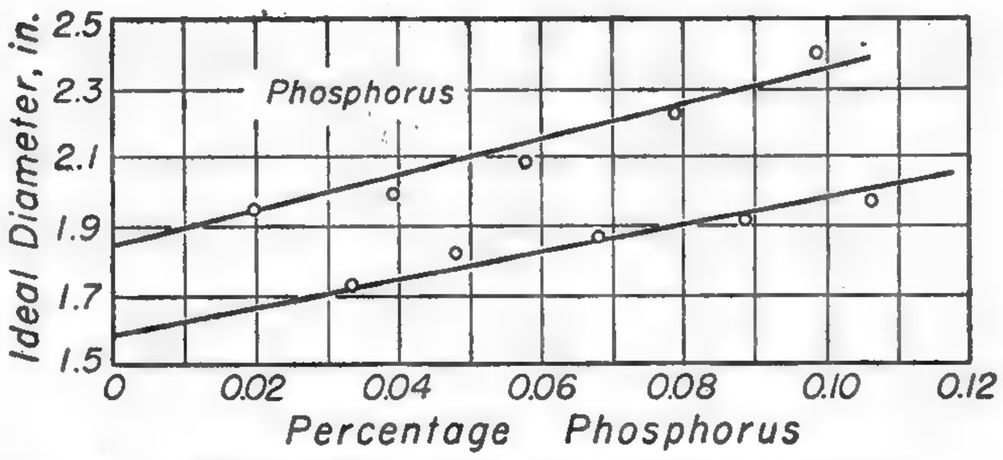

Fig. 1 Hardenability as a function of phosphorus content in two series of steels

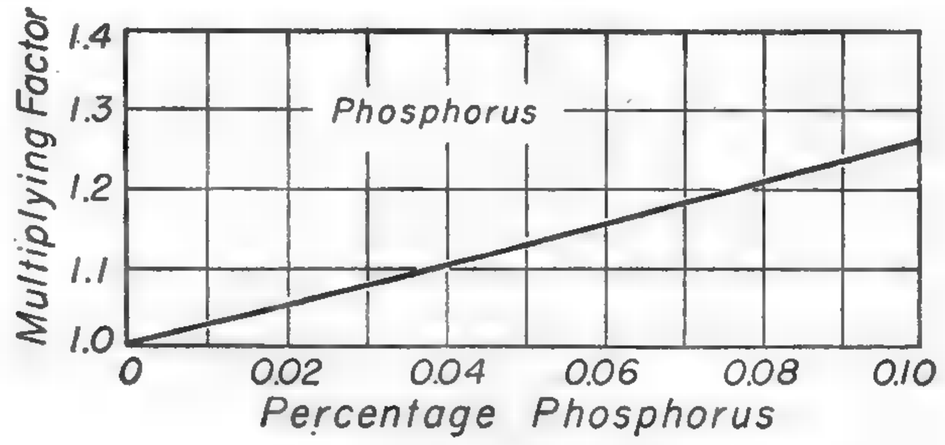

Fig. 2 Multiplying factors for phosphorus

and mutually consistent units. The expression most commonly used for this purpose is "ideal diameter" (D_I). This is the diameter of an infinitely long cylinder which, in an ideal quench, will just transform to a given specific microstructure at the center. An ideal quench is one in which the rate of heat transfer at the surface is infinite; that is, one in which the surface comes instantly to the temperature of the quenching medium. This expression furnishes a very useful single, numerical, fundamental unit for the evaluation of hardenability, which can be derived from the results of standard measurements of hardenability in the laboratory, by using known cooling rate relationships.

The most direct method of measuring hardenability in terms of ideal diameter is the cylinder series method. In this method a series of round bars of increasing diameter are quenched under a standardized set of quenching conditions and the diameter of the bar is determined that just quenches to the desired microstructure at the center. This diameter is known as the "critical diameter" (D).

In order to convert this critical diameter value into terms of the more fundamental expression of ideal diameter, it is necessary to evaluate the quenching conditions quantitatively. The expression used for this purpose is the "severity of quench factor" or H value. This value can be determined from a cylinder series by means of the chart of Fig. 3. This chart is used in the following manner. The D_u/D values (the ratio of the diameter of the center portion that remains unhardened to the full diameter) for several of the bars of the series, are plotted against the D values (the full diameter) on transparent paper with the same co-ordinates as the chart. This curve, formed by the points on the transparent paper, is then moved until it matches one of the curves of the chart. The H value will then be the quotient of the HD value of any point on this curve and the corresponding actual diameter.

Table I. Severity of Quench (H Value)

Agitation	Oil	Water	Brine
None	0.25 to 0.30	0.9 to 1.0	2.0
Mild	0.3 to 0.35	1.0 to 1.1	2.0 to 2.2
Moderate	0.35 to 0.40	1.2 to 1.3	....
Good	0.4 to 0.5	1.4 to 1.5	....
Strong	0.5 to 0.8	1.6 to 2.0	....
Violent	0.8 to 1.1	4.0	5.0

Although, wherever possible, this H value should be measured by the method described above, typical values of this coefficient, which may be used as a guide, are shown in Table I.

When the H value of the quench has been determined, the hardenability values in terms of critical diameter can then be converted into values of ideal diameter by means of the curves of Fig. 4, which show the relationships among critical diameter, H value, and ideal diameter.

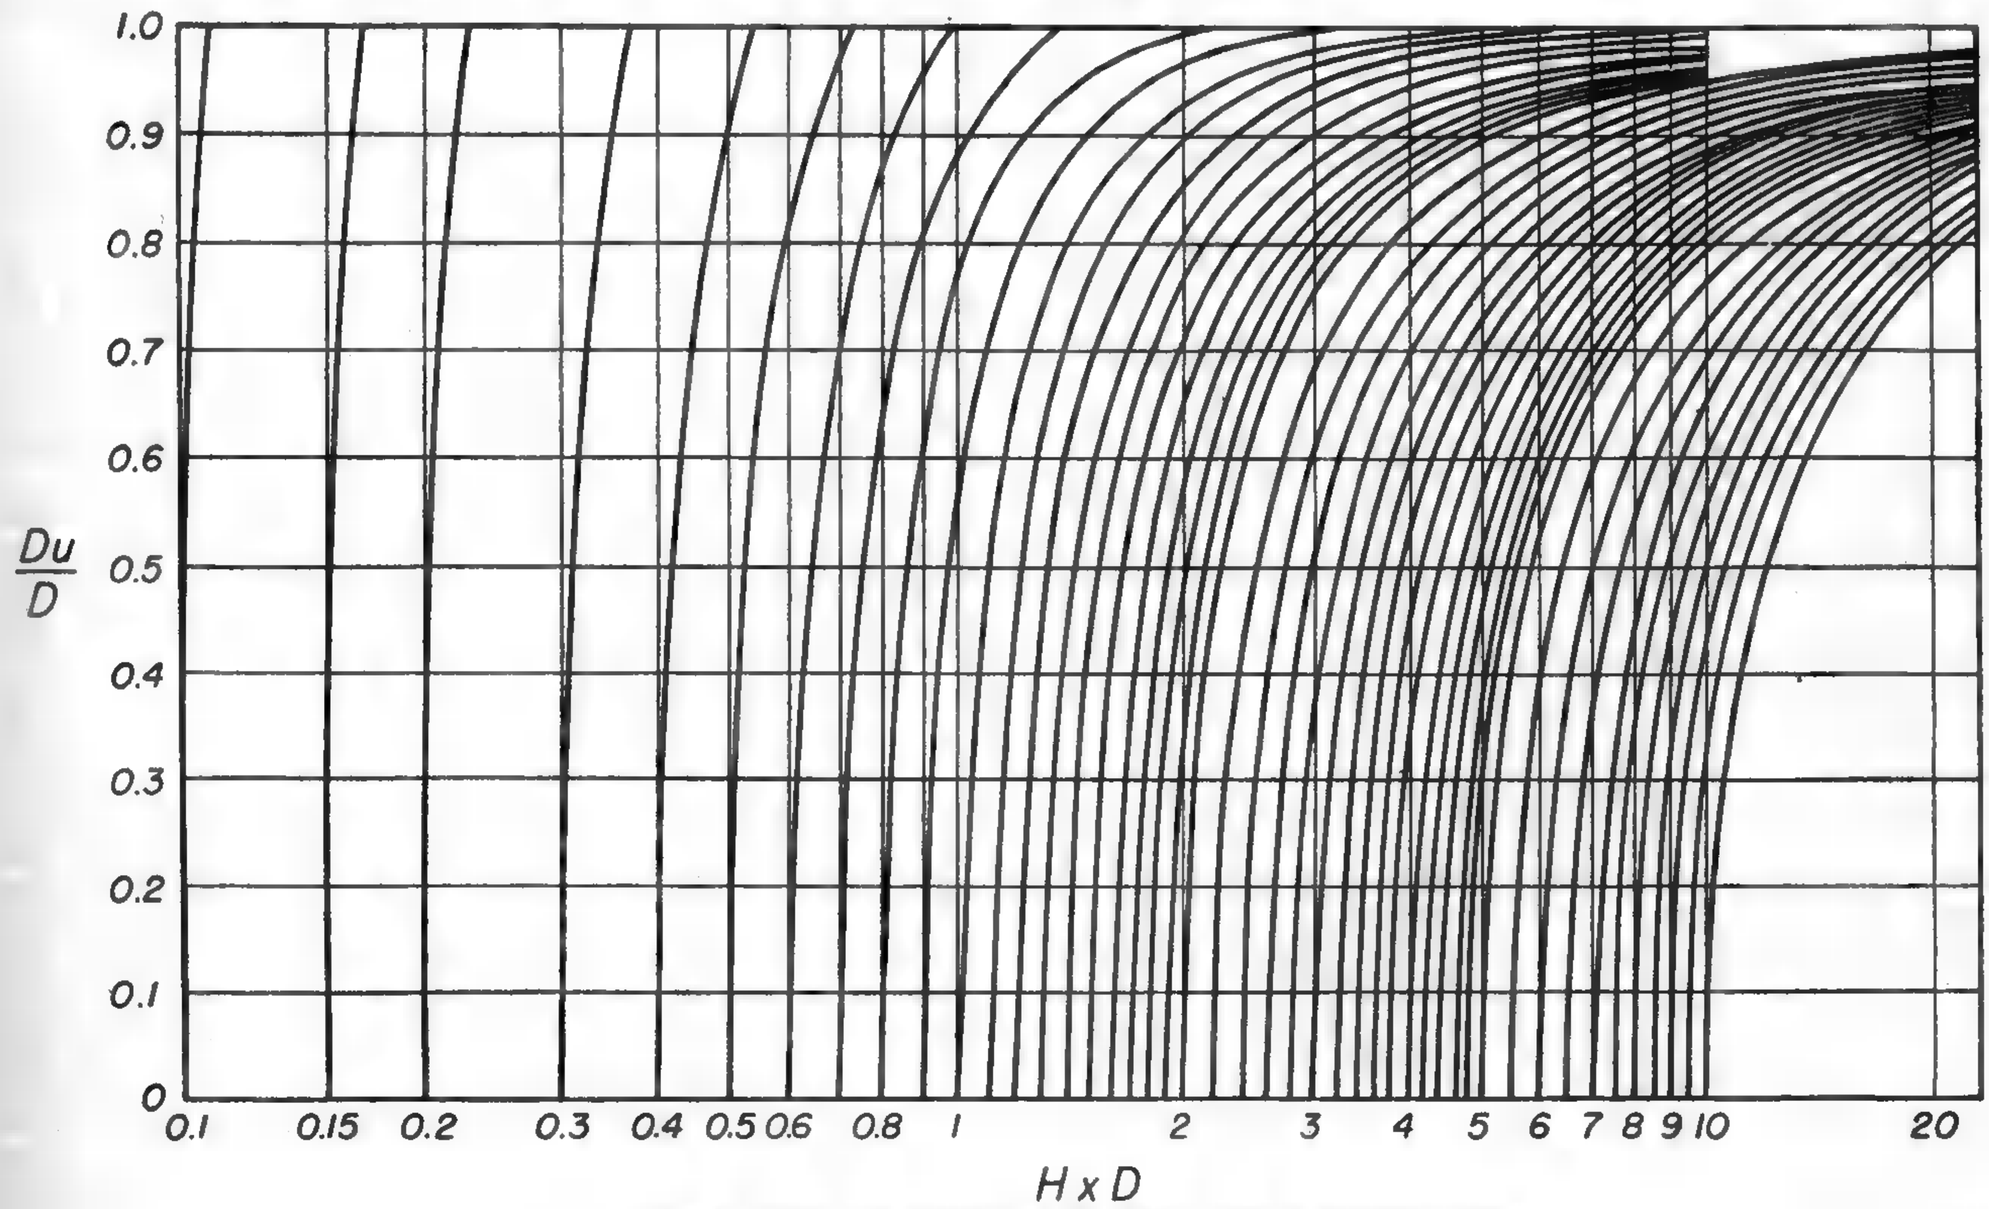

Fig. 3 Chart for estimating H value from a cylinder series

By means of these curves, this ideal diameter value can then be used likewise to evaluate the size of round that can be quenched to this microstructure at the center under any quenching conditions of known *H* value.

It should be emphasized, however, that these values of hardenability are all in terms of the microstructure at the center of the bar, and that, except in through hardening to full martensite, there will be a continuously changing series of microstructures from the surface to the center. Thus a bar that has a 50% martensite microstructure at the center might have a surface layer of considerable depth that is completely martensitic, and in many instances the microstructure of this surface portion may determine the performance of the part. Therefore, although it is more convenient to use the microstructure at the center as a criterion in measuring and expressing

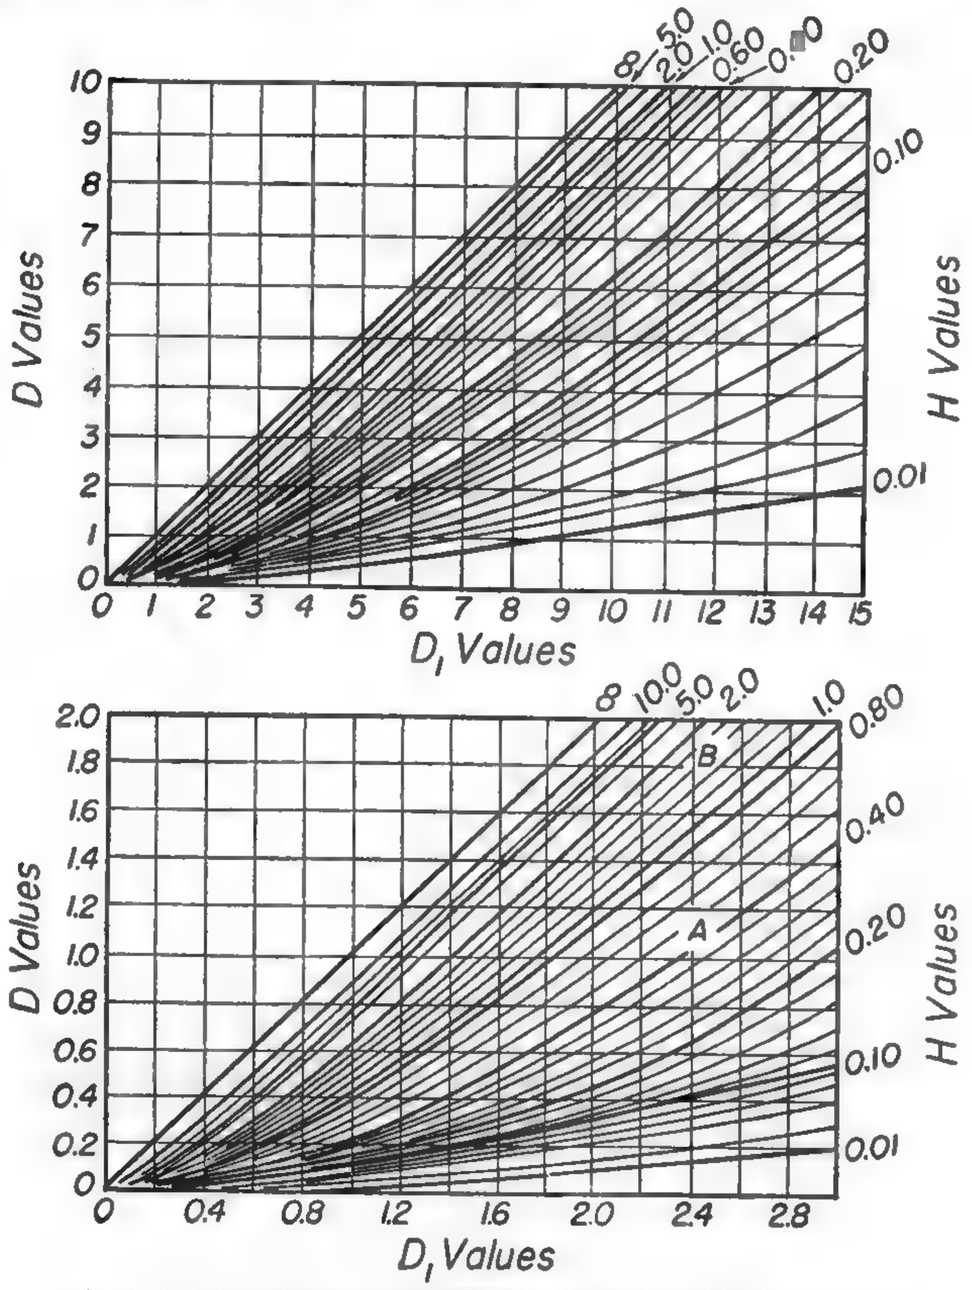

Fig. 4 Relationship among critical diameter, ideal diameter and *H* value.

hardenability, it is nevertheless important that the over-all microstructure of the piece be considered in applying the results of hardenability measurements or calculations.

Although the cylinder series method, just described, is the most direct method of measuring hardenability values in terms of ideal diameter, the method of hardenability measurement that is now by far the most commonly used is the end-quench test developed by Jominy and Boegehold. This test consists of heating a specimen 1 in. in diam by 4 in. long to the desired hardening temperature and then quenching the specimen in a fixture by impinging a stream of water on one end. The quenched bar is ground to a depth of 0.015 in. below the surface and hardness readings are taken 1/16 in. apart along the length of the specimen. (See the article on page 489.)

Measurements of end-quench hardenability may be converted to values of ideal diameter by means of the correlation curve of Fig. 5. This conversion requires measuring the distance from the quenched end of the end-quench test to the point of the desired microstructure and reading the corresponding ideal diameter from the correlation curve. The accuracy of this conversion is questionable at distances nearer than 0.3 in. from the quenched end, and a revised curve (dashed) is also presented. This dashed-line curve, based on an actual comparison of cylinder series and end-quench tests, is probably more accurate in this region.

The microstructure that has been most commonly used as a criterion in these various methods of measurement has been a mixture of 50% martensite and 50% products formed at higher temperatures. This microstructure should be located preferably by metallographic examination but several indirect methods may be used, permitting a more rapid and convenient determination of its location. This location may be determined from a cross-sectional fracture or etch test by noting the point at which a marked change occurs in the appearance of the fracture or etched surface. It will correspond to the point of steepest slope (the inflection point) in a cross-sectional hardness survey, or in an end-quench hardenability curve. Finally, the hardness values corresponding to this microstructure in plain carbon and alloy steels have been determined as a function of carbon content (Fig. 6). This curve furnishes a fairly accurate method of locating the 50% martensite microstructure in plain carbon steels, but the variations in the nature and hardness of the nonmartensitic products in alloy steels lead to considerable variation in the hardness value for a given carbon content in these steels.

Similar curves are shown in Fig. 7, representing the hardness values that correspond to other microstructures

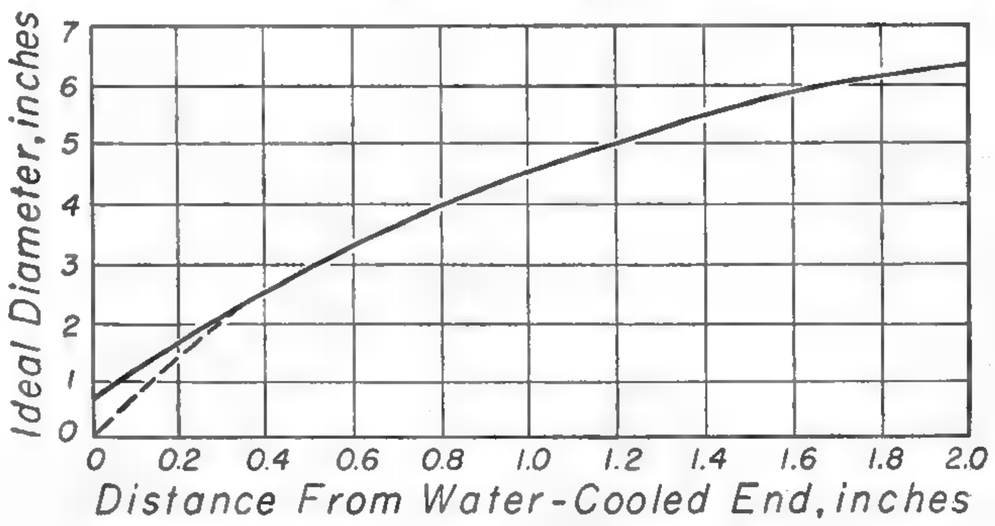

Fig. 5 Correlation between distance from the water-cooled end of a standard end-quench specimen, and ideal diameter

in terms of the percentage of martensite, as determined in a number of low-alloy and medium-alloy steels. The curves may be used as a general guide in locating these microstructures from a cross-sectional hardness curve or an end-quench hardenability curve.

It will thus be seen that, although the principle of multiplying factors furnishes a straightforward method for the numerical evaluation of hardenability effects, the methods of measurement involve several uncertainties that make a precise determination of these numerical values difficult. Such uncertainties leave in question many experimentally determined values of multiplying factors.

In the first place, the numerical values of the multiplying factors depend entirely on an accurate evaluation of the hardenability of the base composition at zero content of alloying elements. These hardenabilities will usually be relatively low, and unfortunately it is in this low hardenability range that the difficulties of accurate measurement are most pronounced. If the cylinder series method is used, the *H* value must be accurately determined and this determination is both indirect and particularly difficult with a series of small cylinders. If the end-quench test is used, the significant values of distance will fall near the quenched end, and the correlation between these values and ideal diameter is questionable in this region.

Using measurements of hardness as a criterion of the location of the microstructure containing 50% martensite, is a practice that has been followed in many of these determinations with resulting uncertainty since, as was shown above, there may be wide variations in the hardness values corresponding to this microstructure in alloy steels.

Still another factor, apparently very important in the uncertainties of these results, is the possible heterogeneity of the austenite. In many of these determina-

tions, particularly those involving alloy steels that contain carbide-forming elements, the homogeneity of the austenite is uncertain, and obviously the full hardenability effect of an element will not be realized unless it is completely dissolved in the austenite. The carbon and alloying elements contained in undissolved carbide are unavailable for increasing hardenability; instead these carbide particles may act as nuclei for transformation and decrease hardenability still further. Any heterogeneity in the austenite, even though visible undissolved carbide may not be present, will tend to decrease hardenability, since transformation will take place first in the areas of low alloy or carbon content. Therefore completely homogeneous austenite is essential to an accurate evaluation of the full effects of the alloying elements on hardenability. However, the homogeneity of the austenite is difficult to evaluate and this uncertainty leaves many of the determined hardenability factors open to question.

Multiplying Factors for the Alloying Elements. The multiplying factors for the individual elements, as determined by the several investigators in this field, are depicted graphically in Fig. 8 to 18.

The earlier values of Kramer[4] are omitted from this summation, since they have been superseded by the more recent work of Kramer, Siegel and Brooks.[15]

The methods of measurement used by these investigators were as follows:

Investigator	Method of Measurement	Method of Locating 50% Martensite
Grossmann	Cylinder series	Critical hardness
Crafts and Lamont	End-quench test	Metallographic
Kramer, Siegel and Brooks	Cylinder series and end-quench test	Critical hardness

In the numerical values of many of the hardenability factors as determined by the different investigators, the rather large differences reflect the uncertainties involved in the methods of measurement and, particularly in the carbide-forming elements, the numerical values are influenced by heterogeneity of the austenite, as described above. The cross-hatched areas in the curves for chromium, molybdenum and vanadium represent the effects of inhomogeneous austenite, as observed in the determination of these factors.

The wide discrepancy between the multiplying factors for manganese, as determined by Grossmann, and by Crafts and Lamont, and those determined by Kramer, Siegel and Brooks, illustrates still another source of uncertainty in these results. In the original work of Grossmann, the manganese factors were determined from rather limited data and were then used in the evaluation of the effects of carbon content in a series of commercial steels in which carbon content was the only variable. However, because of the difficulties involved in the measurement of the very low hardenabilities of pure iron-carbon alloys, the effect of carbon content in the absence of manganese was not actually determined. These factors for manganese and carbon were then applied to a number of plain carbon-manganese steels covering a wide range of manganese contents, and the effect of manganese content was thereby verified. It will be seen, therefore, that the numerical values of the factors for manganese depend on the values for carbon, which were not actually measured. Likewise, in the work of Crafts and Lamont the factors for manganese were based on the assumption that the original values for carbon were correct, and the values for manganese as determined by these investigators, are essentially similar to those presented by Grossmann. In the work of Kramer, Siegel and Brooks, however, the hardenability of several iron-carbon alloys was actually measured by the cylinder series method. The values indicated by these measurements were considerably higher than the original values of Grossmann, and the values for manganese are correspondingly lower. However, it should be noted that over a considerable range of carbon and manganese contents, the product of the values for carbon and manganese is essentially the same, whether these values or the original values for carbon and manganese are used.

The Effect of Carbon Content and the Cumulative Effects of the Alloying Elements. When the effects of the individual alloying elements have been evaluated in terms of multiplying factors, all that is needed to permit calculation or prediction of the hardenability of a steel is an evaluation of the hardenability of the iron-carbon base, and the cumulative effects of the alloying elements and of grain size on this base hardenability.

As mentioned above, the hardenabilities of the plain iron-carbon alloys, in terms of 50% martensite microstructures, have been evaluated by Grossmann and by Kramer, Siegel and Brooks. The effect of grain size has also been evaluated and these base hardenability values at the different grain-size levels are shown in Fig. 19, 20 and 21. It should be emphasized that, because of their interdependence, these higher carbon values of Kramer, Siegel and Brooks, should be used only in conjunction with their lower manganese values, and that likewise the lower

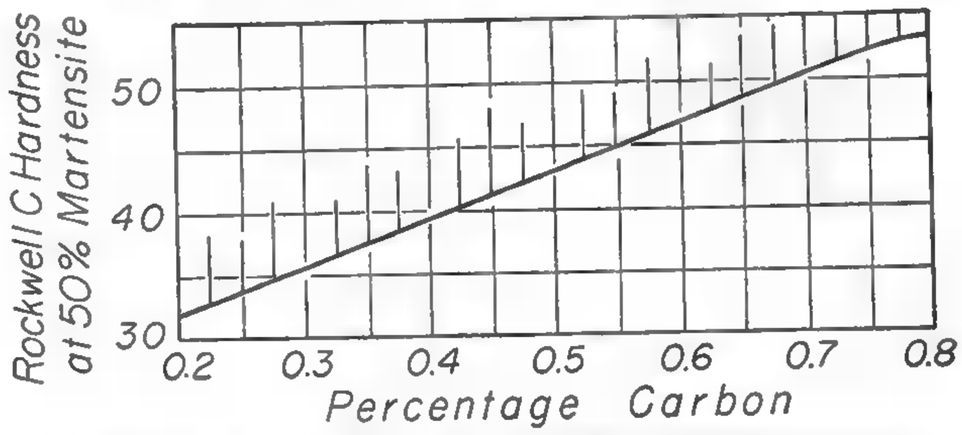

Fig. 6 The hardness of 50% martensite microstructures as a function of carbon content.

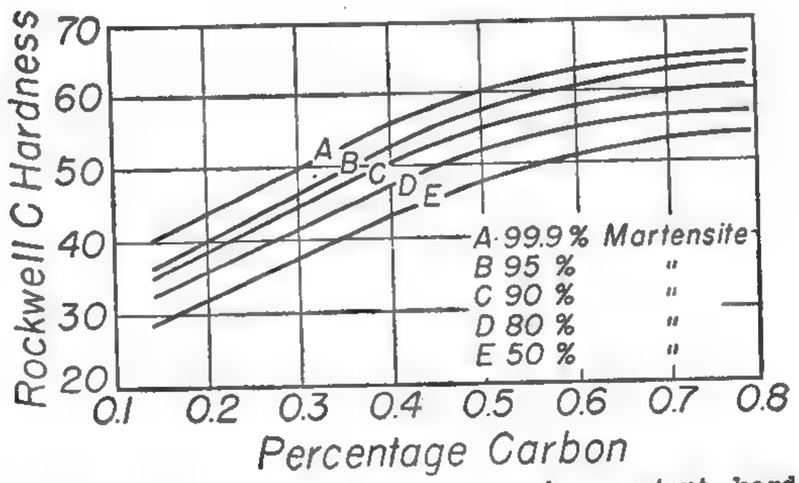

Fig. 7 Average relationships among carbon content, hardness and percentage of martensite.

carbon values of Grossmann should be used only in conjunction with the higher manganese factors.

When the base hardenability and the multiplying factors for the alloying elements have been evaluated, the cumulative effects are represented by the product of the base hardenability and these multiplying factors. Thus, to calculate the hardenability of a given composition, the base hardenability value corresponding to the actual carbon content and grain size should simply be multiplied progressively by the multiplying factors for each of the alloying elements making up the composition. The answer will then be the hardenability value in terms of ideal diameter for a microstructure of 50% martensite.

Representative values of the multiplying factors for the alloying elements, as chosen by the American Iron and Steel Institute, are shown in Fig. 25. These values are based on the original carbon values of Grossmann and should, of course, be used only in conjunction with these carbon values. The factors for manganese contents as high as 1.20%, for nickel as high as 2.00%, and for molybdenum, are those of Grossmann, while the values for silicon and chromium are those of Crafts and Lamont. The factors for manganese contents greater than 1.20% and for nickel contents greater than 2.00% represent compromise values between those of the various investigators. Experience has shown that these factors, if used with due regard for the precautions and limitations enumerated below, will permit a reasonable prediction of the hardenability of steels of medium hardenability, but will not predict accurately the hardenability of steels

Fig. 8 to 18 Multiplying factors for individual elements in steel, as determined by the several investigators. In the numerical values of many of the hardenability factors as determined by the different investigators, the rather large differences reflect the uncertainties involved in the methods of measurement and, particularly for the carbide-forming elements, the numerical values are influenced by heterogeneity of the austenite, as described in the text. The cross-hatched areas in the curves for chromium, molybdenum and vanadium represent the effects of inhomogeneous austenite, as observed in the determination of these factors. The wide discrepancy between the multiplying factors for manganese, as determined by Grossmann, and by Crafts and Lamont, and those determined by Kramer, Siegel and Brooks, illustrates still another source of uncertainty. *See text.*

possessing high hardenability, particularly those containing relatively large percentages of carbon-forming elements, nor of steels containing less than 0.20% C.

Limitations of Hardenability Calculations. The principle of multiplying factors has been repeatedly checked and does permit a reasonably accurate prediction of hardenability based on composition and grain size in plain carbon and low-alloy steels, if the following limitations and precautions are observed.

1 Since all the alloying elements in the composition will have a cumulative effect on hardenability, it is essential that all elements, including residuals, be taken into account.
2 If substantial amounts of carbide-forming elements are present, the actual hardenability will depend on the degree of solution of the carbides and cannot be accurately predicted.
3 The grain size at the hardening temperature must be known.
4 In applying the results to practice, the factor for severity of quench must be evaluated accurately.
5 The results are in terms of ideal diameter for a microstructure of 50% martensite and must not be applied to other criteria.

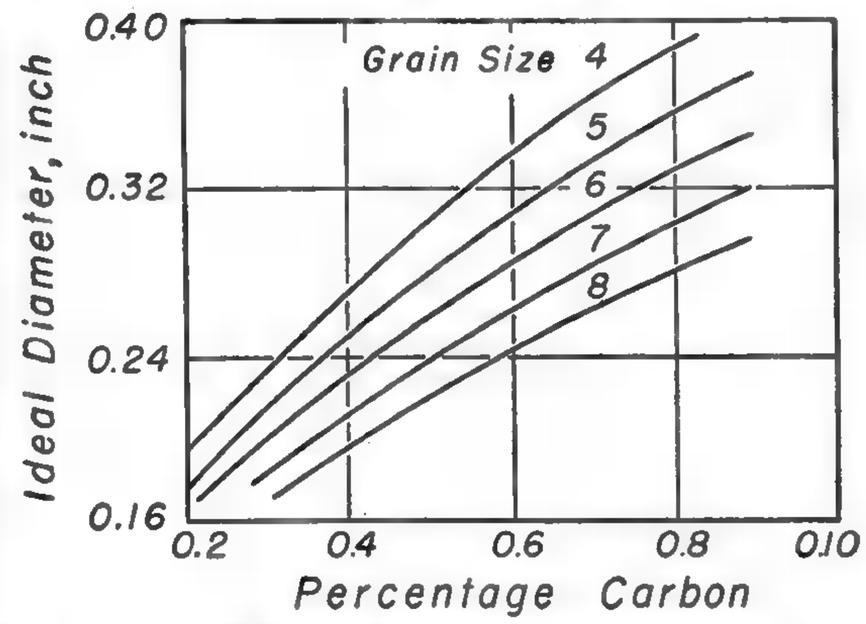

Fig. 19 The hardenability of pure iron-carbon alloys as a function of carbon content and grain size (Grossmann).

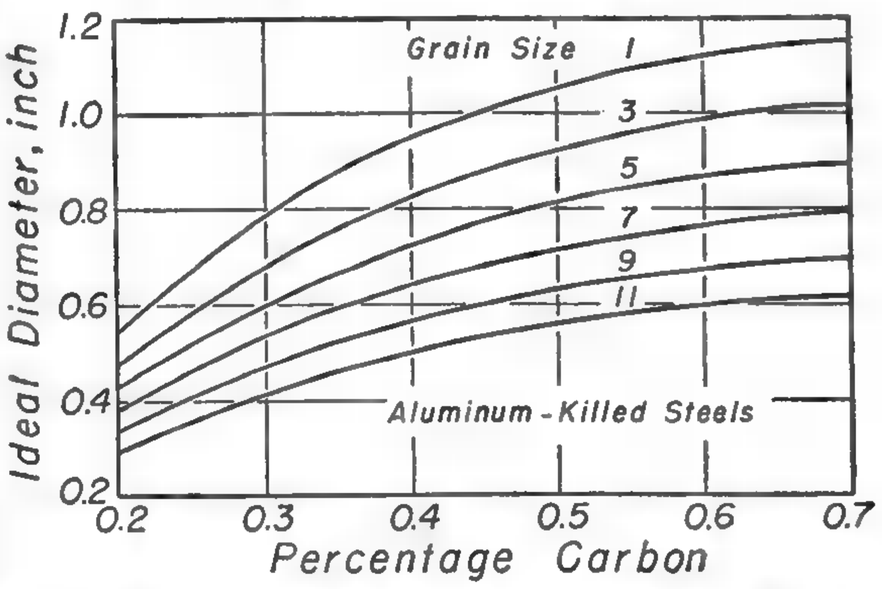

Fig. 20 The hardenability of pure iron-carbon alloys as a function of carbon content and grain size in aluminum-killed steels (Kramer, Siegel and Brooks).

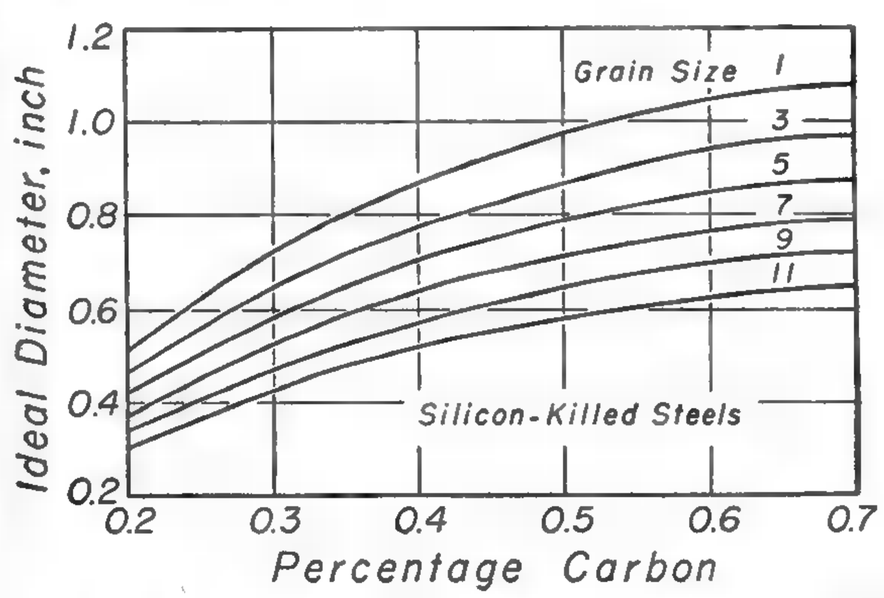

Fig. 21 The hardenability of pure iron-carbon alloys as a function of carbon content and grain size in silicon-killed steels (Kramer, Siegel and Brooks).

This limitation to microstructures containing 50% martensite may be serious, particularly in steel of higher hardenability, since in such steels the differences will be relatively large between hardenability values in terms of this microstructure and hardenability values in terms of the full martensite criterion associated with the optimum properties of tempered martensite. However, the relationship among hardenability values based on criteria of 50, 95 and 99.9% martensite have been studied in a number of low-alloy and medium-alloy steels and the average relationships are shown in Fig. 22. These data will serve as a guide to the application of hardenability values based on the criterion of 50% martensite to steels in which the optimum properties of tempered martensite are desired. Furthermore, recent work by Hodge and Orehoski indicates strongly that the values of the multiplying factors for the alloying elements are essentially independent of the criterion of hardenability used in their determination; that is, that an individual alloying element will affect hardenability in terms of a 50% martensite microstructure in a manner essentially the same as it affects hardenability in terms of a microstructure containing 95% martensite. Thus, knowing the base hardenability values for iron-carbon alloys, in terms of the specific microstructure of interest, hardenability values in terms of this microstructure may be calculated by multiplying this base value for carbon by the multiplying factors for the alloying elements as described above. Such hardenability values for iron-carbon alloys at a grain size of 8, in terms of microstructures of 50, 95, and 99.9% martensite, as evaluated by Hodge and Orehoski, are shown in Fig. 23. It should be noted that the values for 50% martensite are similar to those determined by Kramer, Siegel and Brooks and that, therefore, their lower manganese values should be used in conjunction with these carbon values.

Thus, there are now two methods of estimating values of hardenability in terms of microstructures other than 50% martensite, and the principle of multiplying factors may be applied to the calculation of hardenability in terms of microstructures that correspond more closely to optimum properties.

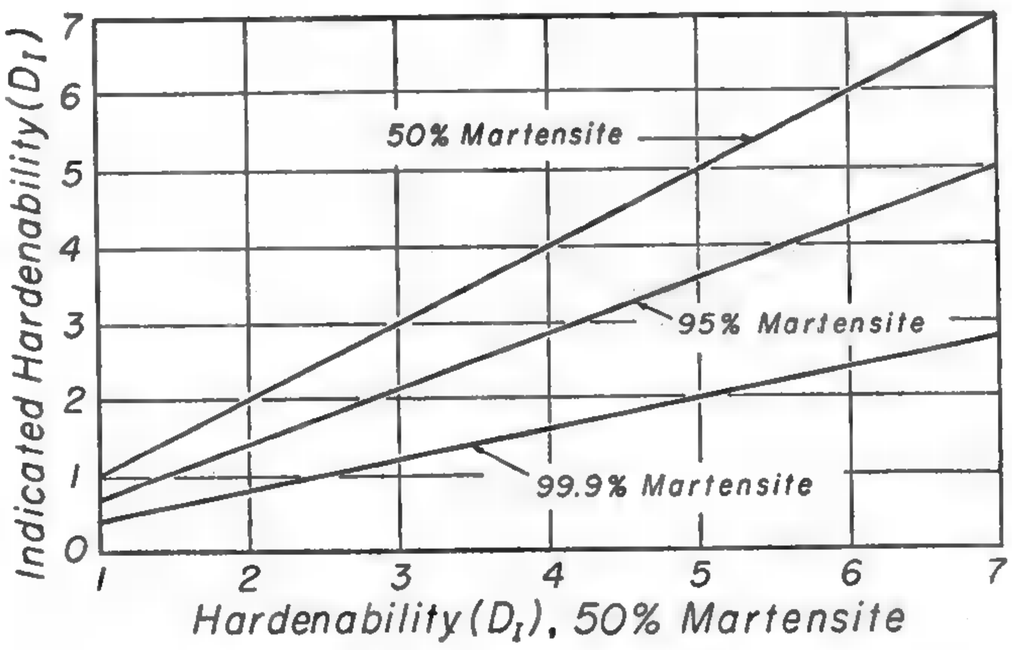

Fig. 22 Average relationships among hardenability values in terms of 99.9, 95 and 50% martensite microstructures.

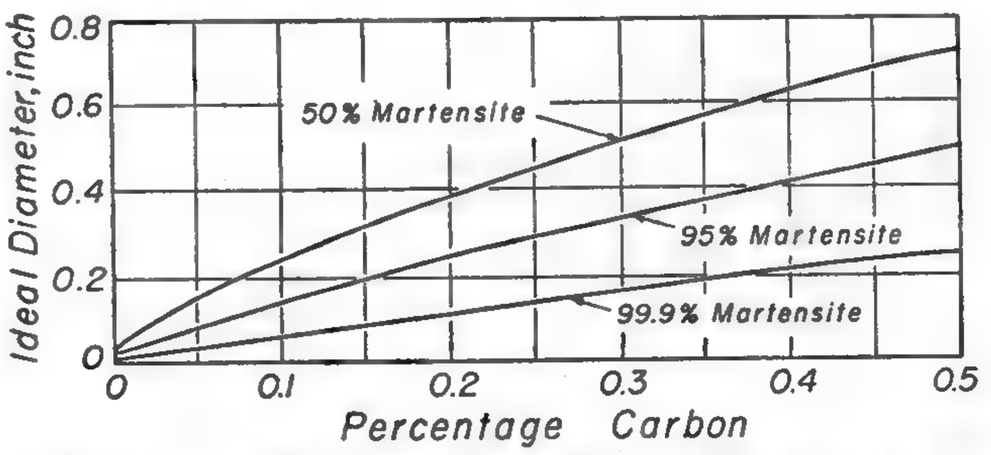

Fig. 23 Hardenability of iron-carbon alloys as a function of carbon content and microstructure—grain size No. 8 (Hodge and Orehoski).

An aluminum-killed, low-alloy steel of the following composition, at a grain size of 8, will serve to illustrate these methods: 0.40% C, 0.80% Mn, 0.20% Si, 0.20% Mo.

The hardenability corresponding to 50% martensite will be the product of the base carbon value for 50% martensite and the multiplying factors for the manganese, silicon and molybdenum, as follows:

$$0.6 \times 1.45 \times 1.2 \times 1.5 = 1.57 \text{ in. } D_I$$

According to Fig. 22, this would correspond to a hardenability of 1 in. D_I on the basis of 95% martensite or 0.6 in. on the basis of 99.9% martensite.

Using the carbon values of Fig. 23, the hardenability values in terms of 95 and 99.9% martensite would be calculated as follows:

1 For 95% martensite
$0.4 \times 1.45 \times 1.2 \times 1.5 = 1.05$ in. D_I

2 For 99.9% martensite
$0.21 \times 1.45 \times 1.2 \times 1.5 = 0.55$ in. D_I

Calculation of the End-Quench Hardenability Curve. As a result of statistical studies of the relationship between calculated hardenability and the corresponding end-quench hardenability curves, Joseph Field has developed factors that permit a reasonable prediction of the actual end-quench curve from the composition and grain size of the steel. These factors express the relationship between the hardness value at 1/16 in. from the quenched end of the test specimen, which is characteristic of the carbon content, and the hardness values at distances of 2 in. or less from the quenched end. The factors used in these calculations are shown in Fig. 24, 25, 26 and 27. The base carbon values, which are those of Grossmann, are repeated in order that all the factors for this type of calculation may be together. The multiplying factors for the alloying elements are those that have been found by the statistical studies to correlate most closely with the end-quench curves.

The calculation is carried out as follows:

1 The D_I is calculated by multiplying the D_I value for the carbon and grain size progressively by the multiplying factors for the alloying elements.

2 The hardness at 1/16 in. is determined from the curve correlating this value with carbon content.

3 The ratio between this hardness and the hardness values at ¼, ½, ¾, 1, 1¼, 1½, 1¾ and 2 in. from the quenched end, is read from the curve correlating this IH/DH ratio with calculated hardenability.

4 The actual hardness values at these locations are determined by dividing the initial hardness value by the IH/DH ratio.

This method will permit a reasonably accurate prediction of the end-quench curve, except in steels containing less than 0.20% C or in plain carbon steels. Low-alloy steels of 0.20 to 0.30% C have also been found to indicate hardness values somewhat higher than the actual results.

Correlation of hardness values on standard end-quenched specimens and oil-quenched round bars, taken from the 1946 SAE Handbook. H = 0.35 approx. Hardness values for 50% and 90% martensite are taken from Fig. 7 on page 497 of this Handbook. The AISI-SAE minimum end-quench hardenability data are taken from the minimum curve of the AISI-SAE Tentative Hardenability Bands.

Maximum Diameters (in inches) of Bars of Required As-Quenched Hardness at the Center (H Steels)*

Wrought Iron

By A. W. F. Green*

WROUGHT IRON is a ferrous material, aggregated from a solidifying mass of pasty particles of highly refined metallic iron with which a minutely and uniformly distributed quantity of slag is incorporated without subsequent fusion.

Manufacturing Terms. The following terms are particularly applicable to wrought iron and the products manufactured from it:

puddled ball. The agglomerate cellular mass of refined iron intimately mixed with a siliceous slag, which is the result of hand puddling, mechanical puddling, or the pouring of molten refined iron into a siliceous slag as in the Aston or Byers process.

bloom. The product that results from the squeezing of the *puddled ball.*

muck bar. A bar rolled from a squeezed *bloom.*

busheling. The process of heating to a welding heat in a suitable furnace, miscellaneous iron, steel or a mixture of iron and steel scrap cut into small pieces. (The welded mass is then squeezed into a *bloom* and rolled into scrap bar for piling or *fagoting.*)

fagoting. The making of a "fagot" or "box", the bottom and sides of which are formed of *muck bars* or scrap bars and the interior, of miscellaneous iron scrap or a mixture of iron and steel scrap.

slab pile. A pile built up wholly of flat bars of iron, all running the full length of the pile.

box pile. A pile, the outside of which is formed of flat bars and the interior of which is formed of a number of small bars, all running the full length of the pile. Used in the manufacture of wrought iron bars.

refined bar iron or refined wrought iron bars. Iron bars rolled from a *muck bar pile* or from a *box pile,* of muck bars and wrought iron scrap free from steel; all bars run the full length of the pile.

double-refined iron. Iron to be classed as "double refined" should be all new wrought iron, which should be rolled first into *muck bars.* These bars should then be twice piled and rolled. All iron should be free from steel and from foreign scrap.

common iron. Iron made from rerolled scrap iron or a mixture of iron and steel scrap, when no attempt is made to separate the iron and steel scrap.

Methods of Manufacture. Five methods have been employed for the making of wrought iron: (1) hand puddling, (2) mechanical puddling, (3) the Aston or Byers process, (4) busheling and (5) fagoting.

Hand Puddling Process. In early times wrought iron was produced directly from the ore by reduction with carbonaceous fuel. In later times wrought iron has been produced by a variety of processes, usually by indirect means; that is, the ore is first reduced to pig iron and the pig iron is then transformed to wrought iron by puddling or by some other process.

Henry Cort of England is credited with the invention of the reverberatory type of furnace for the production of puddled wrought iron. The date given for this invention is 1784. Hand puddling was employed with only slight modification until about 1930, by which time the process had been almost entirely abandoned.

Mechanical Puddling Process. The first attempts to use mechanical puddling involved retaining the furnace as it was and substituting mechanical for manual power in manipulating the rabbles or stirring rods. The early developments that showed the most promise centered about the use of revolving furnaces. These were of three types: (1) those having a variable axis of revolution, (2) those having an approximately vertical axis, and (3) those having a horizontal axis.

The reactions in mechanical puddling procedures are virtually the same as those in the hand puddling procedure. The metal is refined in the furnace and, because of a decreasing content of impurities, the charge solidifies to form a pasty mass of iron and slag, which is then agglomerated by mechanical working.

The Aston or Byers Process. The most important invention having to do with the making of wrought iron is known as the Byers or Aston process. The work that resulted in this invention started about 1918. The Byers or Aston process is very different from puddling either by hand or by mechanical means. The metal is melted in cupolas. The molten metal is then carried in suitable ladles where it is desulfurized and, immediately thereafter, is poured into Bessemer converters where it is refined according to regular steel procedure. Silicon, manganese and carbon are oxidized in this refining operation. The blown metal is then tapped into a ladle and taken to the processing platform, where it is poured into the ladle of the processing machine. The molten refined iron is poured at a predetermined rate into the ladle that contains molten slag. The temperature of the slag is maintained several hundred degrees lower than the freezing point of the refined metal, so the metal is continuously and rapidly solidified. This rapid solidification of the metal liberates dissolved gases with sufficient force to shatter the metal into small fragments, which settle to the bottom of the ladle. Because of the heating temperature and fluxing action of siliceous slag, these fragments weld together, making an agglomerate cellular mass in the

* Chief Metallurgist, Allison Division, General Motors Corporation, Indianapolis

form of a sponge. Immediately after the pouring, the ladle is transferred and excess slag is poured off into an adjoining empty ladle. The sponge ball, weighing from 6000 to 8000 lb, is dumped, at the rate of one every five minutes, on a platform of an electrically driven 900-ton press, where the ball is squeezed, collecting the mass into solid blooms for rolling.

Squeezing. Three types of squeezers are used for compressing the sponge balls into suitable shape for rolling into muck bar, bloom or billet sizes. The first is the small so-called "coffee mill" type that has a drum operating on a vertical axis. The second is a generally larger type with a drum that operates on a horizontal axis. The third type includes steam, electric or hydraulic presses where pressures are applied on the ends as well as on the four sides of the ball.

Table I. Typical Compositions of Wrought Iron

Type of Iron	Composition, percentage C	Mn	Si	P	S	Slag by Weight
Byers No. 1.....	0.08	0.015	0.158	0.062	0.010	1.20
Mechanical iron..	0.08	0.029	0.183	0.115	0.015	2.85
Hand-puddled iron	0.06	0.045	0.101	0.068	0.009	1.97

Chemical Composition. Genuine wrought iron is distinguished by its low carbon and manganese contents. Many specifications written to cover wrought iron compositions, lay particular stress on the manganese content. It is generally conceded that freedom from contamination by steel or by poor quality wrought iron can be shown if the manganese content is less than 0.07%. Some typical chemical compositions are shown in Table I.

Carbon. A carbon content greater than 0.10% is usually construed to mean imperfect refining, or causes suspicion that steel scrap has been used in making up the customary "piles".

Manganese. Well-made wrought iron contains less than 0.10% Mn. If more than that amount is present, imperfect refining may be indicated, or adulteration by use of steel in busheling or piling.

Phosphorus. The phosphorus content of wrought iron is largely in the incorporated slag. Good wrought iron will

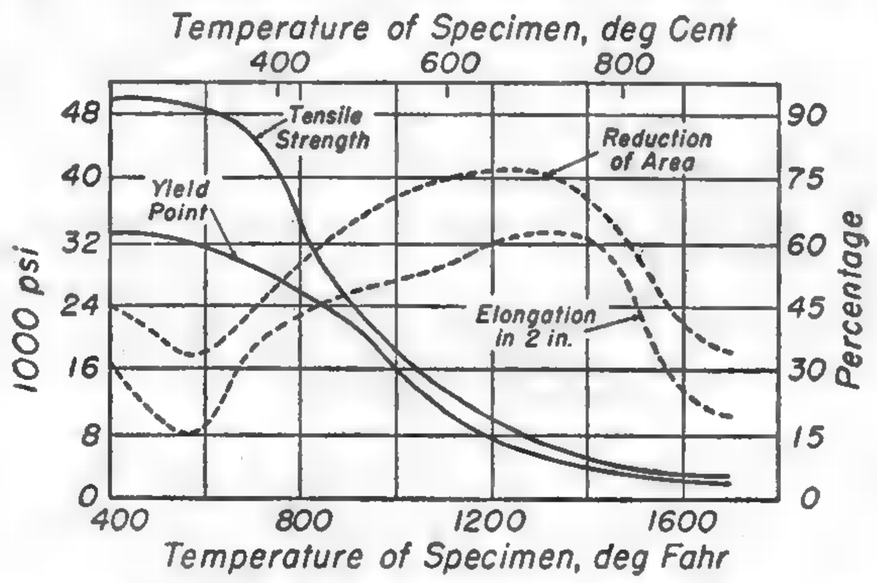

Fig. 1 Tensile properties of wrought iron at elevated temperature

contain from 0.08 to 0.160% P, of which from 40 to 30% will be combined with the slag.

Sulfur. High-grade wrought iron contains as much as 0.035% S. Larger amounts indicate imperfect refining and are known to produce "red shortness".

Silicon. The amount of silicon is usually from 0.10 to 0.20%. The proportion associated with the base metal is virtually nil. The presence of less than 0.10% Si indicates either that the amount of slag is less than normal or that the composition of the slag is not suitable for properly refined wrought iron. The presence of approximately 0.20% Si may indicate poor distribution of slag, probably because of improper mechanical working.

Slag. A considerable amount of slag is present in wrought iron. A typical percentage composition of the slag found in wrought iron is as follows: SiO_2, 14.58; Fe, 58.72; FeO, 70.49; MnO, 1.51; Al_2O_3, 2.72; CaO, 2.59; P_2O_5, 0.80; S, 0.08; Cu, trace; and Fe_2O_3, 5.65. The amount of slag present in wrought iron, by weight, varies from 1% to as much as 4%, and is generally about 2%.

Alloy Wrought Iron. The most prominent of the alloy wrought irons are those containing up to about 3½% Ni. Molybdenum has been alloyed successfully and nickel and molybdenum have been used together. Copper is often found in wrought iron. It is possible to alloy copper in the making of wrought iron. There is a question as to whether or not the presence of copper has a deleterious effect on the "red shortness" characteristic. Numerous experiments have shown, however, that copper does not affect this condition appreciably in percentages as high as about 0.3% and it is possible that the presence of copper is desirable from the standpoint of corrosion. The presence of 3½% Ni raises the elastic limit and tensile strength substantially. Molybdenum does not seem to have a marked effect on physical properties, and no concise data have been found that show the presence of molybdenum to have a substantial effect on the general quality of wrought iron. A typical percentage composition of nickel wrought iron is as follows: C, 0.06; Mn, 0.035; P, 0.070; Si, 0.18; S, 0.011; Ni, 3.25; and slag, 1.90.

Table II. Mechanical Properties of Wrought Iron

Material	Endurance Limit, Rotating Beam, psi	Axial, psi	Tensile Strength, psi	Charpy Notched Bar, ft-lb	Brinell Hardness Number
Wrought iron, longitudinal	23,000	16,000	46,900	17.5	105
Wrought iron, transverse	19,000	11,000	34,400	4.8	105
Ingot iron, as rolled	26,000	17,000	42,400	19.3	69
Structural steel, 0.18% C (as rolled)	28,000	.....	61,500	...	...

Tensile Properties at Low and High Temperature. The tensile properties of wrought iron without nickel are as follows: tensile strength, 42,000 to 52,000 psi; yield point, 26,000 to 35,000 psi; elongation in 8 in., 25 to 40%; and reduction of area, 40 to 55%.

When approximately 3.25 to 3.50% Ni is added, the values are about as follows: tensile strength, 55,000 to 60,000 psi; yield point, 45,000 to 50,000 psi; elongation in 8 in., 25 to 30%; and reduction of area, 35 to 45%.

Results of tensile tests at high temperatures are given in Fig. 1.

Repeated Stress. From the indications of laboratory tests alone, wrought iron is about the weakest ferrous material under repeated stress. Moore has determined the endurance limits in rotating-beam and axial-loading tests, as shown in Table II.

The presence of slag does not greatly reduce the resistance of wrought iron to fatigue as long as the applied stress is longitudinal.

Impact Strength. The results of impact tests on wrought iron are listed in Table III.

Physical Properties.

Specific gravity	7.70
Melting point	2750 F
Coefficient of thermal expansion, 18 to 100 C.....	11.40×10^{-6}
Heat conductivity at	
16 C	0.152
18 C	0.144
100 C	0.143

Bend Tests. Bend tests are included in the testing of wrought iron to indicate not only the ductility but also quality, correct piling, and freedom from adulteration with steel. These tests are made both hot and cold and also by the nicking of cold bars.

Hot bend tests on wrought iron of highest quality require bending the sample flat on itself from a temperature of 1700 to 1800 F. The poorer grades of wrought iron are bent around a pin, equal in diameter to the diameter or the thickness of the bars being tested. It is sometimes required that hot bend tests be made at temperatures of 1400 to 1500 F to determine whether or not the iron is "red short", a condition that is not uncommon.

Pickling. The usual procedure for the pickling of

Table III. Izod Value for Wrought Iron

Common iron	1 in. diam	63½	70
Common iron	1 in. sq	62½	71
Common iron	2 by ½ in. flat	43	51

wrought iron pipe, rod, and bar, is to use a 4 to 5% solution of sulfuric acid at 160 to 170 F. The pickling time for pipe varies from 1 to 1¼ hr and for rods or bars, 30 to 45 min. After the pickling, material should be washed in water, and then passed through a bath of ½% caustic soda and ¾% trisodium phosphate by volume.

Carburizing. Wrought iron can be case hardened. The usual process is to pack the parts in suitable compounds and to quench from the carburizing box in water, or to cool the material in the box, to reheat to a suitable temperature and then to quench in water.

The type of iron to be case carburized should be selected carefully since best results are obtained from iron made from box piles. The temperatures for carburizing and hardening are much the same as would be used for carburized 1010 steel.

Protective Coatings. Protective coatings adhere firmly to wrought iron. This is to be expected because of the nature of the material. In general, any protective coating that is applied to steel can be applied to wrought iron.

Welding.* The ease with which wrought iron can be welded is attributed to the relative purity of the base metal and the siliceous slag, which confers a self-fluxing quality easily observable in hammer and pressure welds. Because of this self-fluxing quality, uniform strong welds are rapidly secured.

Wrought iron is readily welded by oxyacetylene and arc methods. With most metals a fluxed or greasy surface is ordinarily an indication that the temperature is high enough for starting to apply fused secondary or weld-rod metal. However, this is not true of wrought iron since the self-fluxing characteristic causes a greasy appearance initially at a somewhat lower temperature.

Resistance to Corrosion. Through centuries of application, wrought iron has exhibited great resistance to progressive corrosion, primarily because of the distribution of slag throughout the mass. Where wrought iron is exposed to corrosive mediums it is quickly coated with a film of oxide or rust. As corrosion proceeds, additional oxide is formed but the slag filaments begin to function as rust-resisters. The initial oxide film is securely fastened to the surface of the metal by the pinning effect of the slag filaments, thus serving to protect the metal from further oxidation.

All grades of wrought iron do not offer the same resistance to progressive corrosion. Busheled and fagoted iron, especially the types known as "common iron", do not have high resistance to progressive corrosion. Resistance to progressive corrosion is limited to wrought iron that has not suffered by adulteration through working.

Applications and Forms Available. Wrought iron is used by the railroads, by shipbuilding industries, oil industries, and public utilities, as well as for architectural purposes and for farm implements.

Wrought iron is available in blooms and billets, in all types of hammered bars and forms, and in hot rolled shapes, including sheets and plates; also in the form of wire for nails, barbed wire and general manufacture.

Weight of Wrought Iron. In calculating the weight of wrought iron bars and shapes, it is common practice to use the tables that are applicable to steel and to subtract 2% from the weight shown in such tables.

Cast Iron

By H. Bornstein* and J. W. Bolton*

THE GENERAL term "cast iron" includes gray irons, pig irons, white cast irons, chilled (white face) cast irons and malleable iron. Cast irons are alloys of iron, carbon and silicon in which more carbon is present than can be retained in solid solution in austenite at the eutectic temperature. Therefore cast irons contain eutectiferous components, or decomposition products of such components. The carbon content is usually more than 1.7% and less than 4.5%.

The ductility of cast irons as cast is relatively low, from virtually zero in white irons to possibly 2% in lower-carbon gray irons. No irons can be wrought at room temperature as cast; the majority are not usefully malleable at any temperature. However, they can be cast into complicated shapes, certain types of which cannot be made by forging, rolling, stamping, extrusion or other forming processes even when more ductile and malleable metals are used.

Pig Iron.† Pig iron is produced by reduction of iron ore in the blast furnace. Most of the molten metal is cast into pigs (ingots) for remelting. A small percentage of molten pig iron is used directly in castings and, for that reason, is known as "direct metal". Some pig iron

* Deere & Company, Moline, Ill.
* The Lunkenheimer Co., Cincinnati

† *See* "The Iron Blast Furnace Process", page 315 in this Handbook.

is transported in the molten state and used in open hearth processes of steelmaking. A large amount of solid pig iron is remelted and refined in open hearth furnaces and converters in steelmaking processes. Most of the remainder is used as the basic material in the manufacture of gray iron and malleable iron.

Gray Iron. Gray iron is the most widely used of cast metals. Its tonnage production exceeds that of all other cast metals combined.

The term "gray iron" covers a series of eutectiferous alloys that offer a wide selection of mechanical properties together with economy in the production of cast shapes and in subsequent machining.

Composition and processing are adjusted so that usually the matrix structure is largely pearlitic, with many graphite flakes dispersed throughout. The presence of graphite flakes imparts the characteristic "gray" fracture, promotes ready machinability, and imparts useful damping properties and resistance to wear.

Typical applications of gray iron are in the automotive industry (cylinder blocks, and other parts), in machine tools, agricultural implements, cast-iron pipe, flanges, fittings and the like. Gray iron castings are used in all the manufacturing, transportation, chemical, power, and mining industries, as well as in every household and on every farm.

The wide range of strengths in gray irons (from 20,000 to more than 60,000 psi) plus manufacturing economy, explain the extensive use of these irons where high resistance to dynamic stress is not a governing factor.

Gray irons are usually made within the composition ranges of 1.00 to 2.75% Si, and 2.70 to 3.60% total C.

Alloy Iron. The term "alloy iron" is used to designate cast iron to which chromium, nickel, molybdenum, copper or other elements have been added deliberately to modify or augment the properties attainable by the "normal" elements—iron, carbon, silicon, manganese, phosphorus and sulfur.

Austenitic Cast Iron. These are gray cast irons containing sufficient and suitable percentages of alloying elements to lower the eutectoid transformation temperature to such an extent that austenite is retained as the matrix at room temperature, with graphite flakes dispersed throughout the structure. Nickel is the alloying element commonly used for this purpose. Copper, chromium and molybdenum may be used to abet the action of nickel, or to modify the properties, or both. Austenitic cast irons have unusual magnetic properties and corrosion resistance.

White Cast Iron. In white cast iron almost all the carbon is in the combined form. The presence of free cementite or iron carbide (Fe_3C) makes this metal hard and nonductile. White iron may be classified further according to the process. Chilled cast iron is produced by casting the iron against metal chills. When cast into a sand mold, such iron may be gray iron, but the chills cause rapid cooling at the adjacent areas; consequently cementite is formed there.

Besides chilled irons and white irons for the manufacture of malleable cast iron, other irons, white throughout as cast, are used for special purposes, particularly for resistance to wear and abrasion. When maximum hardness is desired, alloying elements are usually added, both to promote the formation of the cementite and to increase the hardness of the matrix. (*See* section under Alloy Cast Irons.) Special white iron rods are used for welding white iron layers to various ferrous metals. The very high-chromium cast irons (25% Cr and more), used for their resistance to corrosion, are white irons, properly speaking, yet are not much harder than some gray irons.

Malleable Cast Iron. This term is applied to castings in which all the combined carbon in a special white cast iron has been changed to free or temper carbon (temper graphite) by suitable heat treatment. (See the article "Malleable Iron", on page 520 in this Handbook.)

Manufacture and Uses of Cast Iron

Cupola Melting.[2] Most of the gray iron produced in this country is melted in the cupola furnace. The cupola is a vertical, cylindrical type of furnace, consisting of a steel shell lined with firebrick (*see* Fig. 1). Usually the charging door is located 15 to 25 ft above the bottom plate. At the lower end of the furnace is the wind box or air box as shown in the diagram. Air enters the cupola through openings called tuyeres. Some cupolas are equipped with a single row of tuyeres; others have an auxiliary upper row of tuyeres. Opinion is divided as to whether a single or a double row is more desirable. A patented cupola known as the "balanced blast cupola", developed by the British Cast Iron Research Association, has three rows of tuyeres. A number of furnaces of this type have been installed in this country.

The cupola is a simple and economical melting unit, because the fuel and the metal are in intimate contact with each other.

Fuel, metal and flux enter the cupola through the charging door. The initial charge of coke is known as the "bed charge". The metal is deposited on the coke. Then alternate layers of coke and iron are added. Generally a flux

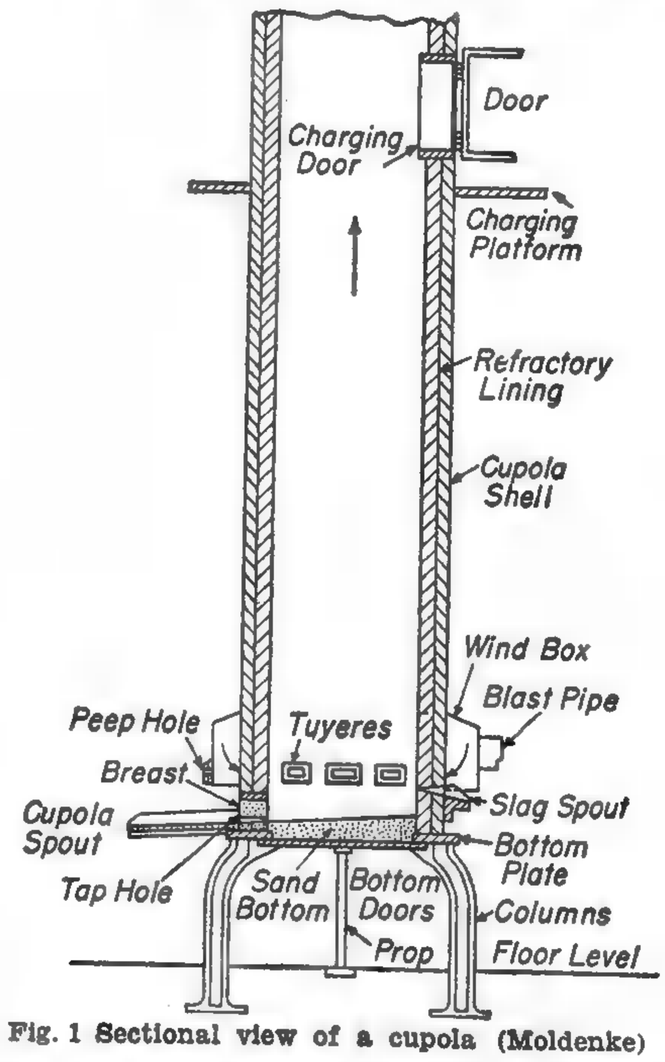

Fig. 1 Sectional view of a cupola (Moldenke)

is charged on the coke and the coke bed is ignited by means of kindling wood or an oil torch. This bed usually extends from 36 to 60 in. above the top of the lower tuyeres. The make-up of the charge and the charging are most important in obtaining uniform results in melting. Careful weighing and placing of the components of the charge are essential. The method of charging the materials into the cupola is important. Good results can be obtained both by hand charging and by mechanical charging but the tendency is towards the mechanical practice.

There is an optimum charge of coke for each size of cupola and the size of the metal charge depends on the ratio of metal to coke. The cupola sizes, designated according to the inside diameter of the lining of the cupola, may range from 18 to more than 100 in. ID. The sizes used for commercial practice usually range from 42 to 84 in. ID. The rated capacities of these sizes are from 5 to 25 tons of metal melted per hour.

The amount of metal charged into the cupola varies considerably because of many conditions and opinions. Following are sizes of charge that can be considered typical: 48-in. cupola, 1500-lb charge; 60 in., 2000 lb; 72 in., 3000 lb. The size of a charge may vary considerably from these figures and still be considered good practice. The tendency has been towards smaller charges to obtain greater uniformity of metal and economy of fuel.

The quantity of metal charged depends on the quantity of coke between charges. The bed charge is a definite

height above the lower tuyeres. Consequently, this portion of the coke goes in by volume, but the succeeding charges of coke are put in by weight. The proportion of metal to coke will usually range from 7:1 to 12:1.

The metal charged into the cupola ordinarily consists of returns (sprue and local scrap), purchased gray iron scrap, and pig iron. Steel scrap is used also, particularly where increased strength is desired. The proportions of gray iron scrap, pig iron and steel scrap are governed by the type of castings desired. Ordinarily the mixtures of metals differ considerably, even among foundries making the same class of work. Availability of certain types of scrap is frequently a controlling factor.

The mixture of metal to be charged into the cupola is determined by the composition of the metal desired for the finished castings. The base of the charge is usually pig iron. Charges are seldom entirely of scrap metals. Since the pig iron is of known composition, the greater the amount of pig iron and the smaller the amount of purchased scrap, the more uniform will be the composition of the resulting castings. For high-grade castings, such as automobile cylinders, the percentage of pig iron may range from 25 to 45% of the charge, while for castings such as sash weights, almost no pig iron will be used.

Limestone is ordinarily used as a flux in the operation of a cupola. The purpose of the flux is to form a slag with the dirt, impurities in the metal, and the coke ash. Fluorspar (calcium fluoride) is sometimes used as a fluxing agent, in combination with the limestone, to thin the slag and also to aid in the removal of sulfur. Soda ash is used as a cupola flux together with limestone. A number of available proprietary fluxes are also commonly used in connection with limestone. Soda ash, sometimes used as a flux in the ladle, reduces the sulfur content and improves the fluidity of the metal. Proprietary fluxes are also used for this purpose.

Air is introduced into the cupola through the tuyeres, to aid in the combustion of the coke, which in turn melts the metal. The volume of air introduced is important and governs the melting rate of the cupola. About 30,000 cu ft of air is required to melt one ton of metal. Under ordinary conditions the blast pressure will range from 8 to 20 oz, depending on the height of the cupola, the number of charges and the character of the metal charged. In some of the larger production foundries, where blast pressure has been increased to obtain greater capacity from the cupola, blast pressures in the neighborhood of 30 oz are frequently employed.

Auxiliary devices may be used for controlling the weight of air entering the cupola. The weight of the air is more important than the volume, and control of the weight is considered essential for good operation of the cupola. The weight of air can be determined by means of a volume meter and knowledge of air pressure and temperature. In the hot blast cupola the air is preheated to temperatures between 350 and 500 F. This results in more uniform operation of the cupola and in improved fuel economy. Balanced blast cupolas also have resulted in more uniform operation and fuel economy. The control of moisture for the cupola air blast is being practiced more widely; this has resulted in more uniform melting and in more uniform properties of castings.

Summary of Cupola Furnace Data for Cast Iron. The following figures are given for typical operations of a cupola. Cupola practice varies considerably; consequently the figures shown are given only as a guide. Wider limits beyond these figures may be used and may still be consistent with good practice.

Area of melting zone of cupola in square inches multiplied by 0.75, gives a suitable weight in pounds for the iron charge.

One pound of coke is required to melt 6 to 10 lb of iron; this includes both the coke in the bed and that between the charges.

To burn 1 lb of coke to carbon dioxide, 125 cu ft of air is needed.

Approximately 30,000 cu ft of air is required per ton of metal melted.

To melt 10 lb of iron per square in. of cupola area per hour is considered a good rate.

The tuyere area for a 36-in. cupola may be ⅛ of the cupola area, and for an 84-in. cupola may be 1/10, with other sizes in proportion.

Electric Furnace Melting. Although the electric furnace is used to only a limited extent for melting cast iron, this type of furnace affords accurate control of composition and temperature. In some instances large quantities of scrap, such as borings, can be utilized. The lower cost of scrap metals for electric furnaces helps to compensate for the higher cost of melting, as compared with the cost of melting in the cupola.

Table I. Typical Compositions of Some Commercial Gray Iron Castings

Casting	Composition, percentage							
	T C	Si	Mn	P	■	Ni	Cr	Mo
Auto cylinder, plain iron	3.25	2.25	0.65	0.15	0.10	....	....	....

Two types of electric furnaces are in general use—the three-phase direct arc and the single-phase indirect arc of the rocking type.

In some instances, the electric furnace is used for the entire melting process; in other instances a duplex method is used. In the duplex method all or part of the charge is melted in the cupola and the molten metal is superheated in the electric furnace. Alloying elements and steel may be added to the metal in the electric furnace. For steady production the duplex method is usually more economical because of the lower cost of melting in the cupola.

Air Furnace Melting. The air furnace, employed to a limited extent in the production of gray iron castings, permits accurate control of composition and is sometimes used for making castings of higher strength.

Horizontal rotary furnaces (cylindrical in shape) heated with pulverized coal or oil, are used to a considerable extent in Europe. Two well-known furnaces of this type are the Brackelsberg and Sesci, which permit good control of composition and temperature. The Brackelsberg furnace has not been widely used in the United States.

Uses. Gray iron castings, used for a large variety of articles, vary in weight from a fraction of a pound to many thousands of pounds. A few of these applications are automobile cylinders and pistons, locomotive cylinders, agricultural machinery, machine tool castings, stove castings, car wheels, dies, engine frames and beds, flywheels, water pipe, soil pipe and hardware (*see* Table I).

White and Chilled Irons

Virtually all the carbon in white cast irons exists in the combined form, chiefly as free cementite (Fe_3C) and as pearlite or one of its transitional forms. The presence of a large amount of cementite makes the material hard and brittle.

"Chilled iron" is cast iron in which the carbon is retained in the combined form in desired areas so that a mottled or white structure is obtained. For accomplishing this result, means are employed to accelerate cooling to such an extent that normal graphitization is prevented in the chilled areas.

White cast iron is produced by proper adjustment of composition. A low silicon content is usually required. Elements that stabilize carbide—for example, chromium—may be added. For methods used in producing white iron in the malleable iron industry, see the article on "Malleable Iron" in this Handbook.

"Completely white" cast irons are limited in engineering applications because of brittleness and lack of machinability. These irons are ordinarily employed where resistance to wear is a major problem and the service does not require ductility. Castings of "completely white" cast iron are usually finished by grinding.

In many castings, it is desirable that a portion of the surface (or the complete surface) should be extremely hard in order to combat certain types of abrasive wear. It is possible to produce castings that have hard white iron surfaces and tough gray iron cores. Such castings, called "chilled castings", are produced by rapid cooling of the surface, usually by means of metal "chills". The depth of the chilled portion depends not only on the composition and thickness of the casting but also on the rate at which the "chills" abstract heat. The thickness of the chill (usually cast iron) and its initial temperature are important. The compositions used for the castings are such that a gray fracture would result if the metal were cast into sand molds without the use of "chills". The hardness of the chilled surface and the strength of the gray iron core may be increased by proper additions of alloying elements.

The carbon content of the metal for both white and chilled iron castings is important. As the carbon content increases, the hardness usually increases. The lower carbon contents (about 2.5% C), such as are used for malleable white iron, generally result in relatively lower hardness. For such white irons, the hardness will be approximately 350 Bhn. When the carbon content is increased to about 3.50%, the hardness of the white or chilled iron areas will be greater than 500 Bhn, and may be increased further by addition of alloying elements.

Among the more common chilled and white iron castings are chilled rolls, chilled car wheels, plowshares, balls, stamp shoes, dies, and wearing plates of various sorts.

Some Physical and Metallurgical Properties

Transformation Ranges. The values given for transformation ranges of cast iron have been determined by means of thermal phenomena exhibited during slow cooling of ordinary gray irons.

1 The initial solidification point varies with the composition, and is lowered by an increase in carbon and silicon content. This point may be as low as about 2066 F in an iron of eutectic composition, and as high as about 2500 F in a white iron containing 2.00% C and 0.85% Si.
2 The "final" or eutectic solidification occurs within the range from 2066 to 2102 F, according to the composition of the metal.
3 Steadite formation occurs at about 1750 to 1800 F.
4 Transformation of austenite (nonmagnetic) to pearlite (magnetic) occurs between 1325 and 1350 F in most slowly cooled irons.

Under very slow cooling conditions, that is, when rates permit equilibrium, the austenite-pearlite transformation range is not depressed and occurs at somewhat higher temperatures, from about 1400 to 1450 F for 2% Si, 3% C iron. Increase in carbon and silicon contents raises and

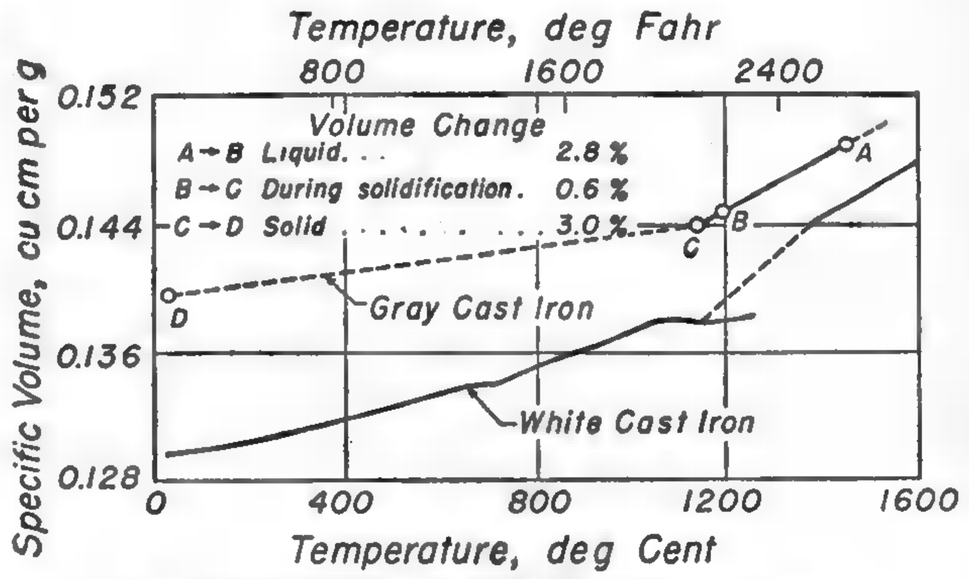

Fig. 2 Volume changes in cast iron (Ash and Saeger[6])

widens the transformation temperature range. The addition of alloying elements affects the transformation appreciably. For one example, high percentages of nickel depress the transformation range to considerably below room temperature so that as cast, the material is austenitic and remains so in spite of any thermal treatments.

Contraction and Expansion. Patternmakers' rules allow ⅛ in. per ft for linear contraction of gray iron, and $\frac{5}{16}$ to ¼ in. per ft for white iron (⅛ in. per ft is about 1%). Often this allowance is found inaccurate in practice, and more adequate allowance must be made for mass, composition, and effects of shape, mold and core. Generally contraction is less with increase in mass and, in gray irons, increases with increase in tensile strength.

Three contraction phenomena are exhibited during the cooling of a cast iron from the molten state to room temperature: (*a*) in the liquid, (*b*) during solidification, and (*c*) subsequent to solidification. These contractions are illustrated in the charts made by Ash and Saeger (Fig. 2).

Shrinkage in volume during solidification ranged from negative shrinkage in "soft" irons to +1.94% in an iron containing about 0.90% combined C. The white irons had 4.0 to 5.5% contraction in volume within the same range of temperature.

Coefficient of Expansion. The coefficient of expansion of gray irons in the range from 0 to 500 C (32 to 932 F) is about 13×10^{-6} per °C. The expansion is about 10.5×10^{-6} per °C in the range from 0 to 100 C (32 to 212 F). The expansion varies somewhat with the type of iron and is somewhat higher in the softer and higher-carbon irons.

For the temperature range from 1070 C (1958 F) to room temperature, the coefficient of expansion varies from 0.0000092 to 0.0000169 per °C. At room temperature the

commonly used figure of 0.000010 per °C is sufficiently accurate for ordinary changes in temperature.

Density. The density (grams per cubic centimeter) of gray irons at room temperature, varies from about 6.95 for open-grained high-carbon gray irons to 7.35 for close-grained low-carbon irons. The density of white iron is about 7.70. The density of liquid cast irons just above the final solidification temperature is about 6.23. For conversion to the weight in pounds per cubic foot, the values for density should be multiplied by the factor 62.428. A gray iron with density of 7.20 weighs about 450 lb per cu ft.

Fluidity. The fluidity, or "running qualities", of cast iron is important from a foundry viewpoint and depends generally on the degree of superheat and the composition of the metal. Increasing the percentage of carbon and silicon as high as the eutectic concentration, increases the fluidity of the metal. Spencer and Walding found that, contrary to the general assumption, higher phosphorus content did not increase the fluidity, aside from its influence in lowering the freezing point. Saeger and Ash found that various metals "run" better in dry sand molds than in green sand molds.

Thermal Conductivity. The thermal conductivity is approximately 0.11 cal per cm per °C per sec.

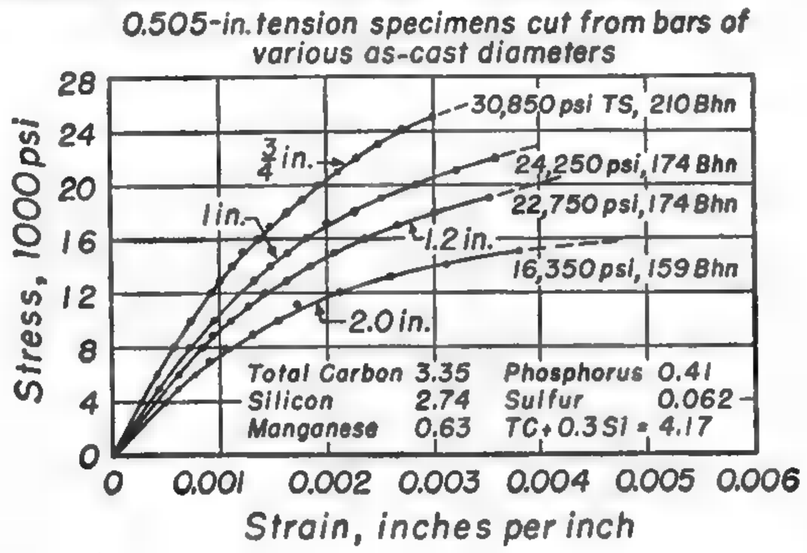

Fig. 3a

Fig. 3a Stress-strain characteristics of gray iron. Rigidity is approximately proportional to tensile strength. (Bolton[4])

Electrical and Magnetic Properties. As compared with that of other ferrous metals, the resistivity of gray iron is relatively high, apparently because of the amount and distribution of the graphite content. Increases in total carbon content and in silicon content increase resistivity. The austenitic cast irons are nonmagnetic.

Hatfield states as follows ". . . the magnetic properties of cast iron may vary within very wide limits, ranging from those of materials having low permeability and high coercive force suitable for permanent magnets, and those having high permeability, low coercive force, and low hysteresis loss suitable for electrical machinery".

Highest magnetic induction and permeability are found in annealed white irons, such as malleable cast iron. Flake graphite, as in gray iron, does not affect the hysteresis loss but prevents the attainment of high magnetic induction. The flakes and attendant discontinuity cause small demagnetizing forces.

As is evident from the preceding discussion, in order to achieve any desired combination of characteristics, the type of cast iron desirable for each application must be selected judiciously.

Mechanical Properties

Tensile Strength. The majority of commercial gray irons have tensile strength within the range from 25,000 to 50,000 psi. Specifications cover seven classes, from 20,000 psi min to 60,000 psi min. In special instances, gray irons have been made with tensile strength as high as 100,000 psi, but such irons are limited in commercial use. Irons above 40,000 psi in tensile strength are usually considered "high-strength irons", and are somewhat more expensive to produce and more difficult to machine.

Gray irons do not exhibit a definite "yield point" as do most mild steels. A stress-strain diagram (Fig. 3*a*) indicates that curvature is exhibited at very low stresses; thus definite moduli of elasticity cannot be established. A usual practice is to ascertain the relative modulus at 25% of the expected tensile strength. As suggested by Fig. 3*b* this modulus is different with different tensile strengths and increases with increase in tensile strength. Such relative moduli lie within the range from 12,000,000 psi for the lower-strength irons to between 25,000,000 and 29,000,000 psi for the higher-strength types.

Gray iron exhibits the phenomenon of set, or permanent deformation. As shown in Fig. 3*b*, the usual stress-strain diagram consists of two components—permanent set and an elastic component (dotted line in Fig. 3*b*). When stresses are relatively high and extreme dimensional accuracy is necessary, prestressing may be resorted to before final machining and alignment.

It has been shown that, at room temperature, gray iron can sustain loads up to 80% of its tensile strength without perceptible continued creep.

Temperatures as high as 650 F and slightly above, do not lower the tensile strength of gray irons.

Shear Strength. The shear test is of value in "exploring" a casting; that is, specimens are taken from the casting itself. The ratio of shear strength to tensile strength varies, and is higher for the weaker irons. In a series of studies dealing with irons of various tensile strengths, the ratio of shear strength to tensile strength varied from 1.64 for the weakest iron tested (20,000 psi tensile strength) to 1.01 for the strongest iron tested (60,000 psi tensile strength).

Compression Strength. Cast iron is much stronger in compression than in tension. In a series of tests dealing with many types of cast iron, the compression strength

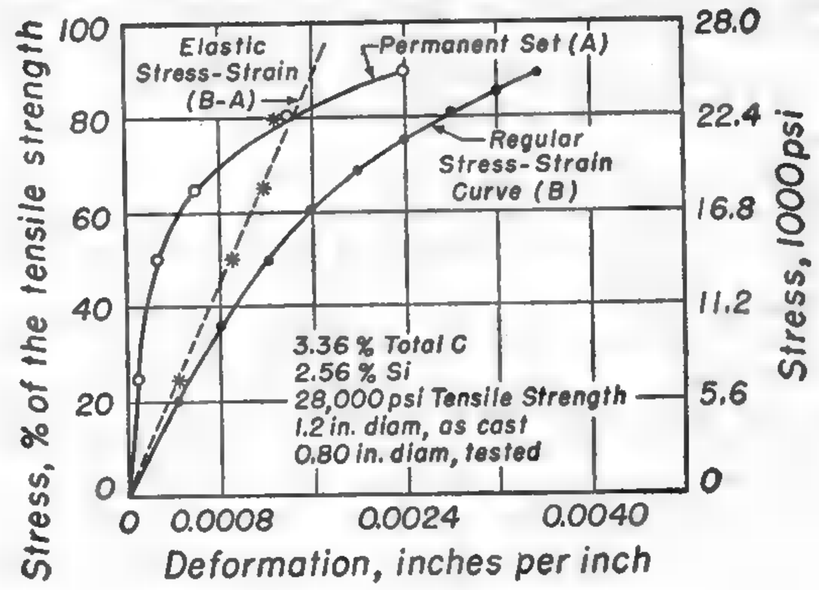

Fig. 3b

Fig. 3b Stress-strain diagram showing elastic and permanent deformations for gray iron (Bolton[4])

ranged from 65,000 to 160,000 psi. The ratio of compression strength to tensile strength varied from about 4.5:1 for the weaker irons to 2.5:1 for the stronger irons.

Hardness. The Brinell hardness test is a useful one for gray iron castings. The Rockwell test also is used, employing the B scale. In the as-cast condition commercial (nonalloy) gray iron castings range from 150 to 220 Bhn. The alloy cast irons are harder and heat treated irons may be harder than 600 Bhn. Ordinary white irons range from 321 to 534 Bhn while alloy white irons may be as hard at 700 Bhn. Fully annealed gray irons may range from 100 to 140 Bhn.

Endurance Limit. The endurance limit, or fatigue strength, appears to vary linearly with the tensile strength. For the endurance limit, values from 0.4 to 0.6% of the tensile strength have been reported. The values for endurance limit are not greatly reduced by temperatures up to 800 F.

Impact Strength. In general, the resistance to impact increases with tensile strength, although this is not true in all instances. For example, cast irons of high phosphorus content are lower in impact strength than lower-phosphorus irons of equivalent tensile strength.

Transverse Bend Tests. For a discussion of the application of bend tests to cast iron and to other metals that have low ductility, the reader may refer to the article on page 125 of this Handbook. Additional information on the mechanical testing of cast iron is included in the article on "Mechanical Testing of Castings", page 136.

General Comments on the Engineering Properties of Gray Iron. Gray iron combines melting and molding at low cost with ease of casting into intricate shapes. It has good rigidity, great compressive strength and ready machinability.

Shrinkage defects may occur when a large section changes abruptly into a smaller section. When designing gray iron castings, it is desirable to use uniform sizes of section if possible.

A close-grained iron, low in total carbon content, is the strongest, toughest and best-finishing type of material. The structure and strength of gray irons are controlled largely by composition and cooling rate. The composition can be controlled in making up the charge. The cooling rate depends on section, size, and somewhat less on pouring temperatures. Hence, castings that are not uniform in section may exhibit diversity in physical properties, and in the same section there is often some difference between the outside and the center of the section. Proper composition will tend to minimize the variation between outside and center.

Effects of Common Alloying Elements

Carbon. Most commercial cast-iron castings contain from 2.70 to 3.60% total C. This carbon may exist as free carbon (graphite) (Fig. 4); as combined carbon (cementite) as found in free massive cementite (Fig. 5), and in the cementite lamellae of pearlite (Fig. 6); or in solution in molten iron and in austenite.

Graphitic carbon is soft and not tenacious, and in gray iron is found as black flakes (Fig. 4).

Cementite is very hard and possesses little ductility. Under certain conditions it may be decomposed into iron and carbon (graphite).

At subcritical temperatures iron can hold only a few hundredths per cent of carbon in solution. This solubility increases rather abruptly to about 0.85% or less at the A_3 transformation temperature (approximately 1350 F, depending on composition) and the solubility increases further as the temperature is raised.

The structure of a given cast iron depends largely on the amount, size and distribution of the various forms of carbon. The amount depends both on the percentage in the charged metal and on the melting process. The size and distribution of the various forms depend on the temperatures, time and other factors involved in the melting process, and on the rate of cooling the metal from the molten condition, as well as on the composition, and on the presence of inoculants. These factors are discussed in detail in various later sections.

Silicon. Because of the relation between the carbon and silicon contents, silicon is a very important element in the metallurgy of gray iron. Silicon promotes the decomposition of the combined carbon (in pearlitic and massive cementite) to ferrite and graphite. Irons that contain no silicon usually have a white (cementitic) fracture. In changing white iron to gray, silicon makes commercial production of gray iron practicable. For strong irons, just enough silicon should be used to ensure decomposition of all massive cementite, but not enough to cause decomposition of the cementite in the pearlite. Excessive decomposition of the pearlite to graphite and ferrite, gives a weak, soft metal.

Silicon also reduces the carbon content of the eutectic by about 0.30% for each per cent of silicon. This means that higher-silicon pig irons are often lower in carbon than lower-silicon irons. It is easier to produce low-carbon cupola metal with higher silicon contents. Silicon raises the eutectic temperature slightly.

An increase in silicon content lowers the percentage of carbon in the eutectoid approximately 0.07% for each per cent of silicon.

Manganese. Manganese may be present in the carbide phase in gray iron or may occur as manganese sulfide in small slate-colored inclusions throughout the metal. In ordinary commercial ranges, manganese has little effect on the mechanical properties of gray iron. About 0.30% more Mn than is required theoretically for combination with sulfur (which is 55/32 times the sulfur percentage) is necessary for mitigating the effects of sulfur. Most American irons contain 0.06 to 0.12% S; hence the usual range of 0.50 to 0.80% Mn is sufficient.

Sulfur. Sulfur occurs largely as manganese sulfide, and rarely as iron sulfide. Under proper operating conditions, sulfur does not seem to exert harmful effects on gray iron in amounts up to 0.16 or 0.18%, provided manganese is present in amounts sufficient to prevent chill. In the absence of enough manganese, sulfur has a marked stabilizing action on the cementite and promotes chill.

Phosphorus. The phosphorus range in most American irons is from 0.10 to 0.90%. The irons from northern ores usually are low in phosphorus, and some of the irons from southern ores are higher in phosphorus. The phosphorus content of many foreign irons is much higher than that

of typical American irons. Virtually all the phosphorus is present in the constituent known as "steadite", the effects of which will be discussed in greater detail under that heading. Phosphorus does not have a marked effect on the static strength of ordinary commercial irons except those of higher strength. High percentages of phosphorus apparently lower the impact strength appreciably.

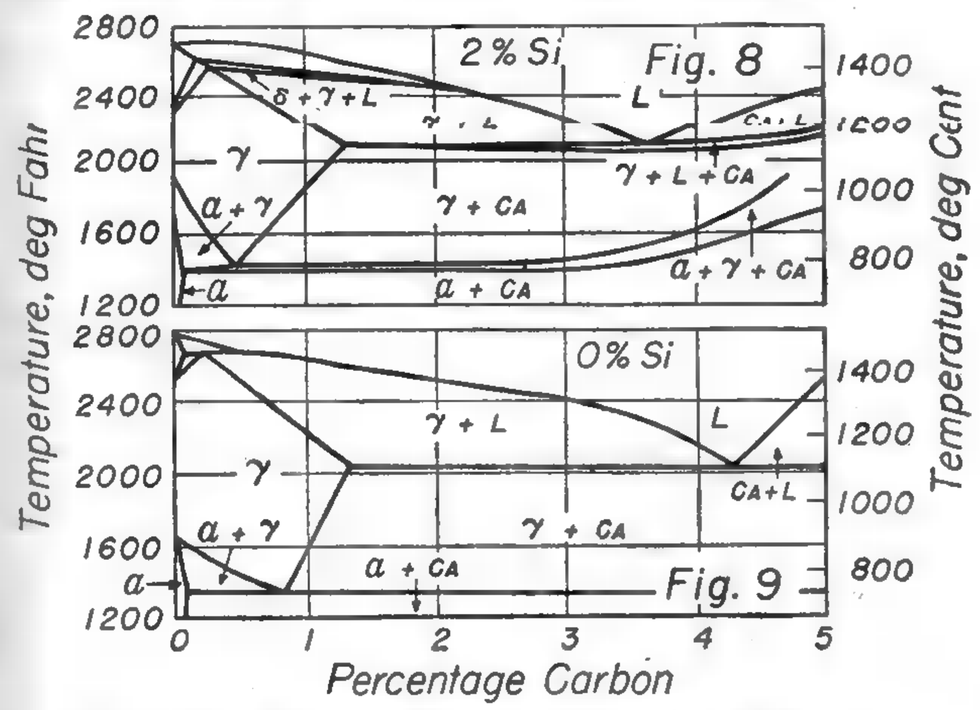

Fig. 8 and 9 Sections through the iron-carbon-silicon system at 2% Si and 0% Si (Greiner, Marsh and Stoughton[8])

Phosphorus increases fluidity at any given temperature and thus increases the castability of thin sections. Where considerable variation exists in sections of a given casting, some foundrymen prefer to use medium-phosphorus or low-phosphorus irons, and to employ higher pouring temperatures.

The present trend is toward greater usage of lower-phosphorus irons. In the automotive industry some foundries are using 0.15% P max increasingly, whereas 0.20% P max was common several years ago. Also, as mentioned above, wider use of higher-strength grades, with attendant employment of higher percentages of steel in the charges, naturally results in less phosphorus in the final composition of the iron.

Structure of Gray Irons

Mode of Formation. Gray iron is essentially a series of alloys of iron, carbon and silicon. The major structural components of the usual castings are pearlite, ferrite and graphite. The mode of formation of these and other components will be apparent from the iron-carbon and iron-carbon-silicon phase diagrams. Figure 8 shows a section through the iron-carbon-silicon metastable ternary diagram at 2% Si. If this is compared with Fig. 9, the diagram for iron-carbon without silicon, it will be noted that the carbon concentration of the eutectic is lower (effect of silicon) and that the temperature ranges of eutectic solidification and of austenite transformation are somewhat higher. In the presence of silicon, there is a range, at the eutectic solidification, where gamma iron, liquid and carbide are coexistent; at the eutectoid transformation, alpha iron, gamma iron and carbide coexist.

Figures 8 and 9 illustrate the metastable (iron–iron carbide) equilibrium. In stable alloys austenite and graphite are in equilibrium above the eutectoid and below the eutectic. In the eutectoid transformation range, ferrite, austenite and graphite coexist.

Under commercial conditions of casting, gray irons us-

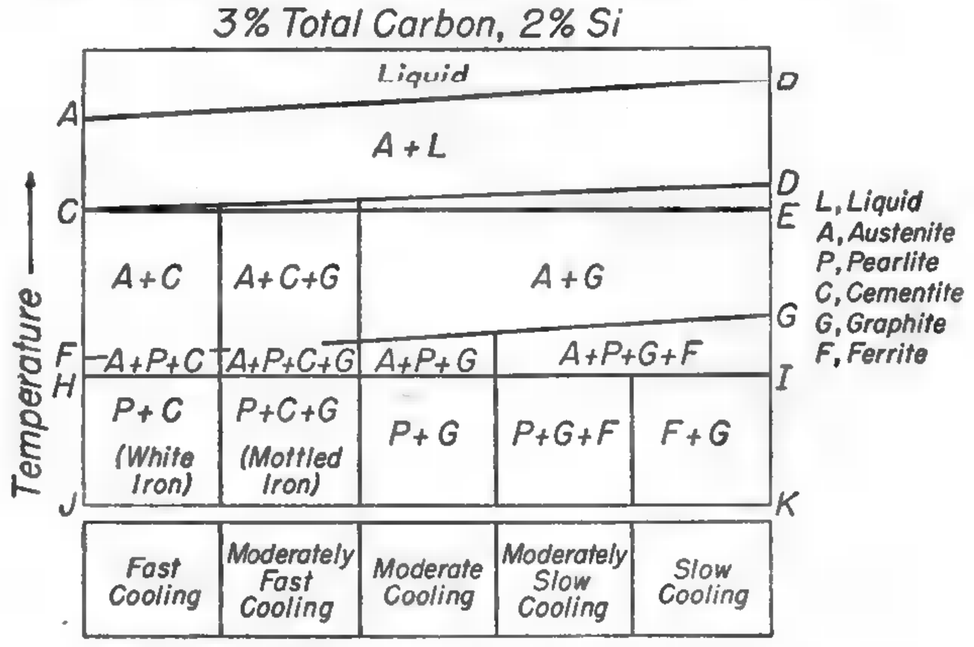

Fig. 10 Transformations during the solidification and cooling of cast iron (C. H. Lorig[9])

ually solidify at rates that do not permit equilibrium. Hence the structures are intermediate between the stable and metastable diagrams. This is illustrated in Fig. 10. The line *AB* represents the liquidus. The area *CDE* represents the final or eutectic solidification. The area *HFGI* represents the eutectoid transformation range.

The qualitative relationship of strength and hardness to the structural conditions outlined in Fig. 10, are shown in Fig 11.

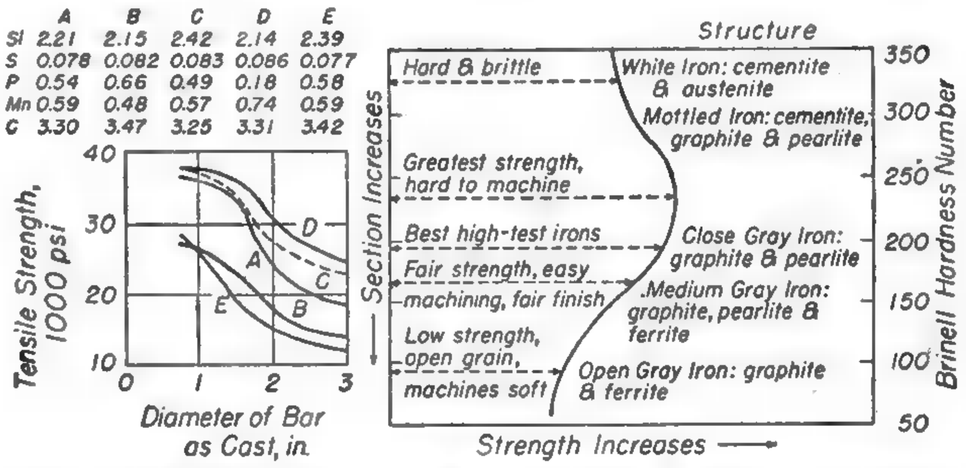

Fig. 11 Qualitative relationships among size of section, structure, tensile strength and hardness of gray iron.

The normal or usual microstructure of gray iron is a pearlitic matrix with graphite flakes dispersed throughout. Too rapid cooling (with respect to carbon and silicon contents) produces mottled iron, consisting of a pearlitic matrix with both free cementite (carbide) and graphite. Very slow cooling of irons that contain larger percentages of

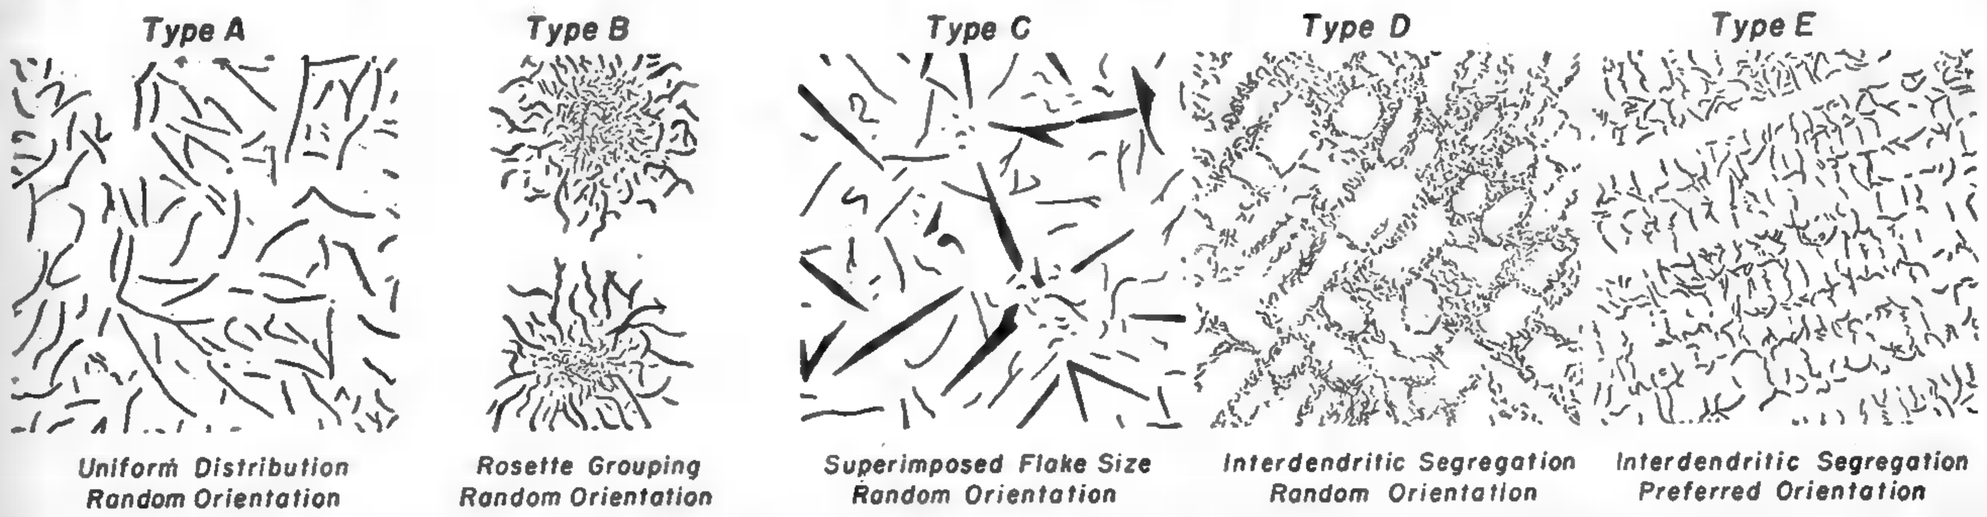

Fig. 12 Chart illustrating the types of graphite flakes in gray cast iron (AFA-ASTM). In the recommended practice,[10] these charts are shown at a magnification of 100 diameters. They have been reduced to one-third size for reproduction here.

silicon and carbon, is likely to produce considerable ferrite as well as pearlite throughout the matrix, together with coarse graphitization. Under some conditions, very fine (so-called "pseudo eutectic" or AFA Type D) graphite may be formed near casting surfaces (Fig. 12). Frequently such graphite is surrounded by a ferrite matrix; hence soft spots result. The deeper layers of metal may show random flakes and pearlitic matrix. Inoculation (*see* page 515) is often effective in preventing formation of Type D graphite and the localized ferritic soft spots.

The action of various alloying elements may retard or even suppress the transformation of austenite to pearlite. The mechanism of transformation of austenite in gray irons and in steels is essentially the same. For a discussion of isothermal transformation diagrams, the reader may refer to page 607.

Suppression of the transformation of austenite (by cooling rates and by additions of alloying elements) may result in the formation of intermediate products, especially martensite. Addition of some alloying elements, notably nickel, in sufficient amounts, may lower the transformation temperature range to such an extent that austenite, rather than pearlite, becomes the matrix constituent.

Pearlite and Ferrite. The combined carbon in ordinary gray irons occurs in the cementite lamellae of the pearlite. Because of the influence of other structural formations and the presence of silicon and manganese, a gray iron of pearlitic matrix may have from 0.50 to about 0.80% combined C. As in steel, with other factors equal, the strength and hardness are increased with increase in the amount of pearlite. Except for martensitic and other special cast irons, the highest strength irons are almost wholly of pearlitic matrix. However, because of the influence of graphite flakes and other factors, pearlitic matrix alone does not ensure maximum strength.

Ferrite, lower in strength and softer than pearlite, is usually situated along the graphite flakes. Highly ferritic gray irons are deficient in strength, hardness and wear resistance; however, they are usually highly machinable.

Steadite. Steadite, a structural component in cast iron that contains phosphorus, is identified by certain white dendritic formations distributed throughout the metal. These formations sometimes form a loosely joined network. The distribution of the formations indicates that they have concentrated in the portion of the metal that was last to solidify.

Steadite is a ternary eutectic structure that consists of alpha iron, cementite and iron phosphide (Fe_3P). In irons of low phosphorus content (less than 0.50%) some of the phosphorus is in solid solution. In irons that contain higher percentages of phosphorus, much of the phosphorus is present in the cellular steadite eutectic (Fig. 7), containing about 10.2% P. The melting point of this eutectic is about 1800 F.

Steadite is hard and improves resistance to some types of wear. If continuous, it may somewhat improve resistance to corrosion and oxidation also.

Free Cementite. White and mottled irons contain free cementite, which causes the metal to be hard and brittle.

Graphite. The metallic matrix of gray irons is filled with thousands of curved flakes of graphitic carbon. These flakes are soft and weak and are similar in crystalline make-up to natural graphite (plumbago). Graphite flakes are responsible for the typical dark gray fracture of gray iron, for the lack of appreciable ductility in gray iron, and for the ease with which it can be machined. By breaking up the matrix, these flakes decrease the strength of the iron; in fact their influence is so pronounced that it often outweighs all other factors controlling strength. Graphite flakes produce these effects in various degrees, according to their size, distribution and amount.

Structure of Cast Irons

Effects of Mass and Cooling Rate. Gray irons (and the related iron-carbon-silicon alloys, such as mottled and white irons) are affected markedly by the rate of cooling from the casting temperature. In these alloys, the stable structure is ferrite and graphite. As mentioned above, compositions are chosen with respect to cooling rates so that the usual cast iron is structurally somewhere between the metastable and stable systems. Very rapid cooling (also low silicon and carbon contents) promotes retention of the metastable structure, free carbide (cementite) and some pearlite (or martensite, or even some retained austenite) as found in white irons. Very slow cooling promotes approach to the stable system, ferrite and graphite. The rate of cooling also influences grain size and the size of graphite flakes. Just as in other metals, slow cooling produces coarser structural formations.

In ordinary commercial practice, the rate of cooling depends largely on size of section. Heavier sections cool more slowly than light sections. In simple shapes, the relative cooling rates can be compared on the basis of the V/A relationship, where V = volume in cubic inches, and A = area of exposed surface in square inches. The volume is approximately proportional to the amount of heat to be dissipated. The area is the surface through which the heat must flow.

The more slowly a given gray iron casting cools from the pouring temperature, the lower in strength and hardness it is likely to be. This is frequently referred to as "effect of mass" or "effect of section size"; a more accurate term is "effect of cooling rate".

The more slowly a given iron is cooled through the graphitization range, the more complete the graphitization will be. Furthermore, during slower cooling there is greater opportunity for grain growth, including grain size and degree of lamination of pearlite, and grain or flake size of graphitic carbon. These effects on the structure are reflected in the mechanical properties (Fig. 11), which indicate loss of strength with increase in size of section.

Changes in strength and structure with variation in size of section, are much less apparent in irons of comparatively low total carbon content. For example, when properly made, an iron that contains 2.75% C, 2.25% Si and no alloying elements, can be cast into a 0.5-in. diam test bar with no trace of chill and into a 3.0-in. diam bar with pearlitic matrix that has good strength and hardness throughout. Quite frequently the intelligent use of alloying elements is also beneficial in the maintenance of uniformity in strength and hardness over a range of sizes.

The foregoing discussion indicates that the composition of the metal must be chosen so that it is suitable for the particular sizes of section to be cast. For example, an iron composition fully suited for a lathe bed, may be chilled and useless if cast into automotive piston rings, and an iron composition suited for piston rings may be weak, soft and open-grained if cast into a lathe bed. For similar reasons, it is undesirable to have extensive heavy and light sections in the same casting.

Alloy Cast Irons and Inoculated Irons

Because the term "alloy cast iron" has been used imprecisely, it is desirable to define both plain cast iron and alloy cast iron.[1]

Plain Cast Iron. "Cast iron" is essentially an alloy of iron and carbon in which the carbon is present in excess of the amount that can be retained in solid solution in austenite at the eutectic temperature.

Alloy Cast Iron.[1] "Alloy cast iron" is cast iron that contains a specially added element, or elements, in sufficient amount to produce a measurable modification of the physical or mechanical properties of the iron in the section under consideration. Silicon, manganese, sulfur and phosphorus, as normally obtained from raw materials, are not considered alloy additions.

Alloying elements are added to cast iron for improvement of mechanical properties or for development of a special characteristic, such as resistance to corrosion, heat or wear. The alloying elements that have important effects on the structure of the metal, should be added to well-made cast irons in order to improve them. Such additions to poorly made cast irons are not economical.

Additions of alloying elements have a marked effect on graphitization. Some alloying elements will accelerate graphitization while others will retard this transformation. The control of graphitization is one of the important reasons for the use of alloying elements in cast iron.

Some of the more common alloying elements will be discussed here; many others may be used in cast iron.

Chromium. Chromium, a powerful carbide former, increases the combined carbon and intensifies the chilling propensities of cast iron. When added to cast iron, chromium forms complex iron-chromium carbides, which are more stable than Fe_3C. The chromium irons graphitize less readily than plain cast iron.

Because of the effect of chromium on structure, small amounts of chromium increase strength, hardness, depth of chill, and resistance to heat and to wear, but decrease machinability. For general improvement in mechanical properties, chromium is used in amounts from 0.15 to 1.00%, with or without other alloying elements. Chromium in amounts from 1 to 1.5% is added for moderate resistance to the softening and scaling effects of heat at temperatures up to 1400 F. In the production of special irons to resist corrosion or high temperatures, or both, as much as 35% Cr has been used.

To illustrate carbide-forming characteristics of chromium additions, the following effects on a soft gray iron may be cited:

Percentage Chromium	Structure
0	Ferrite and coarse graphite
0.3	Less ferrite, some pearlite and finer graphite
0.6	Fine graphite and pearlite
1	Fine graphite, pearlite and small carbide
3	Disappearance of graphite
5	Much massive carbide
10 to 30	Fine carbide

An important use of chromium is the addition to base irons where additional hardness or resistance to wear is required. A nonalloy iron containing 2.25% Si and 3.40% total C may be satisfactory for most castings that are light in section. Increased hardness and better structure are required for heavier sections. Additions of chromium ranging from 0.30 to 1.0% are frequently made in order to increase hardness and improve the structure. In heavy sections, the use of chromium helps to give a more uniform structure and tends to eliminate porosity.

The stability conferred to the carbide by chromium is useful in the heat treatment of gray iron castings because it tends to prevent excessive graphitization.

Chromium is used in conjunction with other elements, such as nickel, copper, molybdenum and vanadium. Typical combinations are nickel-chromium, chromium-molybdenum, nickel-chromium-molybdenum, copper-chromium and nickel-chromium-vanadium.

Copper. Copper promotes the formation of graphite and has about one-tenth to one-fifth as much graphitizing ability as silicon. The usual range of copper contents is from 0.25 to 2.5% for engineering applications. The amount that can be alloyed is limited by the solubility of copper in liquid cast iron; the maximum is about 3.75%.

Copper is a mild strengthener in cast iron, acting to break up massive cementite spots and also strengthening the matrix. Copper may harden or soften the cast iron, depending on the structure of the base metal. If the iron has a tendency to chill, copper will reduce hardness; however, in normal gray irons copper will increase hardness and resistance to wear and will combat certain types of corrosion.

Copper, frequently used with other alloying elements, is effective when used with those that form carbide. Some typical combinations are copper-chromium, copper-chromium-molybdenum, copper-molybdenum, copper-manganese and copper-vanadium. Proper balance should be maintained between the addition of copper and elements that stabilize carbide. Copper additions should be from three to six times as large as the chromium additions, depending on carbon content. The higher ratios should be used with the lower carbon contents (below 3%). Copper will balance equal additions of molybdenum or manganese but ten parts copper are required for one part vanadium.

Molybdenum. Molybdenum, a mild stabilizer of carbides, tends to increase the depth of chill in cast iron. Under no circumstances does it act as a graphitizing agent. Improvements in mechanical properties of cast iron can be obtained by the use of molybdenum, in most instances without changing the normal melting practice.

The addition of molybdenum to gray iron increases tensile strength, transverse strength and deflection, and hardness. Molybdenum, usually added in quantities from 0.25 to 1.25%, is the most effective alloying element added to gray iron to increase strength. Molybdenum additions are also considered beneficial in improving resistance of gray iron to fatigue.

Molybdenum is used in combination with other alloying elements, for instance, nickel-molybdenum, chromium-molybdenum, nickel-chromium-molybdenum, copper-molybdenum, copper-chromium-molybdenum and molybdenum-vanadium.

The addition of molybdenum to cast iron promotes structural uniformity in heavy sections. As a result, good density, high Brinell hardness and high strength are maintained throughout the cross section. Molybdenum promotes machinability by improving structural uniformity and because it does not result in massive carbides.

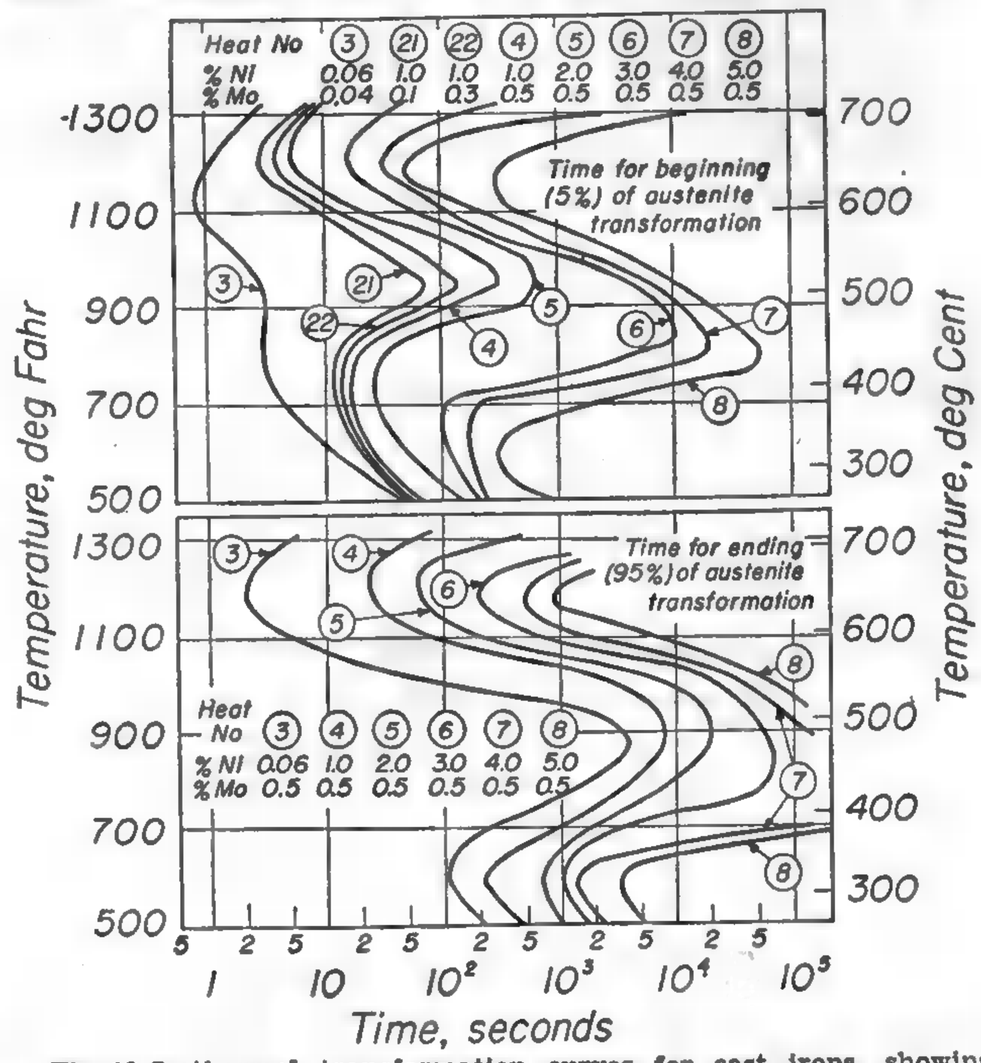

Fig. 13 Isothermal transformation curves for cast irons, showing the effect of nickel and molybdenum on the times for the beginning (5%) and ending (95%) of austenite transformation at constant subcritical temperatures. Base composition: 2.5% total C, 2.5% Si, 0.85% Mn, 0.10% S and P (Flinn, Cohen and Chipman[5])

Molybdenum retards the rate of transformation of austenite, thereby increasing the hardness and strength in the as-cast or heat treated condition. Molybdenum, in cast iron as in steel, contributes to the retention of strength at elevated temperatures.

Molybdenum is of value in the heat treatment of gray iron castings because of hardenability, freedom from cracking and distortion, and slight carbide stability. Freedom from cracking is a result of the sluggishness of the transformation of matrix austenite, which reduces the probability of quenching cracks.

Nickel. Nickel is a graphitizer and does not form a carbide. It acts effectively to reduce chill and to eliminate hard carbide spots, chilled areas and mottled areas. Small additions of nickel, 0.10 to 1.0%, are effective in refining the grain and the size of graphite flakes.

Nickel may replace or supplement silicon in making castings graphitic. Two parts of nickel are generally equivalent to one part of silicon in reducing chill.

The major fields of application of nickel cast irons are in the engineering gray irons (0.5 to 6.0% Ni), the martensitic white irons (about 4.5% Ni) that resist abrasion, and the austenitic gray irons (14 to 38% Ni) that resist heat and corrosion and have low expansivity.

Table II. Effect of Nickel on the Hardness of Gray Cast Iron
1.20-in. diam sand-cast sections

T C	C C	Si	Ni	Bhn
2.24	0.73	2.34	1.07	273
2.27	0.68	2.36	2.07	286
2.33	0.74	2.29	3.06	293
2.27	0.71	2.22	4.10	302

Engineering Cast Irons. The primary function of nickel in engineering cast irons is to control structure by (1) retarding transformation of austenite, (2) stabilizing pearlite and (3) maintaining combined carbon at eutectoid quantity.

Quantitative evidence of this control of structure is shown in Fig. 13 and 14 and Table II.

In Fig. 13, S-curves of gray irons with increasing amounts of nickel (plus molybdenum) exhibit retarded austenite transformation in both the pearlite and the acicular regions. By increase in the nickel content, the structure may be changed from coarse pearlite to fine pearlite, to acicular products or to martensite. Figure 14 shows the effects of nickel content and size of section on the microstructure of cast iron that contains 1% Mo.

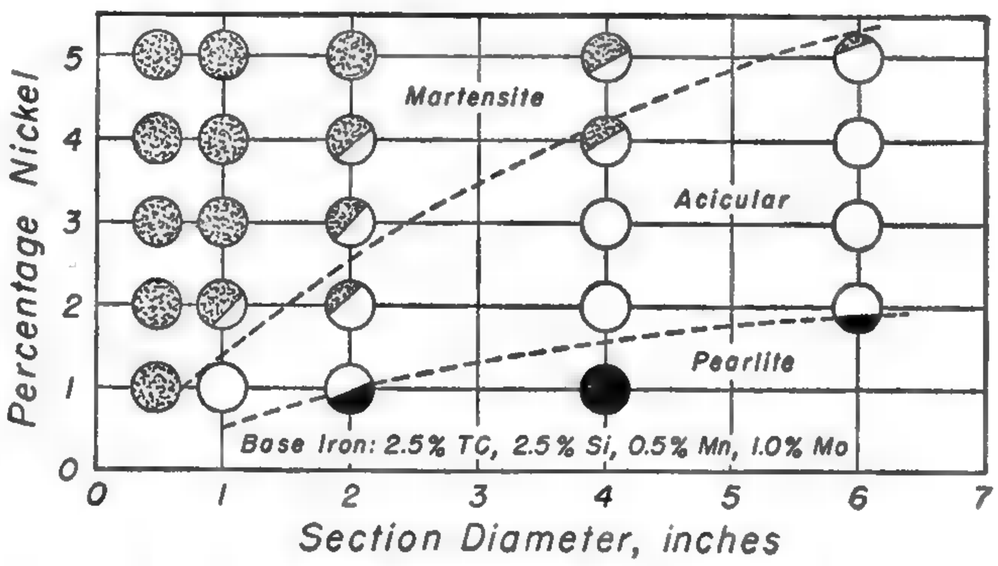

Fig. 14 Effect of nickel content and section size on the as-cast structure of cast iron containing 1% Mo (Flinn, Cohen and Chipman[5])

The same effect is obtained at higher carbon levels (about 3.5% total C) but Brinell hardness is lower (225 to 275 Bhn) because of the greater quantity of graphitic carbon. These types of cast iron have moderate machinability at high hardness.

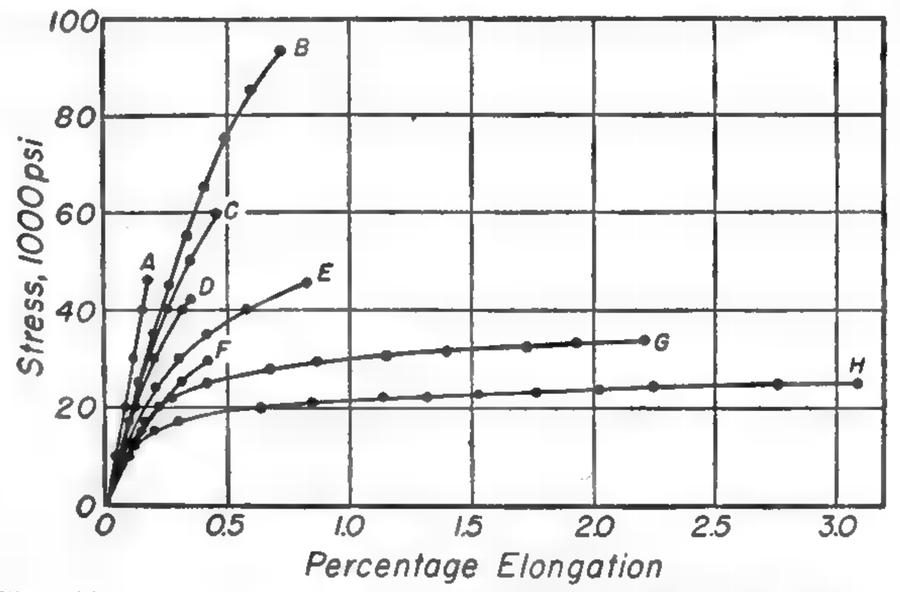
The stress-elongation relationships shown in Fig. 15 also illustrate the influence of nickel in cast iron.

For engineering applications, nickel is frequently used with alloying elements that form carbide. Typical combinations are nickel-chromium, nickel-molybdenum, and nickel-chromium-molybdenum.

Martensitic White Irons for Resisting Abrasion. The combination of iron carbides in a martensitic matrix results in a good combination of hardness (600 to 750 Bhn), abrasion resistance, strength, and toughness. Combinations of 4.25 to 4.75% Ni and 1.4 to 2.5% Cr may be used in either low-carbon (2.9% total C max) or high-carbon (3.0 to 3.6% total C) irons. Composition and mechanical properties are shown in Table III.

Austenitic and Low-Expansivity Cast Irons. Austenitic cast irons are formulated to accommodate a variety of properties such as high or low expansion, high electrical resistance and nonmagnetic response, as well as resistance to heat, acids, alkalies and other chemicals. These irons have about the same mechanical properties as gray iron except that they are much tougher. The various types are indicated in Table IV.

Vanadium. Vanadium, one of the most powerful carbide formers, stabilizes cementite and restrains graphitization.



No.	Material	TC	Si	Ni	Cr	Mo	Cu
		Chemical Composition, %					
A	1.5% Cr white cast iron	3.40	0.68	....	1.55	....	....
B	High-strength Ni-Mo gray iron	2.34	2.64	2.93	0.25	0.97	....
C	Quenched and tempered gray iron	3.51	0.72	....	....	....	....

Fig. 15 Curves of tensile stress versus strain for gray irons of different matrices (Flinn and Chapin[11])

When vanadium is added to cast iron in amounts ranging from 0.10 to 0.50%, the following effects are observed:

1 Interference with graphitization and stabilization of cementite
2 Smaller graphite flakes and more uniform distribution of graphite
3 Promotion of sorbitic structure
4 Decreased grain size of matrix
5 Smaller, less pronounced, and less perfectly aligned dendrites in the surface layers of chilled castings. Because of this and (1) above, greater depth, hardness, toughness and resistance to wear of chill result.
6 Resistance of the carbide to decomposition at high temperatures

Additions of vanadium increase tensile strength, transverse strength and hardness of gray cast iron. For most commercial applications, the vanadium content is 0.10 to 0.25%. Amounts up to 0.12% V are added to highly alloyed irons for the purpose of improving machinability. Vanadium promotes fine lamellar pearlite in compositions that might otherwise be acicular.

Table III. Composition and Properties of Martensitic White Cast Irons

Chemical Composition	High-Carbon	Low-Carbon
T C	3.0 to 3.6	2.9 max
G C	nil	nil
Si	0.4 to 0.7	0.5 to 1.0

Vanadium is used in combination with other alloying elements such as nickel, copper, chromium and molybdenum.

Inoculated Irons. "Inoculated", "processed" or "treated" cast irons have assumed increasing importance. Inoculants are materials that, when added to molten cast iron, modify the structure and thereby change the physical and mechanical properties to an extent not explained on the basis of the change in composition resulting from their use.

Late additions to molten cast iron, usually in the ladle, have a definite effect on the structure and mechanical properties of the metal. It is possible for inoculants to change the structure effectively with little change in chemical composition. For equivalent tensile strengths, inoculated irons are usually lower in hardness than irons not inoculated.

One of the early inoculants was ferrosilicon. If an iron is purposely melted with a lower silicon content than desired in the casting, and a part of the silicon is added to the ladle as ferrosilicon, there is a definite improvement in structure. The mechanical properties are improved and the tendency toward chilled edges and corners is reduced,

Table VI. ASTM Classification of Gray Cast Irons

Class Number	Minimum Tensile Strength, psi	Class Number	Minimum Tensile Strength, psi
20	20,000	40	40,000
25	25,000	50	50,000
30	30,000	60	60,000
35	35,000		

thus producing better and more machinable castings. Other inoculants used for many years are calcium-silicon, ferromanganese-silicon and zirconium-silicon.

Proprietary inoculants containing a combination of graphitizing elements, have been used in the foundry and some of these inoculants are more effective than ferrosilicon. They are known as "graphitizing inoculants" and are sold under various trade names. These materials have become quite popular since the production of inoculated irons has been increasing.

Another type of inoculant contains some element that stabilizes carbide—for instance, chromium. Depending on the composition, such an inoculant can increase or decrease the hardness of the metal. The advantage of reduction in chill is retained together with the alloying effect of the chromium; a stronger, harder and more machinable casting may be the result. This type of inoculant is sold under various trade names.

Inoculants are not a cure-all for the foundry. It is necessary to control carefully both the base iron and the addition of the inoculant in order to secure optimum results. Inoculants do provide a useful tool in the production of quality castings.

Table VII. Minimum Breaking Loads for Transverse Tests of Cast Irons

Transverse test bar...	0.875-in Diam,	1.2-in. Diam,	2.0-in. Diam,

50	1675	3000	10,300
60	1925	3400	12,500

High-Strength Cast Irons

The term "high-strength cast iron" is usually employed to indicate cast irons that have a tensile strength greater than 40,000 psi. The term is rather vague and the ASTM classification (*see next section*) is more desirable.

During the past 15 years, considerable progress has been made in the manufacture of high-strength irons. Many foundries are now regularly producing cast iron that has a tensile strength greater than 50,000 psi. Tensile strengths greater than 70,000 psi may be obtained "as-cast".

The irons of higher strength are more difficult to produce than the irons of medium strength (30,000 to 35,000 psi) and the cost is higher. The machinability usually decreases with increased strength and hardness. Consequently these irons should not be specified except where they are needed and where the increased cost is justified.

The size, shape, distribution and quantity of graphite in cast iron greatly influence the strength. Cast irons higher

Table VIII. Test Bars Used for Gray Cast Iron

Controlling Section of Casting, in.	Test Bar	Nominal Diameter of Test Bar as Cast, in.
0.75 max	A	0.875
0.75 to 1.25	B	1.20
1.25 to 2.00	C	2.00

than 50,000 psi in tensile strength usually have total carbon contents of 3% or lower. It is possible to produce an iron of 50,000 psi minimum tensile strength by making suitable alloy additions to an iron of medium strength. In general, high-strength irons are produced by means of low carbon content or suitable alloying elements, or both.

Table V lists a few typical compositions of high-strength cast irons. Many other compositions have been used successfully.

High-strength irons may be produced in various melting furnaces—the cupola, air furnace and electric furnace. The high-strength irons require closer metallurgical control than the common grades of cast iron. Some high-strength irons are being produced by a combination of inoculation and the addition of alloying elements.

Classification of Gray Cast Irons

The most important classification of gray irons, from an engineering viewpoint, is that employed in the ASTM Specification A 48, where gray iron castings are classed according to the minimum tensile strengths of test bars, as listed in Table VI.

Table IX. Dimensions of Test Bars for Gray Cast Iron

Test Bar	Cast Diam, in.	Diam of Tensile Specimen in Reduced Section, in.	Cast Length, in.	Distance Between Supports in Transverse Test, in.
A	0.875	0.505	15	12
■	1.20	0.750	21	18
C	2.00	1.25	27	24

Transverse tests are optional, and the minimum breaking loads indicated in Table VII, are specified.

By agreement between manufacturer and purchaser, deflection values in the transverse test may be specified.

Three sizes of test bars are specified in order to obtain various cooling rates representative of various thicknesses of castings. If the manufacturer and purchaser agree on the controlling section of the casting, the corresponding test bar used is as listed in Table VIII.

For sections of castings larger than 2.00 in., test bar *C* may be used, or ■ larger test bar may be chosen by agreement between the manufacturer and the purchaser. The dimensions of the test bars are given in Table IX.

It is recognized that there is no definite factor for correlation between tensile and transverse strengths for various types of cast iron. Tables included in the specification give minimum values only.

It is the intent of these specifications to subordinate chemical composition to mechanical properties. By agree-

ment between the manufacturer and the purchaser, the quantities of any chemical elements in cast iron may be specified.

Other ASTM Specifications. The ASTM has developed other specifications for various types of gray iron castings, as indicated in Table X.

Other possible bases for the classification are composition, hardness, and structural features. From an engineering viewpoint there are many definite reasons for the classification employed in the ASTM Specification A 48. Other classifications may serve useful purposes. Advances in the technology of cast irons will undoubtedly encourage development of such classifications.

Wear of Gray Cast Iron*

The term "wear" has general rather than specific significance. "Wear" signifies a gradual removal or dissolution of a structure by the action of agents applied mechanically. Often mechanical wear and deterioration by corrosion act concurrently. The wearing agent may be a fluid (gas or liquid) or a solid.

With a perfect film of lubrication there can be no wear. When there is no lubricant, wear occurs, or when the lubricant film breaks down, or when the lubricant is imperfect and a carrier of wearing agents (abrasives).

In metal-to-metal wear caused by absence of lubricant, gray cast iron is very useful. Its highly heterogeneous structure effectively inhibits seizure and galling. It wears well not only against cast iron, but also in contact with many other alloys. Gray cast iron may cut much softer

Table X. Other ASTM Specifications for Gray Cast Iron

ASTM Designation	Title of Specification
A 44	Specification for Cast-Iron Pipe and Special Castings
A 126	Specification for Gray Iron Castings for Valves, Flanges and Pipe Fittings
A 142	Specification for Cast-Iron Culvert Pipe
A 159	Specification for Automotive Gray Iron Castings
A 278	Gray Iron Castings for Pressure-Containing Parts for Temperatures up to 650 F
A 190	Gray Iron Castings, Light Weight and Thin Sectioned
A 74	Cast-Iron Soil Pipe and Fittings

alloys, but usually works well with alloys as hard or harder than itself. This property of gray iron is among those responsible for the extensive use of this metal in machine tools, where fairly heavy pressures and imperfect lubrication occur; and in automobile cylinders, where temperature and partial breakdown of lubricant are influential factors. An example of metal-to-metal wear is in automobile brake drums. With hardness and lubrication equal, gray iron, with its graphitic structure, is less likely to seize than the nongraphitic ferrous alloys.

The properties in gray cast iron that are associated with low rate of wear are pearlitic matrix, suitable hardness, and high strength. If other factors are equal, an iron with a pearlitic matrix will resist wear better than one that contains free ferrite.

Comparison of dissimilar irons indicates that hardness is not always related directly to wear. However, for the same type or composition of cast iron, higher hardness frequently results in a much lower rate of wear.

Heat treatment or special additions of alloying elements that produce martensite and other hard matrices, improve resistance to wear. Usually some increase in resistance to metal-to-metal wear may be expected from such increased hardness. However, the major gain is from increased resistance to abrasive action (for example, of sand or grit). Localized heat treatment (flame hardening) has proved useful.

White cast irons are relatively resistant to abrasion. Some of the alloyed hard white irons are resistant not only to abrasive influences but also to galling and seizure.

Because there are many types of wear, it is virtually impossible to set up any laboratory test that will measure adequately the resistance of a material to wear in service. However, laboratory tests have been of value in helping to develop better materials for resisting wear. Some of the conclusions from laboratory tests are, as follows:

1 Resistance to wear increases with hardness of matrix
2 With increasing combined carbon content, the resistance to wear of gray irons increases rapidly up to 0.60% combined C and then slightly up to 0.85%.
3 Increasing silicon content decreases resistance to wear.

* See also the article "Wear of Metals", page 216.

Machinability of Gray Cast Iron

Cast irons have wide ranges of machinability. Ease in the machining of cast iron is usually inversely proportional to the strength. Machinability of various metals has been studied with reference to (1) tool life, (2) type of finish obtained, and (3) power required. Since differences in machinability affect tool life, these differences are of great practical importance.

The composition, structure, and mechanical properties of cast iron extend over a wide range. Depending on these factors, cast iron varies from one of the most readily machinable to one of the most unmachinable of ferrous materials. At one extreme of this range, the most readily machinable is cast iron that has been cast in permanent molds and completely annealed; at the other extreme is white or chilled cast iron and iron hardened by heat treatment without having been tempered. Annealed permanent mold cast iron has excellent machinability because the structure consists of iron that contains no combined carbon, and is broken up by a high percentage of finely divided flakes of graphite, besides being free from burned-in sand at the surface. Chilled or white iron is extremely difficult to machine because its structure is composed largely of hard iron carbide in massive form, unbroken by any flakes of free carbon. The machinability of a cast iron depends on the proportions and arrangement of the hard and soft microstructural components. Cast irons may be classified according to microstructure (and in order of decreasing ease of machinability) as follows:

1 Ferritic (free carbon and silicoferrite)
2 Pearlite-ferritic (free carbon, silicoferrite, and pearlite)
3 Pearlitic (free carbon and pearlite)
4 Mottled iron (pearlite, free carbon, and enough massive cementite to produce a mottled fracture)
5 White iron (pearlite and massive cementite)

With lower percentages of silicon or of both silicon and chromium, addition of nickel or copper or both permits the machining of irons of higher hardness than could be machined without this addition. The reason for the ability to machine irons of 225 to 250 Bhn in alloy compositions is that no massive carbides exist in the matrix. As soon as the plain cast iron exceeds a hardness of about 220 Bhn, it usually contains hard carbides, especially at the edges and corners of light castings.

Chromium is a carbide former, and if as much as 0.25% is added to a plain cast iron that is already at the limit of machinability, the iron may become difficult to machine. Therefore, where machinability is a factor, care should be taken in adding chromium. However, as much as 0.50% Cr may be added to many soft irons, with little danger of great difficulty in machining.

Although they are white irons structurally, the high-chromium irons (such as 35% Cr) are softer and more readily machinable than other white irons.

The austenitic gray irons have approximately the same machinability as regular gray irons of equivalent tensile strength. However, the austenitic irons are subject to surface work hardening when surface distortion is incurred without proper removal of metal. Use of improperly sharpened tools should be avoided, as well as rubbing action by tools or by chips. Shot-blasting also may cause complications.

The high-silicon (15% Si) cast irons are quite difficult to machine and, formerly, grinding was usually resorted to. The newer carbide tools may facilitate the machining of these irons.

Frequently molybdenum is used as an alloy addition in cast iron to increase strength and resistance to wear. Where molybdenum is used to increase hardness and strength without the formation of carbides, machinability

will usually be inversely proportional to the hardness and strength produced.

The surface condition of iron castings is most important in determining the machinability. Often castings are condemned as not machinable when the metal itself is quite machinable, and the true source of difficulty is the presence of burned-in sand on the casting. Where burned-in sand is present, any attempt to make light surface cuts will cause rapid failure of the tool. Cutting should be deep enough to ensure that the point of the tool is well below the surface of the casting. For this reason, too scant finish allowances may prove expensive with respect to replacement of tools.

The character of the surface finish obtainable in the machining of cast iron depends on the size of the graphite flakes and on the total amount of the graphite. A high-carbon, high-silicon cast iron with large graphite flakes will show a pitted surface when machined, because particles of metal are torn from between the graphite flakes.

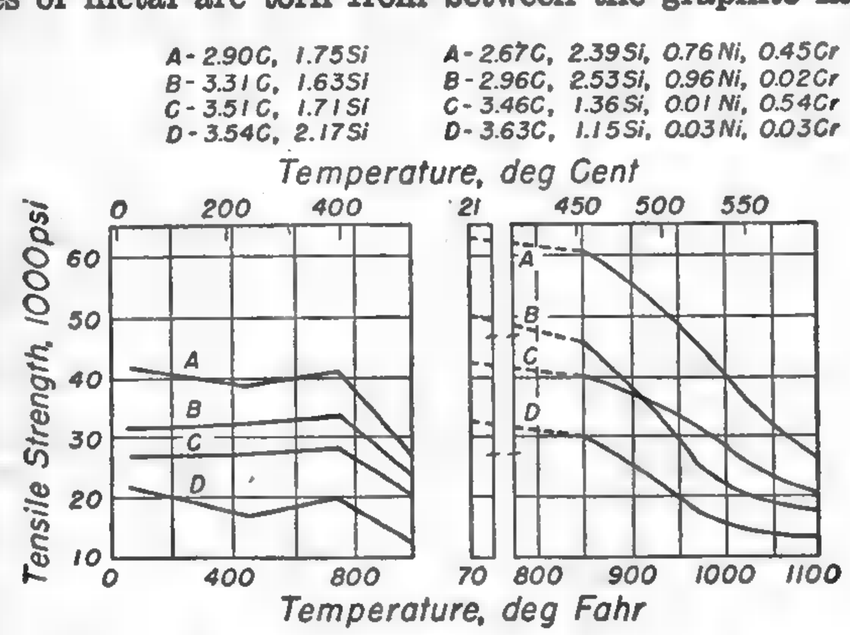

Fig. 16 Tensile strength of gray iron at elevated temperatures. Curves on right were obtained after heating the specimens 500 hours.

Heavy cuts taken on coarse-grained cast iron will exaggerate the pitted appearance by tearing out small particles of iron. Subsequent grinding may cover the coarse-grained appearance of the metal. The lower-carbon irons will have a much better appearance after machining.

Newer types of tool materials, such as tungsten carbide and other carbides, and newer machine-tool designs, permit removal of metal, in some operations, at rates that were not attainable with older tool materials and with older types of machine tools. The newer carbide tools are more resistant toward the abrasive action of small carbide particles, toward the hard phosphorus-rich component, steadite, and toward burned-in sand. The resistance of cast irons to deformation and fracture, usually does not produce high tool pressures. Cast iron is not likely to seize and crater on tool faces. Newer tools and newer machines permit considerably greater speed in the machining of many types of cast iron.

Effects of Temperature on Cast Iron

The effects of temperature on cast irons may be manifested in two ways: (1) effects on mechanical properties and (2) deterioration of the material because of certain structural and chemical changes that may occur at elevated temperature. In some instances, these factors are interrelated.

Codes based on ASME recommendations do not permit the use of cast iron for structures that contain pressure and must withstand more than 250-lb pressure for steam service at temperatures above 450 F. This regulation, based on certain findings by the ASME in 1909, may be unduly restrictive for many modern cast irons. A code proposed in California for unfired pressure vessels permits the use of suitable classes of iron for temperatures up to 650 F.

After having made a survey of service records of gray iron parts used at temperatures above 450 F, a special ASTM Committee concluded that irons of suitable strength and composition are adequate for use in parts that contain pressure, as high as 650 F (*see* ASTM Spec A 278).

In other applications requiring considerable mechanical strength, cast irons of suitable type are frequently used successfully at temperatures up to about 850 F. Above 850 F nearly all ordinary cast irons deteriorate enough to make questionable their utility for severe mechanical duty.

The ordinary lower-strength gray irons are much more susceptible to "growth" and other deteriorating influences than are the classes listed in ASTM Specification A 278. In general, higher percentages of carbon and of silicon increase the likelihood of deterioration. A lower carbon content and use of a carbide former, such as chromium, are relatively effective in promoting stability.

When judged by short-time tensile tests, cast irons show very slight changes in their original tensile strengths at temperatures up to 800 F. This is shown in Fig. 16.

The "creep" curves in Fig. 17 and 18 indicate that cast irons have marked resistance to creep at 600 F. Creep resistance is somewhat lower at 800 F. The curves marked "High Test" and "Nickel" irons in Fig. 17, represent irons that were stressed to 10,000 psi. The iron represented in Fig. 18 was stressed also at 10,000 psi at 600 F. All three irons referred to were in the 40,000-psi gray iron tensile class. The material marked "Gray Iron" was in the 30,000-psi tensile class, and was therefore stressed higher in proportion to its tensile strength than the others.

Endurance or "fatigue" limit is not greatly decreased up to 800 F, and the Brinell hardness number is unchanged. Apparently the compressive strength decreases appreciably within this range. Resistance to wear is one of the unique characteristics of gray irons, and evidently is maintained at moderately elevated temperature. The satisfactory resistance to wear of gray cast irons is demonstrated by their successful applications in cylinders and pistons for automotive, Diesel, and steam engines.

Because of low ductility and comparatively low resistance to impact, cast iron should not be employed to resist high dynamic stresses at elevated temperature, in applications where failure would result in hazard to life or equipment.

Heat-Resistant Cast Irons. The ability of cast irons to resist heat becomes an important factor when the metal

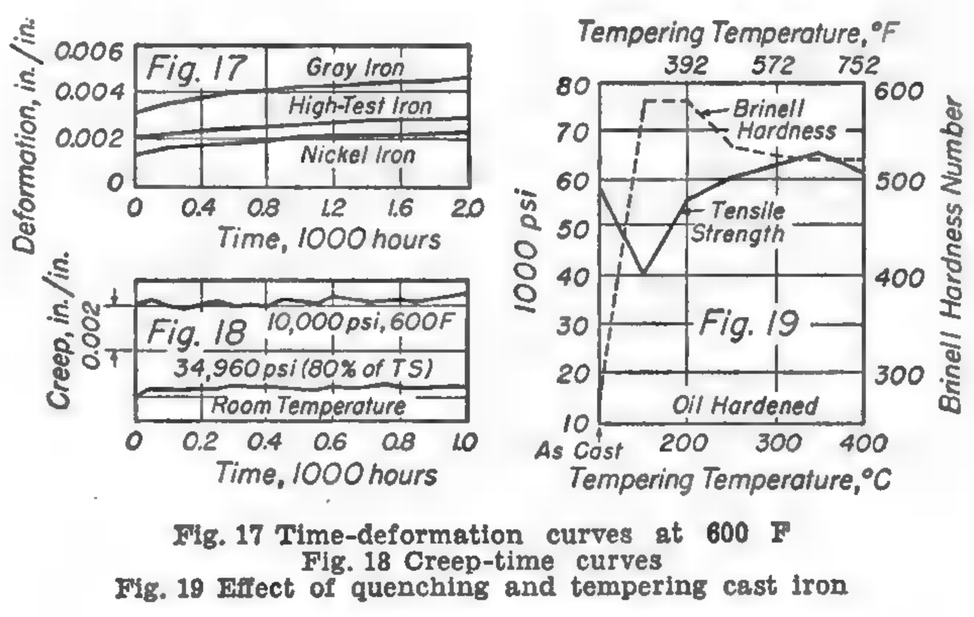

Fig. 17 Time-deformation curves at 600 F
Fig. 18 Creep-time curves
Fig. 19 Effect of quenching and tempering cast iron

is used in air at temperatures above 800 F, or in superheated steam even at lower temperatures. Resistance to heat depends largely on resistance to certain corrosive influences—chiefly oxidation, which may result in serious scaling; and on resistance to growth, which is a permanent increase in size.

In cast irons, growth results both from graphitization and from infiltration of corrosive gases. When ordinary gray iron is heated repeatedly to temperatures above 800 F (depending on the type of iron) it usually exhibits growth also. In a given iron, the amount of growth is ordinarily proportional to the maximum temperature reached, and to the number of heatings. Castings exhibiting growth are weak, misshapen and brittle. Some have been known to increase 50% in volume.

The irons most resistant to growth are found to have stable carbides and close dense grain structure with low total carbon content. Factors that stabilize carbides and produce close grain structure retard growth.

Among commercial engineering irons, those in the higher tensile classes with lower total carbon content are usually more resistant to growth and may be satisfactory in this respect up to about 850 F for long periods. Low silicon content is usually desirable and small percentages of chromium frequently prove advantageous. Under certain conditions, high phosphorus content retards growth somewhat, but because of various disadvantages, high-phosphorus irons are not widely favored for use at elevated temperature.

It is obvious that white irons, with carbon entirely in the combined form, are more resistant to growth than gray irons, which contain graphite flakes. Some white irons are limited in application because of their extreme hardness, brittleness and low strength.

Special irons have been developed that possess extraordinary resistance to growth. Perhaps the most widely used of these irons are the austenitic cast irons containing 14% Ni or more, about 5% Cu, and 1 to 4% Cr. Since they are austenitic, these irons do not expand and contract in passing through the range from 1325 to 1350 F, where the pearlitic transformation in regular gray irons occurs. Austenitic cast irons resist oxidation well, even up to 1500 F. When properly made, these irons are more ductile than regular gray irons.

The British have developed a special 6 to 8% Si cast iron, reported as offering excellent resistance to heat. The resistance of this material to deterioration results from (1) ■ completely ferritic matrix, since there is no carbide to decompose, (2) the raising of the transformation temperature above the working range, (3) fine-grained graphitic structure, and (4) a dense matrix. The effectiveness of very high silicon content is demonstrated by the following comparison of growth in two irons after ten heatings up to 1832 F.

Carbon, %	Silicon, %	Growth, %
2.1	3.7	0.923
2.5	6.1	—0.011

The high-silicon material known as Silal, must not be confused with so-called high-silicon gray irons, which rarely contain more than 3.0% Si. In true gray irons, silicon promotes growth, as mentioned previously.

Irons that contain 6 to 8% Si are rather brittle. Irons that contain 14% Si resist growth and scaling but are quite brittle.

The development of the stainless steels has emphasized that high percentages of chromium are accompanied by high resistance to oxidation. Also chromium stabilizes carbide, as mentioned above. It is therefore not surprising that high-chromium cast irons (15 to 35% Cr) resist both growth and scaling. In spite of a white iron structure, certain of these alloys can be made machinable, and they have been advocated for use at temperatures up to 1800 F.

Certain irons with moderate percentages of chromium (0.30 to 1.00%) have been found much more resistant to growth than unalloyed gray irons, and possibly somewhat more resistant to scaling.

Corrosion of Gray Cast Iron

Gray iron is more resistant to many types of corrosion than are carbon and low-alloy steels. Although gray iron forms a rust coating rather readily in moist atmospheres, continued penetration by rust and consequent disintegration are usually quite slow in comparison with similar effects in steel—perhaps because the underlying graphite flakes form a protective (and adherent) coating.

Cast-iron water pipe has given excellent service; cast-iron soil pipe usually lasts much longer than steel pipe.

Although different classes of gray iron do not vary much in resistance to a given water or soil, different waters and different soils vary quite widely in their corrosive effects. For example, some mine waters contain small percentages of sulfuric acid; others contain copper salts. In these and similar instances, highly alloyed metals may be required for resisting the corrosive solutions.

As with all common metals, the resistance to corrosion of gray iron is impaired when stray electric currents are encountered (chiefly in cities). These currents are particularly severe in their effects when contaminated water and the gray iron act as conductors so that an electrochemical cell is set up.

Many crude oils and refinery products are relatively noncorrosive toward gray iron. High-sulfur oils containing moisture, and some of the crude oils containing salt are rather corrosive toward gray iron and steel.

Gray irons are usefully resistant to most natural and artificial gases.

Although it is resistant to strong sulfuric acid (60 to 66 Bé), gray iron is attacked rapidly by more dilute sulfuric acid. Hot fuming sulfuric acid (oleum) attacks and disintegrates gray iron. This metal is fairly resistant to cold concentrated phosphoric acid and nitric acid but impurities such as hydrofluoric acid and chlorides, impair its resistance appreciably. Dilute phosphoric and nitric acids attack gray iron quite rapidly, and it is not resistant to hydrochloric (muriatic) acid in any concentration.

Gray iron resists many alkaline and caustic solutions—for example, sodium hydroxide, lye, soda ash and ammonia—and is not embrittled by exposure to strong hot caustics. Where some slight discoloration (caused by solution of traces of iron) is not objectionable, gray iron has proved very useful in contact with alkaline fluids employed in the manufacture of glass, sodium silicate, soap, viscose rayon, paper, dyestuffs, textiles, and in the treatment of petroleum and the like. In general, fine close-grained irons (as in the 30,000 to 40,000-psi tensile classes) are more resistant to corrosives than are the lower-strength, more open-grained types.

With few exceptions, small amounts of alloying elements are of little or no benefit in improving the resistance to corrosion of gray irons.

Increase in temperature of corrosive fluids usually increases their corrosive effects.

Frequently gray irons are used at elevated temperatures. At quite high temperatures (850 to 900 F and higher) ordinary gray irons are subject to growth. Above approximately 1100 F, gray irons usually scale rather rapidly, particularly where combustion gases contain corrosives, such as oxides of sulfur.

Several types of special cast iron have been developed to resist various types of corrosives. Prominent among these are the austenitic gray irons, known commercially as Ni Resist and Causul Metal. These are manufactured in several compositions, included within the following range: 14 to 30% Ni, 4 to 7% Cu, 0.5 to 3.5% Cr, and as much as 1.0% Mo. Some of these austenitic gray irons are usefully resistant to sulfuric acid, over the entire range, dilute to concentrated; however, they do not resist attack by hot oleum. They are resistant to the less severely corrosive solutions of hydrochloric (muriatic) acid and to some phosphoric acids but nitric acid attacks these austenitic gray irons severely. They have fair resistance to some organic acids, such as acetic, oleic, stearic and red oils. Types containing 18% Ni or more (with or without other alloying elements) are nearly immune to the corrosive effects of alkalies and caustics, weak or strong. However, these high-nickel types are subject to stress-corrosion in strong hot caustics. If stresses are kept lower than about 10,000 psi, austenitic gray irons of high nickel content can be used safely with boiling concentrated caustics.

Though not immune to rust, these irons form rust slowly, and do not disintegrate by rusting. They are resistant to scaling at elevated temperatures and are not subject to growth. In many services, austenitic irons are economical substitutes for some high-alloy stainless steels.

High-silicon irons (usually about 15% Si) resist many acids; exceptions are hydrofluoric acid and hot concentrated hydrochloric (muriatic) acid. High-silicon irons are useful for conditions where free "wet" chlorine is encountered, and are unusual in their effective resistance to solutions containing copper salts; however, their resistance to hot strong caustics is not good. Furthermore, high-silicon irons have the disadvantages of being hard and brittle, costly to manufacture, and so fragile that they require careful handling in installation and usage.

The high-chromium irons (usually 24 to 35% Cr) resist many corrosives, including nitric acids (except fuming)

and solutions containing free chlorine. High-chromium irons are nearly immune to rust and highly resistant to scaling; however, they are attacked by strong caustics.

Corrosive conditions vary so widely that specific recommendations should be made only after study of the particular problem. Therefore this discussion should be used only as a general guide.

Heat Treatment of Cast Iron

Cast iron may be compared with steel in its reaction to heat treatment. However, cast iron contains (1) graphite flakes and (2) substantially higher percentages of silicon, requiring a higher austenitizing temperature. The graphitizing effect of the silicon is so powerful that an unalloyed iron may become completely graphitized below the A_1 temperature during heating for austenitizing. Thus an unalloyed iron requires a longer interval at the quenching temperature for reabsorption of the desired carbon content in the austenite, because silicon retards the absorption of carbon in austenite.

The lower-silicon irons respond best to heat treatment, and successful hardening of cast iron requires close control both of silicon content and of temperature.

The heat treatment of cast iron may be divided broadly into four general classifications: stress relieving, annealing, quenching, and special heat treatments.

Relieving Residual Stresses. The heat treatment that relieves residual stresses is commonly called "aging", "normalizing" or "mild annealing"; the term "stress relieving" is more accurately descriptive. This treatment can be accomplished by heating the cast iron to between 800 and 1100 F, holding at temperature from 30 min to 5 hr, and cooling slowly in the furnace. This treatment will cause only a slight decrease in hardness, very little decomposition of cementite, and only a slight change in the strength of the metal at room temperature.

Annealing. Sometimes it is desirable to soften the casting in order to facilitate machining. Frequently the production heat treatment of cast iron is performed for this purpose. The temperature range most commonly used is 1400 to 1500 F, although temperatures as low as 1200 to 1250 F have been used satisfactorily. Highly alloyed irons are sometimes annealed at temperatures as high as 1800 F. In all annealing, care should be taken to prevent oxidation of the casting.

In general, softening for machinability is attended by a decrease in strength and in the amount of combined carbon, and by an increase in graphite content. Irons that contain carbide-forming alloying elements, such as chromium, are more resistant to softening than the ordinary gray iron, and therefore must be annealed at considerably higher temperatures.

Completely annealed ordinary cast iron may have a Brinell hardness number from 120 to 130, whereas completely annealed alloy irons may have a Brinell hardness number from 130 to 180, depending on the composition.

Quenching and Tempering. In order to increase the hardness and resistance to wear, cast iron is quenched from above the transformation temperature range. The addition of alloying elements, such as chromium, molybdenum, nickel and vanadium, has a marked effect on the response to heat treatment. It is not customary to quench the common soft gray irons, although they may be hardened to a martensitic structure. Such soft irons would require higher hardening temperatures and longer time at temperature in order to obtain the desired carbon content in the austenite.

For optimum results, the graphite flakes should be small and well distributed; the matrix should be pearlitic or sorbitic. The combined carbon should be from 0.50 to 0.80%. The hardness increases with increasing rate of cooling from above the transformation temperature. After the hardening treatment, softening proceeds uniformly as the tempering temperature is increased above 350 F. The strength and impact resistance are distinctly improved by tempering.

The material as quenched usually has lower strength than the material as cast. The deterioration in strength is restored by tempering (Fig. 19). Thus by suitable hardening and tempering, the strength may be improved appreciably.

The castings should be heated uniformly to the quenching temperature. In common practice, the quenching temperature range is from 1500 to 1600 F. The quenching medium commonly used is oil; however, water is used to a limited extent and some castings may be quenched in air.

The castings are usually rough machined before hardening and are finished by grinding. Growth occurs during heat treatment, so allowance must be made for this in leaving stock for finish grinding.

Cylinder liners for use in heavy-duty internal combustion engines, have been heat treated to secure a marked increase in hardness and resistance to wear. The range of hardness after heat treatment is from 375 to 500 Bhn.

Special Heat Treatments. *Flame Hardening.** Flame hardening is being used where a hardened surface is desired for resistance to wear. The treatment is particularly applicable where only certain portions of a casting are to be hardened, as on a camshaft. In flame hardening, the time interval is short, so the structure of the casting should be of eutectoid composition in order to secure maximum hardness.

Induction Hardening. Gray iron castings may be heated by induction methods, similar to flame hardening in application.

Austempering. This is a trade name for a patented heat treating process that is applied to gray iron castings for the purpose of increasing strength and resistance to wear. The castings are heated between 1500 and 1600 F, and then are quenched in a salt bath maintained at 500 to 550 F. It is usually necessary to leave the castings in the hot bath for a period of 15 min to 1 hr, depending on the composition of the casting and the size of the section.

Nitriding. Castings may be nitrided in order to increase resistance to wear. The nitriding process consists in subjecting the castings to temperatures from 950 to 1100 F during contact with anhydrous ammonia gas, for a period of 20 to 90 hr. Irons of special composition must be used for the nitriding process.

Welding of Cast Iron. Welding is used for the salvage of castings and also for the repair of castings that have failed in service. Usually only minor welds are permitted for the salvage of gray iron castings. Some purchasers of gray iron castings permit no welding.

For information concerning the welding of cast iron see page 371 in this Handbook.

Malleable Iron

By H. A. Schwartz*

MALLEABLE IRON consists almost entirely of ferrite and temper carbon. Temper carbon is graphite in a nodular form instead of in the flaky form in which it exists in gray iron. The reason for the nodular form is that the graphite was separated from cementite (Fe_3C) while the alloy was solid, thus preventing the growth of flakes.

Melting Furnaces. Malleable iron, as made to meet ASTM Specification A 47-33, is usually melted in the reverberatory furnace or in the electric furnace, either of which may be charged with solid metal or liquid metal from the cupola. In some instances a mixture of cupola metal and Bessemer steel is charged, but this process, called "triplexing", is no longer much used. Charging with cupola metal is called "duplexing". A limited amount of malleable iron is melted in open hearth furnaces, and the solid charge is sometimes melted in a modified type of reverberatory furnace that consists of a rotating cylindrical drum. These rotating furnaces have the advantage that the charge is brought in contact with the brickwork, which has just been superheated by contact with the flame; thus the metal is heated while cooling the bricks. Such a furnace is capable of making metal without requiring such high refractoriness of the lining as is required in ordinary reverberatory furnaces.

The fuel of reverberatory furnaces is ordinarily pulverized coal, though a few furnaces are still hand-fired, and some furnaces burn oil.

Cupola malleable iron, as made to meet ASTM Specification A 197-39, is used largely for the manufacture of pipe fittings and similar parts where fluidity and soundness of the casting are more important than high tensile strength or elongation. The cupola is not adapted to the making of low-carbon iron as required for the maximum of strength and ductility.

The advantage of duplexing methods is that they furnish a continuous stream of metal. This is particularly desirable in the mechanized foundries where molds are poured on conveyers. Duplexing is somewhat better adapted to the making of moderately high-carbon iron than of low-carbon iron, although it has been applied for producing low-carbon iron. Where quite low carbon content is wanted, batch-type furnaces of the reverberatory or rotating types, or open hearth or electric furnaces are preferable.

Where batch-type reverberatory furnaces are used, the charge consists of pig iron, steel, malleable scrap and "sprue", that is, gates, runners and defectives from previous melts. The ingredients are so proportioned that when the metal is melted and heated to pouring temperature, it contains as nearly as possible the desired percentage of carbon and contains nearly the percentage of silicon and manganese required in the finished product, but not more. For the content of silicon and manganese, ferro-alloys are used for making final adjustments after chemical analysis of the metal.

It is impracticable to produce from a cupola, metal hot enough to pour castings and as low in carbon as is generally desired. It is therefore common to operate an air furnace with the cupola in a duplex operation. Using charges of pig iron, steel and sprue, the cupola is operated to produce metal of about 2.75 to 3.00% C. The flame conditions and the length of time when the metal is in the air furnace are so arranged as to produce the desired carbon content while the metal is being heated to the temperature needed. Silicon and manganese are added at intervals to make whatever small adjustments are required.

Composition of Malleable Iron. The molten metal must have such a composition that when cast at the desired temperature into castings of the required size, it will be free from graphitic carbon so that flakes will not be present. The metal must also be capable of relatively easy graphitization to convert it into malleable iron. For various purposes the carbon may range from 2 to 3%, and the silicon from 1.50 to 0.80%. By the use of graphite-free melting stock, high melting temperatures and quick freezing, it is possible to increase the silicon in low-carbon iron to as much as 1.50 or 1.60%, or even higher, producing an easily graphitizable iron at some risk of forming primary graphite in large castings or with cold pouring. The manganese is generally held at 1.7 times the sulfur, plus an excess of from 0.10 to 0.15%. As long as this ratio is maintained, the sulfur may be as high as 0.16 or 0.17% without detriment. In much of the metal produced by duplexing, the sulfur content is as high as 0.20% without causing trouble. The phosphorus content may be 0.20% or less. If the percentage of phosphorus is too high, especially in relation to the silicon, the iron will be subject to intergranular embrittlement when cooled quickly from the "blue heat" range near 900 F. The difficulty can be overcome by quenching from 1200 F in water.

Annealing Malleable Iron. The heat treatment of malleable iron is executed either in stationary batch-type furnaces, which are large brick chambers heated by flame passing through them, or in car-bottom furnaces, which resemble the stationary batch type, except that the furnace bottom can be rolled in and out on car wheels, permitting the charging or discharging of a hot furnace.

In such furnaces, the castings are protected from con-

Table I. Classification of Industries, With Condensed List of Products in Which Malleable Castings Are Used[a]

Agricultural Implements	Plows, tractors, harrows, reapers, mowers, binders, cultivators, rakes, spreaders, dairy and poultry equipment, presses, tools, pumps, wagons, fence parts
Automobiles	Parts for frame, wheels, springs, brakes, motor transmission, axles, steering gear, body, accessories
Boilers, Tanks, and Engines	Boilers, tanks, fittings, engine parts, outboard motors, Diesel engines
Building Equipment	Hardware for windows, doors, garage equipment, awning hardware
Conveyer and Elevator Equipment	Chains, buckets, pulleys, rollers, cranes, hoists, fittings
Electrical and Industrial Power Equipment	Motor and generator parts, pumps, stokers, electric locomotives and tractors, steam specialties, outlet and switch boxes
Hardware and Small Tools	Pneumatic and portable tools, miscellaneous tools, saddlery, hardware, table and kitchen utensils
Household Appliances	Stoves, sewing machines, refrigerators, washing and ironing machines, vacuum cleaners, dishwashing machines, oil burners, electric fans and toasters, radios
Machine Tools	Lathes, planers, shapers, grinders, screw machines, gear cutters, drills
Machinery for Special Uses	Textile, cement, rubber, shoe, mining and quarrying, grinding, forging, foundry, bakery, woodworking, bottling, ice, laundry industries
Marine Equipment	Anchors, chains, capstans, fastenings, towing bits, hardware
Metal Furniture and Fixtures	Stoves, beds, desks, filing cabinets, shelving, hotel supply equipment
Municipal, State and Public Service	Manhole covers, posts, guardrail equipment, highway markers, transmission and telephone-line fittings, electric railway fittings
Pipe Fittings and Plumbing Supplies	Elbows, unions, reducers, flanges, valves, bolts, nuts
Railroads	Wide variety of parts for construction of locomotives, freight and passenger cars; guardrails, miscellaneous
Road and Contractor's Machinery	Rollers, excavators, cranes, hoists, tractors, graders, scarifiers, mixers, pavers
Toys and Specialties	Sleds, wagons, automobiles, bicycles, carriages, gun parts

According to the Department of Commerce, there are about 150 plants in the industry, with 1,350,000 tons estimated annual capacity.

tact with the flame by being packed in cast-iron pots. In order to prevent warpage of castings at high temperature, these box-shaped pots may have the space between the castings filled by some refractory material to furnish support. The packing is apart from the metallurgy except occasionally when decarburization at the surface is desired; then iron oxide is added to the packing. It is also common to anneal large castings in brick muffles, heated externally by flame.

Instead of intermittent or batch-type furnaces, kilns are often employed, through which the stock passes continuously. Such furnaces may be divided into two classes.

In one, a train of cars is pushed through a tunnel in which various sections are kept at various temperatures, so that with a predetermined rate of travel, the time-temperature relations are those desired. No effort is made to control furnace atmospheres; the composition is that of the products of combustion of the fuel (usually oil or gas) diluted with infiltrated air. The castings are packed in pots, as in stationary furnaces. Such units are especially suited for rather large daily production.

Alternatively, castings placed in relatively thin layers in trays, may be passed by a pusher mechanism through a suitably heated tunnel, or may be moved through by the well-known "walking beam" mechanism, which picks up the stock, advances it and sets it down. Another alternative is a furnace with a floor that consists of a traveling conveyer. Castings in such furnaces are usually not packed in containers but the composition of the furnace atmosphere is controlled.

Since the control of atmosphere is not feasible in furnaces through which the products of combustion pass, furnaces of the latter type are heated electrically or by "radiant tubes". These are long tubes made of an alloy that resists oxidation and within which the fuel—usually gas, but sometimes oil—is burned. To be effective in transmitting heat, the radiant tube must be operated at temperatures considerably above those of the metal charge.

In batch-type furnaces, the charge is raised on a car, which seals itself hermetically against the furnace structure. Resistance ribbon heats the units inside the furnace. Batch-type furnaces may also be of the "bell" type, in which a box-shaped furnace heated by resistance coils, or more commonly by radiant tubes, is lowered over a charge placed on a suitable platform. The heat treating time is governed by the composition of the metal and some other details of its manufacture, and still more by the design of the furnace, which determines how fast the furnace temperature can be increased or decreased without producing excessive temperature gradients.

In large stationary batch-type furnaces, it may take 45 hours to heat the metal to 1500 F, 50 hours for higher temperatures, to the maximum of 1650 or 1700 F, and 60 hours to cool. It is desirable to cool the metal through the transformation range at less than 10 °F per hour in the interest of producing pearlite-free material with a minimum cycle of annealing.

The influence of the furnace atmosphere is also connected with annealing time. Atmospheres containing hydrogen should be avoided since they retard annealing. Too much CO in proportion to CO_2 is also objectionable. In practice, the CO should exceed the CO_2 but the amount should not be more than twice that of CO_2, in order to obtain free annealing and to avoid scale. Furnace atmospheres are controlled by introducing partially burned fuel, usually gas, at a rate sufficient to maintain the desired composition against the tendency of the gas to come to equilibrium with the carbon of the metal.

The elements silicon, titanium, aluminum, zirconium, uranium, and especially boron—the last in amounts of 0.001% B—accelerate annealing vigorously. Nickel and copper are slight accelerators. Chromium is an energetic retarder, as is boron in amounts greater than 0.1%. Manganese is also a retarder, and vanadium and molybdenum act similarly. Tungsten is a slight retarder, and the nonmetals sulfur, selenium and tellurium inhibit graphitization by forming films through which carbon cannot migrate.

Especially if packing is not used to support the metal, stationary batch-type furnaces, if not too large, can be operated in a cycle of approximately 70 hours. Furnaces of the continuous type can complete a cycle in approximately 40 hours, and even shorter cycles have been reported. It has been asserted that the high-silicon types of malleable iron can be annealed in 15 to 30 hours. In most instances, furnace design is responsible for these differences.

To permit short annealing times, the furnaces must be small and mechanically operated. Thus the cost may increase, a disadvantage since the annealing cycle is dictated by economic considerations.

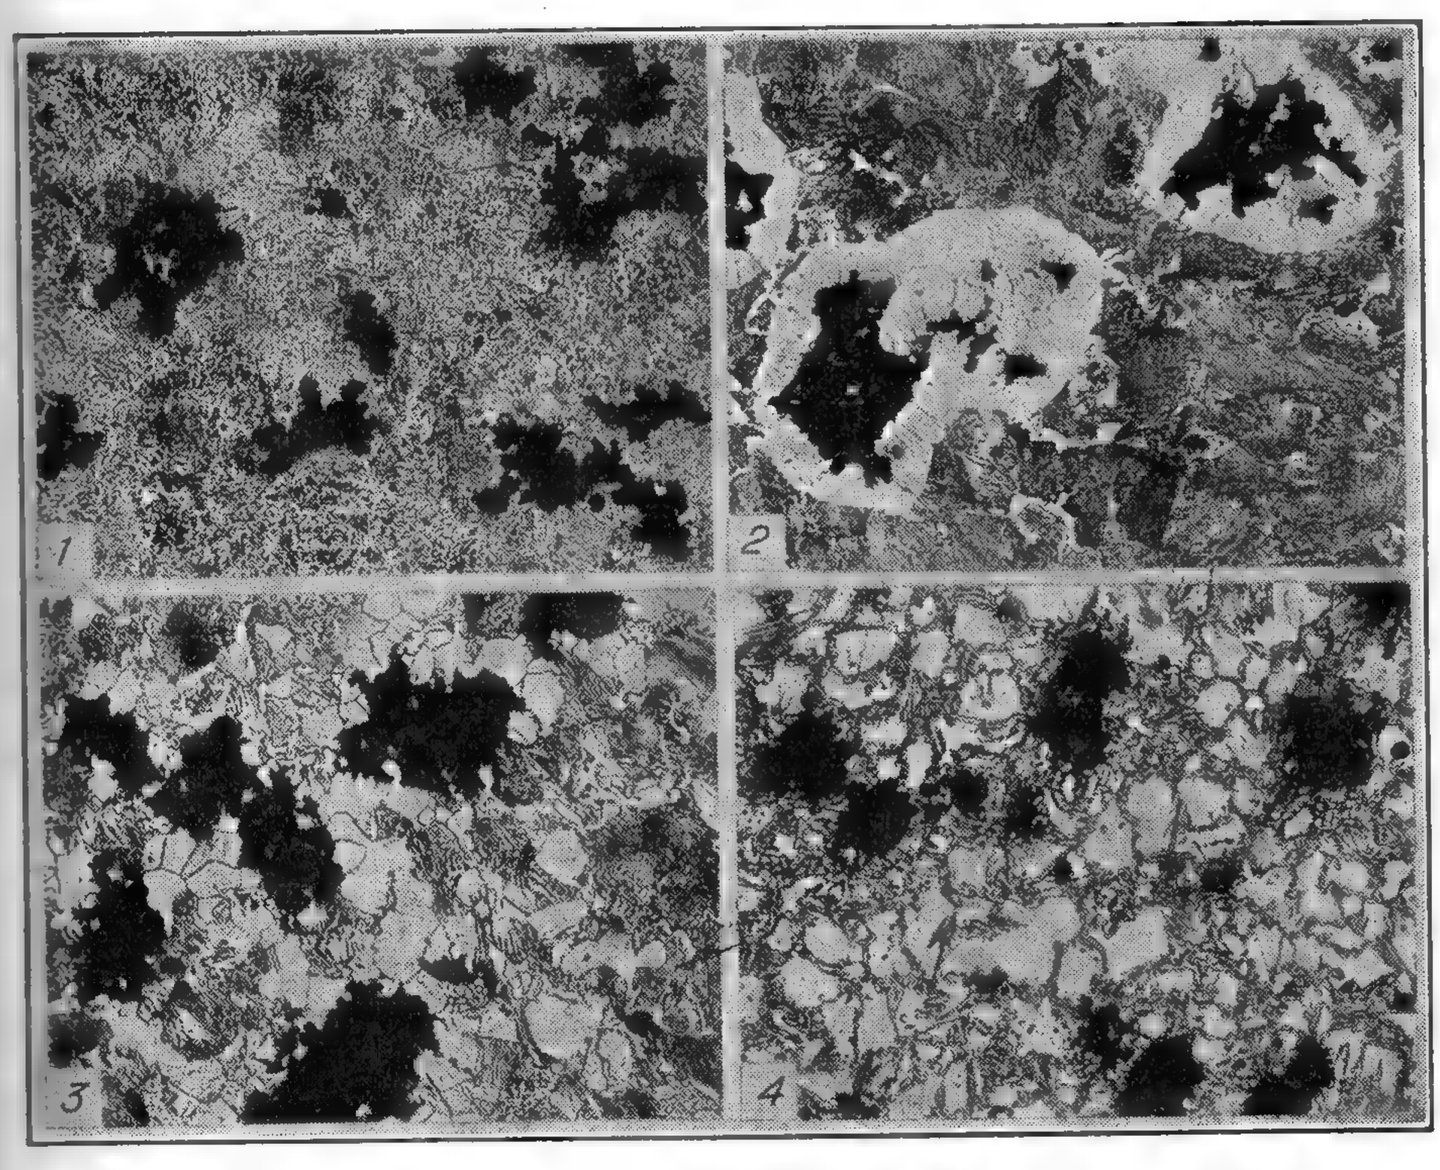

Fig. 1 Temper carbon in spheroidized matrix produced by controlled rapid cooling of high-manganese (about 0.75%) white irons completely graphitized to equilibrium above A_1, followed by spheroidizing (× 100, nital)

Fig. 2 Bull's-eye malleable iron produced by normal graphitizing cycle applied to high-manganese (about 0.70%) hard irons (× 100, nital)

Fig. 3 Granular ferrite and pearlite in high-silicon and chromium white iron with normal graphitizing heat treatment (× 100, nital)

Fig. 4 Sorbitic structure produced at grain boundaries by reheating malleable iron just above A_1, then quenching and tempering (× 100, nital)

Metallurgical Principles. The fundamental purpose in making malleable iron is to produce a casting entirely free from flaky graphite, and having a carbon content high enough for the desired fluidity and machinability, as well as low enough for the desired tensile properties. When once this iron has been produced, the purpose of the annealing cycle is to hold it at a temperature well above the transformation range. At this temperature graphite will crystallize out and cementite will dissolve until nothing remains but graphite and solid solution.

Table II. Physical and Mechanical Properties of Malleable Iron[a]

(b) The longer range of values for grade 35018 material is in part the result of more frequent investigations.
NOTE. Cupola malleable iron, as made to conform with ASTM Specification A 197-39, has a tensile strength of 40,000 psi min, a yield strength of 30,000 psi min, and an elongation in 2 in. of 5% min.

Since gamma iron will dissolve carbon at these temperatures, the process cannot be completed above the transformation range. Pearlite will change into ferrite and graphite by a mechanism the same as that mentioned above, but the reaction by which ferrite and carbon form from austenite in the region between A_1 stable and A_1 metastable is so much faster that it is desirable to hold iron in this range rather than below A_1. This is usually accomplished by slow cooling. Malleable iron is used for castings that are required to withstand shock, to have considerable ductility, and to be easily machinable.

A condensed list of uses is given in Table I.

The properties of two standard grades of malleable iron are shown in Table II. Minimum tensile properties of cupola malleable iron are listed also.

The only alloying elements that are used to a considerable extent in the malleable iron industry are copper and molybdenum, best used together. Copper used alone, especially after precipitation hardening, gives a decided increase in tensile strength—at slight sacrifice of ductility—and seems to be more effective in high-carbon iron than in low-carbon iron. When copper and molybdenum are used together, it is customary to add about 0.50% of each, or perhaps a little more copper. Such additions to malleable iron of the 35018 grade, may increase the tensile strength by as much as 8000 psi while reducing the elongation 5 or 6%.

Table III. Uses of Pearlitic Malleable Iron

Automobiles	Motorcycle parts, axle and differential housings, camshafts and crankshafts
Conveyer equipment	Gears, chain links, sprockets, elevator brackets
Machine parts	Rolls, pumps, nozzles, cams, rocker arms, universal joints
Ordnance	Gun mounts, pistol parts, tank parts
Tools	Wrenches, hammers, clamps, shears

Pearlitic Malleable Iron. This series of alloys contains combined carbon in various forms in the matrix, thus differing from normal malleable iron, in which the matrix is ferritic. Pearlitic malleable iron is produced either by stopping the heat treatment before the combined carbon has all been transformed to graphite or by reheating normal malleable iron above the transformation range. Rather than to stop the heat treatment, it is sometimes more convenient to add a retarding alloy, usually manganese, in an amount about 0.5% greater than that for normal malleable of similar composition, and then to carry on a normal annealing cycle. Especially when a sufficient amount of a retarding element is present to prevent rapid graphitizing, the microstructure of the matrix can be given almost any of the characteristics found in the heat treated steels, by treatments that parallel those for such steels. The pearlitic malleable irons that seem to have been most generally useful, are those in which the cementite is present as spheroids, whether the structure is produced by air-cooling high-manganese alloys or by cooling normal malleable iron more rapidly. In either instance a spheroidizing treatment should follow. Microstructures of various types of pearlitic malleable are shown in the micrographs of Fig. 1 to 4.

Depending on the amount of combined carbon retained and the form of its distribution, the properties of the resulting product will vary. The tensile and yield strengths are always higher than for normal malleable iron, and the ductility and impact resistance are lower. The machinability also is decreased. The fatigue ratio is probably near 0.50. The tensile strength may be as high as 90,000 or 100,000 psi, and the elongation as low as 2 or 3%. As the tensile strength decreases, the elongation increases.

Chromium and aluminum have been added to certain pearlitic malleable irons in order to make nitriding feasible.

Uses of Pearlitic Malleable Iron. The uses of pearlitic malleable iron are manifold, since the material can be made to have a great range of properties. For example, some forms are rigid and resist deformation and others deform considerably before breaking.

Table III gives a summary.

Pearlitic malleable iron is especially well suited to induction hardening. Since temper carbon is rather widely dispersed in malleable iron, an appreciable period of time must be allowed for diffusion to obtain uniform hardness. This difficulty can be overcome when it is possible to use pearlitic malleable iron for the part. The finely laminated, and still more finely spheroidized carbides are dispersed so uniformly that they will dissolve quickly and easily, resulting in a correspondingly rapid saturation of the austenite with carbon. The finely divided carbide of pearlitic malleable iron dissolves readily in gamma iron in the brief periods of time used in local induction hardening, and produces great uniformity of hardness and a very hard surface, since it can be made to contain approximately the amount of combined carbon that will produce martensite of maximum hardness.

Steel Castings

By Charles W. Briggs*

CAST steel is steel that is poured into metal or refractory molds and allowed to solidify. This steel may be used commercially in the cast form (steel castings) or it may be further processed by hot or cold working to become wrought steel. A steel casting is a steel object that has been cast initially into the shape desired for the finished product and does not require mechanical working. The many types of steels produced as wrought steel can all be made as steel castings.

Classes. There are five classes of commercial steel castings:

1 Low-carbon steels (carbon content less than 0.20%)
2 Medium-carbon steels (0.20 to 0.50% C)
3 Higher-carbon steels (carbon content above 0.50%)
4 Low-alloy steels (total alloy content less than 8%)
5 High-alloy steels (total alloy content more than 8%)

Carbon Steel Castings. Carbon steel castings contain less than 1.70% C, along with other elements normally present. These elements vary somewhat but are usually present in amounts ranging as follows: 0.50 to 1.00% Mn, 0.20 to 0.70% Si, 0.05% P max and 0.06% S max. In addition, carbon steel castings contain small percentages of other elements, which are not added but are residual in the scrap steel that constitutes a portion of the melting charge.

The medium-carbon class, comprising the bulk of the steel casting output, is the regular grade product. Low-carbon and high-carbon grades have been developed for steel castings so that useful properties imparted by high and low carbon contents may be available for specialized products and uses.

Alloy Steel Castings. A steel casting is considered to be an alloy steel casting if the alloying elements, either residual or added, are present in quantities greater than those listed as follows: 1.00% Mn, 0.70% Si, 0.50% Ni, 0.50% Cu, 0.25% Cr, 0.10% Mo, 0.05% V, 0.05% W, 0.05% Al, 0.05% Ti. Limitations of phosphorus and sulfur contents apply to cast alloy steels as they do to cast carbon steels, unless they are specified for the purpose of producing an alloying effect.

The low-alloy casting class represents a sizable portion of the total steel casting production. High-alloy steel castings of the types that resist heat and corrosion and of the austenitic manganese type are discussed in detail on pages 549, 570 and 526 of this Handbook.

Distribution of Product. The normal distribution of steel castings by major classification is as follows:

Application	Per Cent
Railroad and transportation castings	35
Machinery castings	25
Rolling mill castings	15
Material handling equipment	8
Valves and pressure fittings	7
Road and building construction	5
Miscellaneous	5

In a normal year the steel casting industry ships approximately a million net tons of castings. In 1943, the peak year for war production, the shipments were 2,700,000 net tons of steel castings.

Range of Weight. Steel castings range from tiny ones weighing only a few ounces to others weighing many tons. The largest steel casting on record had a finished weight of 230 tons. Steel castings are being made in every conceivable size and shape; some have sections 2 ft thick while other measure less than ¼ in.

Manufacture of Steel Castings. Steel castings are being manufactured by approximately 300 companies throughout the United States. In some foundries (for example, in those producing railroad and transportation castings) manufacturing processes are highly mechanized, whereas in jobbing foundries the production scheme is usually fairly flexible and easily adaptable to the requirement of varied products. Since there is considerable diversity in the manufacturing process, it is preferable to describe only those general activities that are common to all steel foundries. It should be pointed out that one method of melting steel, or a particular molding method used by one manufacturer may or may not be duplicated by another manufacturer. These differences in manufacturing processes depend on the nature of the product of each foundry.

Steel Melting Practice. Steel for steel castings is produced commercially by almost all the currently used processes of making steel, namely: open hearth (acid and basic), electric arc (acid and basic), converter (side-blown, acid), and electric induction.

The manufacturing methods used by any one manufacturer depend on certain general conditions and circumstances. The choice of the steelmaking method to be employed depends on the policy of the organization concerning plant capacity, size and intricacy of the castings, type of steel to be produced, operation desired (acid or basic), raw materials available and the prices thereof, fuel costs, and capital to be invested. More than one steelmaking method may be employed in a foundry; in fact, in some foundries as many as four processes are used.

Details concerning the various processes listed above are available in the sections of this Handbook that deal with steelmaking processes, pages 315 to 342. The methods described are based primarily on ingot production, except for the acid electric-arc and high-frequency practices, which apply directly to the production of steel castings. The primary differences in the production of steel for castings and steel for ingots are that steel for castings must always be dead-killed and must have a high degree of fluidity.

A short, fast melting cycle is normally used, since high fluidity has become associated with short refining times, and steel of excellent fluidity is always desired in the running of castings. For information concerning the fluidity of steel, see the article on page 199 in this Handbook.

The steels are deoxidized with ferrosilicon and ferromanganese in such quantities that the residual silicon content will be between 0.35 and 0.60%, and the manganese content will be between 0.60 and 0.85%. If green sand molds are to be used, special deoxidizers are always added to the ladle. The deoxidizers may be aluminum, calcium-silicon, ferrotitanium, or a combination of these or other prepared alloys, added to prevent the evolution of gases during the solidification of the metal in the molds.

Approximately 75 to 100 grades of carbon and alloy cast steels are being made by the industry.

Molding Practice. Most steel castings are produced in synthetic molding sands. These sands are prepared by obtaining a classified silica sand, of either the washed or the crude variety, to which is added a refractory clay such as bentonite or a fire clay, in quantities from 2 to 6%. An addition of an organic binder (approximately 1%) is made in order to assist in developing proper molding qualities and sand properties. These additions are mulled together with water (from 2 to 6%) to obtain the desired plasticity. Sands for cores are prepared in much the same way, except that usually core oil is substituted in part for the clay addition. Most cores are oven-baked or dried; however, a number of green sand cores are used.

Molding practices are classified according to the manner in which the mold is prepared for pouring. These practices are (1) green sand, (2) skin dried, (3) dried, (4) core assembly, (5) Chamotte, (6) cement-sand practice and (7) investment molding. The green sand practice consists of pouring steel into molds shortly after they have been made, with no additional heat processing of the mold except possibly drying in air. The skin-dried practice consists of drying the surface of the mold cavity by flame torches before pouring the mold. The dried-sand practice consists of heating the green sand molds from 200 to 600 F in ovens until the moisture content is low. The molds are then returned to the pouring floor and the steel is poured into them either while they are hot or after they have reached room

* Technical and Research Director, Steel Founders' Society of America, Cleveland

temperature. The practice for core assembly consists of assembling a mold from green or baked cores or both.

The Chamotte practice consists of preparing molds from a ground and classified calcined clay to which is added raw clay and water for bonding purposes. Molds prepared from this mixture are dried by torch or in an oven. The cement-sand practice consists of bonding silica sand with about 10% cement and 5% moisture and permitting the cement to set by drying in air before the mold is poured. In the investment molding process for steel castings, the wax pattern is surrounded with a material consisting of a refractory aggregate (such as silica flour) and a binder. After the investment has hardened, the mold is heated and the wax melts and is poured out. The mold is then ready for the steel to be poured into it.

The molding practice used by a foundry will depend on the shape, size and type of castings to be produced. Selection of a suitable molding practice depends on the experience, equipment and handling methods possessed by the foundry. Molds are rammed either with hand tools or pneumatic rammers, or on various molding machines of the jolt-and-squeeze type as well as with sand slingers. Many kinds of automatic and semiautomatic equipment are used for handling sand and molds while the molds are being prepared and placed in position for pouring.

Gating and Feeding. Considerable importance is attached to the manner in which molten steel enters a mold. Steel foundrymen have long been aware that to be satisfactorily made a casting must be properly gated. The primary purpose of the gate system is to furnish a way for the steel to enter the mold. A gate has other necessary functions also —as a venting system for the removal of gases from the mold and as a riser to furnish liquid metal to the casting.

In pouring a mold, the aims are as follows: (1) to fill the mold cavity completely, (2) to avoid deterioration of the mold by the liquid metal, and (3) to establish proper gradients of temperature in the mold so that the gate will not be responsible for the occurrence of contraction cavities in the casting.

While steel is solidifying, it contracts in volume. If no attention were given to this fundamental characteristic in the process of molding, the casting would be internally defective, because the metal solidifies from the outside inward toward the center of the section. To forestall the formation of cavities, reservoirs of molten metal are provided at suitable locations. These reservoirs, which are not a part of the casting but are essential to the integrity of the casting, are called "risers" or "feed heads". When the casting is cleaned, the risers are removed and the casting is ground smooth to the pattern contour.

The shape, size and position of the riser must be controlled effectively. A riser must meet five primary requirements: (1) It must completely cover the casting section that requires feeding. (2) The volume of the riser must be sufficient to compensate for the contraction of metal within the casting. (3) The fluidity of the metal in the riser must be maintained so that the metal can flow from the riser and penetrate to the last contraction cavity. (4) The riser should be effective in establishing a pronounced temperature gradient within the casting so that the casting will solidify directionally toward the riser. (5) The riser must be the last portion of the casting to solidify.

Finishing Operations. After the steel castings have been poured, have solidified and have been allowed to cool somewhat in the molds, they are shaken out of the molds and the gates and risers are removed by sledging, shearing, torch burning or cold sawing. A grinding operation is then required for the removal of pads, fins, lumps and metal added to make the design castable.

Blast cleaning is performed to remove cores effectively, to clean away adhering sand and scale, and to improve the appearance of the castings. Blasting operations may precede heat treating, follow heat treating, or both.

Heat Treating. Steel castings are heat treated by all the various methods used for wrought steel. Depending on the requirements of service and property specifications, steel castings may be (1) annealed, (2) normalized, (3) normalized and tempered, (4) quenched and tempered, (5) nitrided, (6) carburized, (7) differentially quenched, (8) differentially heated, (9) spheroidized and (10) precipitation hardened. The heat treatment of steel castings is discussed on page 633 in this Handbook.

Welding. The repair of a casting by welding, the joining of one cast part to another, or the joining of a casting to a wrought steel shape, are operations commonly performed in the manufacture and assembly of steel castings. Welding progress in the steel foundry has kept pace with welding developments elsewhere. Qualified welders are employed and careful control is maintained over welding technique and procedures. The welding of cast steel presents the same problems as the welding of rolled steel of similar chemical composition (see page 371 in this Handbook).

Inspection. All steel castings are carefully inspected as to dimensions, conformity with pattern layout, tolerances, surface finish and soundness.

Many castings, depending on service requirements, are subjected to pressure tests, hardness tests, magnetic particle inspection or radiographic examination.

The steel is tested for tensile properties and chemical composition. In some instances, depending on requirements of specification, the steel is tested for notched-bar impact properties and hardenability characteristics, and is inspected for grain size and microstructure.

Centrifugal Casting of Steel. The term "centrifugal casting" is an all-embracing one, referring to any casting that has been rotated during solidification. There are three types of centrifugal steel casting: (1) true centrifugal casting, (2) semicentrifugal casting and (3) centrifuged or pressure casting.

In true centrifugal casting, the steel is poured into a mold that rotates around a horizontal or vertical spindle. The mold may be either a metal die or a sand-lined metal jacket. There are no gates or risers and yields approaching 100% may be obtained.

The molds for semicentrifugal casting may be either dies, sand molds or core assemblies, where the inner surfaces of the castings are formed not by centrifugal force alone but by cores. Gates of various types are employed to act as feed heads. Most molds are produced on the vertical spindle machine.

"Pressure casting" refers to the use of centrifugal action to generate a high pressure to force the molten steel into the mold. This method is used for asymmetrical castings which cannot be spun around their own axes or for castings too small to be spun in that manner. The mold is arranged so that the steel is poured into a gate at the center of rotation. In-gates distribute the steel to mold cavities arranged around the central down-gate.

Design of Steel Castings. Correct design of steel castings is of paramount importance, both for satisfaction in service and for economical production in the foundry.

The purchaser of steel castings is interested in the principles of casting design because of new demands and more exacting engineering requirements, involving either heavier loads or higher pressures. Many of these developments have resulted in a reduction or redistribution of metal in the castings. In some instances sections have been produced that are not only lighter in weight, but are actually stronger than those employed formerly.

Unsatisfactory design is responsible for many defective castings. Co-operation between the steel foundrymen and the purchaser of castings, particularly while the design is in the formative stage, will result in improvements.

Cast steel has certain characteristics that are inherent and must be considered as natural phenomena. The volumetric contraction that takes place when steel transforms from the liquid to the solid state is comparatively high. This means that considerable thought must be given to the casting design so that ■ further supply of liquid metal will compensate for the contraction. Also, steel, in common with other metals, possesses very low strength and ductility at temperatures just lower than the solidification temperature; hence, careful attention must be given to features of design in an effort to reduce stresses that may act upon the casting. Further, in comparison with other common metals, liquid steel has poor fluidity; therefore the designer should not insist on sections so thin as to cause losses from failure to run, or sections that would increase manufacturing costs greatly by impracticably high pouring temperatures.

Unsuitable casting design can cause several types of de-

fects in steel castings. The shape of the casting and drastic variations in section may result in hot tears following solidification and resulting from restricted contraction. Shrinkage cavities result from insufficient feed metal. These cavities are likely to be found in sections designed to be fed through smaller sections that solidify too quickly to be of adequate feeding value.

Rules for Steel Casting Design. The following rules are recommended for the design of steel castings:

1 An attempt should be made to provide uniform thickness, not less than ¼ in., for all sections in a casting.

2 Abrupt changes in sections are not desirable.

3 Sharp corners should be eliminated at adjoining sections.

4 When a design for a cast steel structure becomes very complicated or intricate, it should be divided into parts that can be cast separately and then assembled by welding.

5 In the design of sections that join in L or V shapes, all sharp corners at the junctions should be replaced by radii so that these sections become slightly smaller than those of the arms.

6 In the design of sections that join in an X, two of the arms should be offset considerably.

7 In the design of any joining sections, all sharp corners at the junctions should be replaced by radii. In T and X sections these radii should be ½ to 1 in., regardless of the thickness of the section.

Physical Properties. The physical properties of cast steel are similar to those of wrought steel and are listed for reference.

Elastic Constants. As determined at room temperature, the elastic constants of steel used for steel castings are little affected by composition or structure. The modulus of elasticity is about 30,000,000 psi, Poisson's ratio is 0.3, and the modulus of rigidity is 11,200,000 psi.

Changes in Volume. The changes in volume that take place in steel castings are affected to some extent by the variations in carbon and alloy contents. Average values for medium-carbon steels (about 0.30% C) based on percentage contraction of volume at atmospheric temperature are: liquid contraction, 1.6% per 100° C; solidifying contraction, 3.0%; solid contraction, 7.2%; total contraction from 1600 C, 11.8%..

Density. The density of cast steel is sensitive to changes in composition, structure, temperature and phase. The density decreases with increasing carbon, with quenching and with increasing temperature. The density of medium-carbon cast steel is in the range of 7.835 to 7.845 ■ per cu cm. Steel castings have a weight of 490 lb per cu ft or 0.283 lb per cu in.

Electrical Properties. The resistivity values for various annealed carbon steel castings of 0.07 to 0.20% C are 13 to 14 microhm-cm; for castings of 0.20 to 0.45% C, the resistivity values are 14 to 16 microhm-cm.

Magnetic Properties. Low-carbon dynamo cast steel has excellent magnetic properties and has supplanted other cast metals for use in housings and frames of installations for magnetic circuits. The magnetic properties of low-carbon cast steel are compared with other alloys in the table below.

Material	Coercive Force, oersteds	Residual Induction, gausses	Maximum Permeability	Induction for H = 150	Saturation Magnetization, gausses
Electrolytic iron	0.36	10,800	14,400	18,900	21,630
Low-carbon cast steel, annealed ...	0.37	11,000	14,800	19,100	21,420
Cast iron, annealed ...	4.60	5,350	600	11,000	16,800

Mechanical Properties. The outstanding mechanical properties of cast steel are strength, ductility and resistance to impact. Steel castings possess high rigidity and are capable of withstanding both elevated and low temperatures and high stresses. These properties, in various combinations, have resulted in the use of steel castings for a wide range of exacting engineering applications.

Tensile and Yield Strength. It is well known that if ferritic steels are compared at a given value of hardness or hardenability, the tensile strengths of cast, rolled, wrought, and welded metal are identical regardless of the alloy content; consequently, for purposes of design involving tensile and yield properties, the engineer can interchange rolled, wrought, cast and welded steel with full confidence.

Ductility. Similarly, if the ductility properties of steels are compared in relation to their hardness values, cast, wrought, and rolled steels and welds are almost identical in their properties. The longitudinal properties of the forged and rolled steels are slightly higher than those of cast steel or weld metal; however, the transverse properties are lower, by an amount that depends on the degree of working. Since most service conditions involve several directions of loading, the securing of uniform directional properties in cast steel is sometimes particularly advantageous.

Impact. The notched-bar impact test is often used as a measurement of the toughness of materials. Cast steels have excellent impact resistance at normal and low temperatures. Generally, the properties of wrought steels are listed in the direction of rolling, and show higher impact values than cast steels of similar composition; however, transverse impact values will be 50 to 70% of these values. Cast steels do not show directional properties. If the directional properties are averaged for wrought steels, the values obtained are comparable to the values obtained for cast steels of similar composition.

Specifications for Mechanical Properties. Since there are approximately 75 types of carbon and alloy cast steels, it does not seem advisable to present here the properties of any one or even of several cast steels, or to illustrate the effect of heat treatment on these properties. Some property values of heat treated alloy cast steels are given on page 634 in this Handbook. Most steel castings are purchased according to specifications for mechanical properties rather than according to ranges of chemical composition. These ranges of composition are used as the basis of purchase requirements when the purchaser is considering certain definite engineering properties, such as wear resistance, weldability, service at high temperature and resistance to corrosion.

An indication of the mechanical properties of cast steels can be obtained from the specification requirements for steel castings established by the American Society for Testing Materials. However, it should be pointed out that the values specified are minimum values used as rejection limits. The normal values expected of cast steel meeting these requirements are from 10 to 40% above the minimums specified. (*See* Table I.)

Table I. ASTM Requirements for Steel Castings, Mechanical Properties

Grade	Tensile Strength, min, psi	Yield Point, min, psi	Elongation in 2 in., min, per cent	Reduction of Area, min, per cent
ASTM A 27-46T				
60- 30	60,000	30,000	24	35
65- 35	65,000	35,000	24	35
70- 36	70,000	36,000	22	30
ASTM A 148-46T				
80- 40	80,000	40,000	18	30
80- 50	80,000	50,000	22	35
90- 60	90,000	60,000	20	40
105- 85	105,000	85,000	17	35
120-100	120,000	100,000	14	30
150-125	150,000	125,000	9	22
175-145	175,000	145,000	6	12

Hardenability. The hardenability of cast steels is influenced by composition and other variables in the same manner as the hardenability of wrought steels.

Endurance Properties. The ratio of the endurance limit to the tensile strength for cast steel varies from 0.42 to 0.50, depending somewhat on the composition and heat treatment of the steel.

Engineering Properties. *Resistance to Wear.* In wear testing, cast steels react similarly to rolled steels and give corresponding values, depending on composition, structure and hardness. Cast steels that have given excellent resistance to wear in service are carbon cast steels of approximately 0.50% C, and low-alloy cast steels of the chromium, chromium-molybdenum, nickel-chromium, chromium-vana-

dium and medium-manganese types, all of which contain more than 0.40% C.

Resistance to Corrosion. Cast steel and wrought steel of similar composition and heat treatment appear to be equally resistant to corrosion in the same environments. Small amounts of copper in cast steel increase the resistance of steel to atmospheric attack. High-alloy cast steels of chromium and chromium-nickel types are normally used for resistance to corrosion.

Resistance to Heat. Although not comparable to the high-alloy steels of the nickel-chromium type especially designed for heat resistance, the 4.0 to 6.5% Cr cast steels, particularly with additions of 0.75 to 1.25% W, or 0.40 to 0.70% Mo and 0.75 to 1.00% Ti, show good strength and considerable resistance to scaling at 1000 F and lower.

Machinability. The machinability of carbon and alloy cast steels is similar to that of wrought steels having equivalent strength, ductility and hardness, and similar microstructure. It is well known that the skin on a casting wears cutting tools rapidly. For this reason many manufacturers consider cast steel difficult to machine. However, once the surface skin is removed, the machining of a cast steel product is similar to the machining of a wrought steel product. In order to conserve the life of cutting tools, it is suggested that the first cut be a deep or "hogging" cut to remove the casting skin.

Weldability. The welding of steel castings presents the same problems as the welding of wrought steels.

Austenitic Manganese Steel

By Howard S. Avery* and M. J. Day*

AUSTENITIC MANGANESE STEEL, also called "Hadfield's manganese steel" after its inventor, is an extremely tough nonmagnetic alloy in which the usual hardening transformation has been suppressed by a combination of high manganese content and rapid cooling from a high temperature. This steel is characterized by high strength, high ductility and excellent resistance to wear. In the form of castings or of rolled shapes, it serves many industrial requirements economically and has built up an enviable record as the outstanding material for resisting severe service that combines abrasion and heavy impact.

Manufacture. Present production is confined chiefly to open hearth and electric furnaces, though other methods are possible. Manganese, as either high-manganese scrap, ferromanganese or electrolytic manganese, may be added in the charge or melted separately and mixed before pouring. Basic-lined furnaces are almost necessary if much of the manganese is charged, because manganese oxides dissolve and weaken refractories that contain much silica or alumina. The basic electric-arc furnace is currently preferred for melting in foundries, while the basic open hearth or basic electric furnace, plus a ladle addition of ferromanganese melted in an electric furnace, is favored in melting this steel for the production of ingots that are to be rolled.

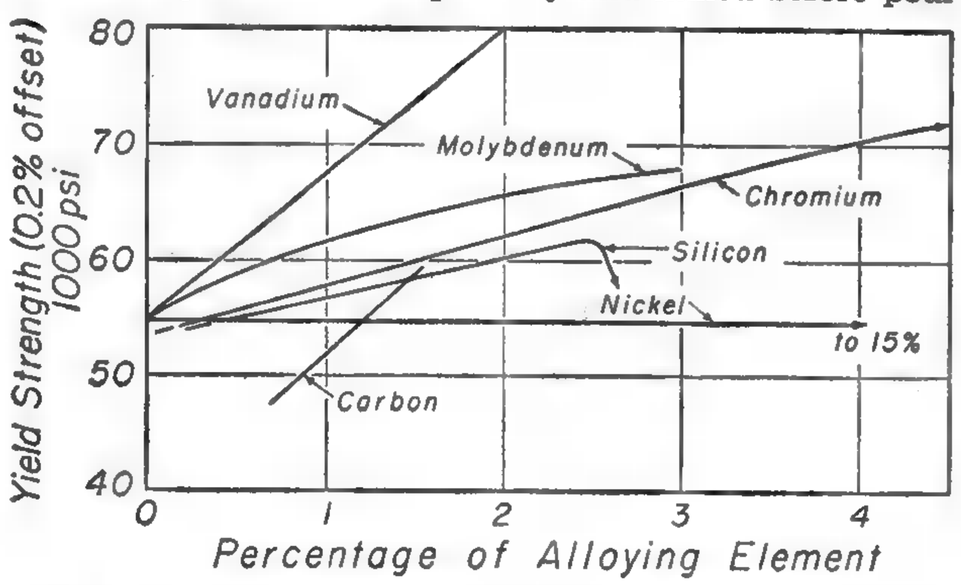

Fig. 1 Effect of alloying elements on the yield strength of toughened austenitic manganese steel (Previously unpublished results, American Brake Shoe Company)

The molten metal freely evolves a reddish brown oxide smoke, which interferes with optical pyrometry. These oxides may also attack mold refractories. In cement-sand molds, manganese has been detected almost half an inch away from the interface between mold and metal.

The alloy is available as castings weighing from a few ounces to several tons, and as sheet, plate and bar stock, wire, rails and the like.

Composition. In the nominal composition, 1.2% C and 12 to 13% Mn are essential elements. Commercial alloys will usually vary within the range 1.0 to 1.4% C and 10 to 14% Mn, as established by ASTM Designation A 128-33 and some other specifications. There is a tendency to operate close to the midpoint of the carbon range and with 12 to 13% Mn, since the lower limit of the composition range is associated with somewhat inferior tensile properties, and the upper extreme provides no economic advantage.

Carbon has a slight but distinct effect on yield strength; reduction in carbon content causes reduction in yield strength (Fig. 1). The effect of carbon content on other tensile properties is overshadowed by variables such as grain size, but there is a suggestive indication of an optimum carbon content around 1.15%. The higher carbon contents may cause trouble in heat treatment or in the foundry. Low carbon content is helpful in avoiding the embrittling effect of carbide precipitation during cooling below the limit of solubility. For this reason, low carbon content is generally employed in alloys to be used for welding-rod and for other modifications where the normal heat treatment, involving a water quench, is impracticable.

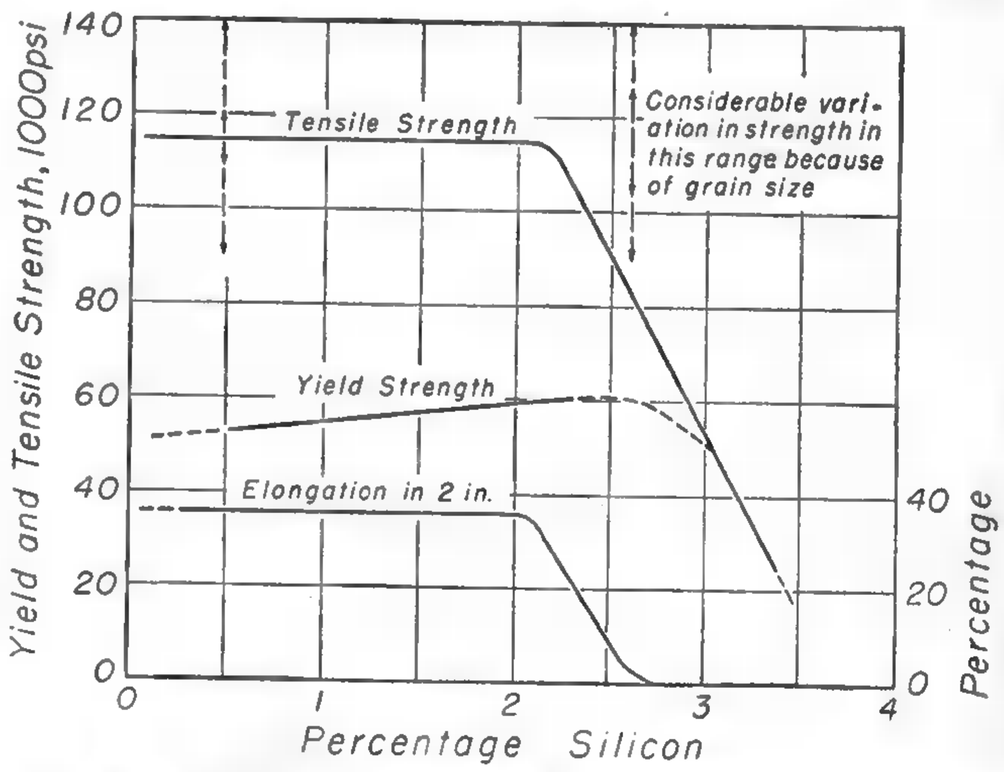

Fig. 2 Effect of silicon content on austenitic manganese steel, water quenched from above A_{cm}, 1.08 to 1.17% C, 11% Mn minimum (Previously unpublished results, American Brake Shoe Company)

* Research Metallurgist, American Brake Shoe Company, Mahwah, N. J.
* Manager, Alloy Bureau, Carnegie-Illinois Steel Corporation, Chicago

Manganese contributes a vital austenite-stabilizing effect, operating to delay transformation rather than to eliminate it. Thus, with a simple steel that contains 1.1% Mn, the beginning of isothermal transformation at 700 F may occur in about 15 sec, while with 13% Mn, about two days may be required. Below 500 F, phase change and carbide precipitation are so sluggish that for practical purposes they may be neglected, in the absence of deformation, if the manganese content exceeds 10%.

Manganese, within the limits of 10 to 14%, has almost no effect on yield strength, but it does benefit tensile strength and ductility. The difference between 10 and 13% Mn can be demonstrated, though it requires careful control of other variables to make it apparent. Below 10% Mn the tensile properties decline rapidly to perhaps half their normal level at about 8% Mn.

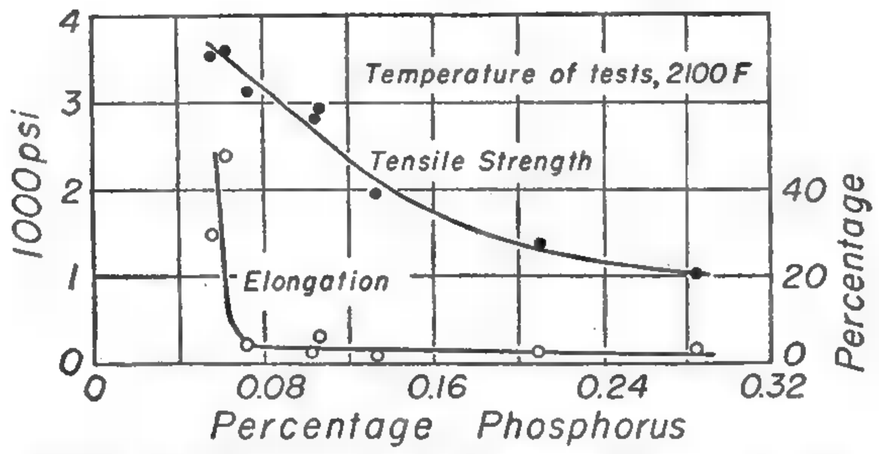

Fig. 3 Effect of phosphorus content on tensile strength and elongation of austenitic manganese steel at 2100 F (Reference 1 and previously unpublished results, American Brake Shoe Company)

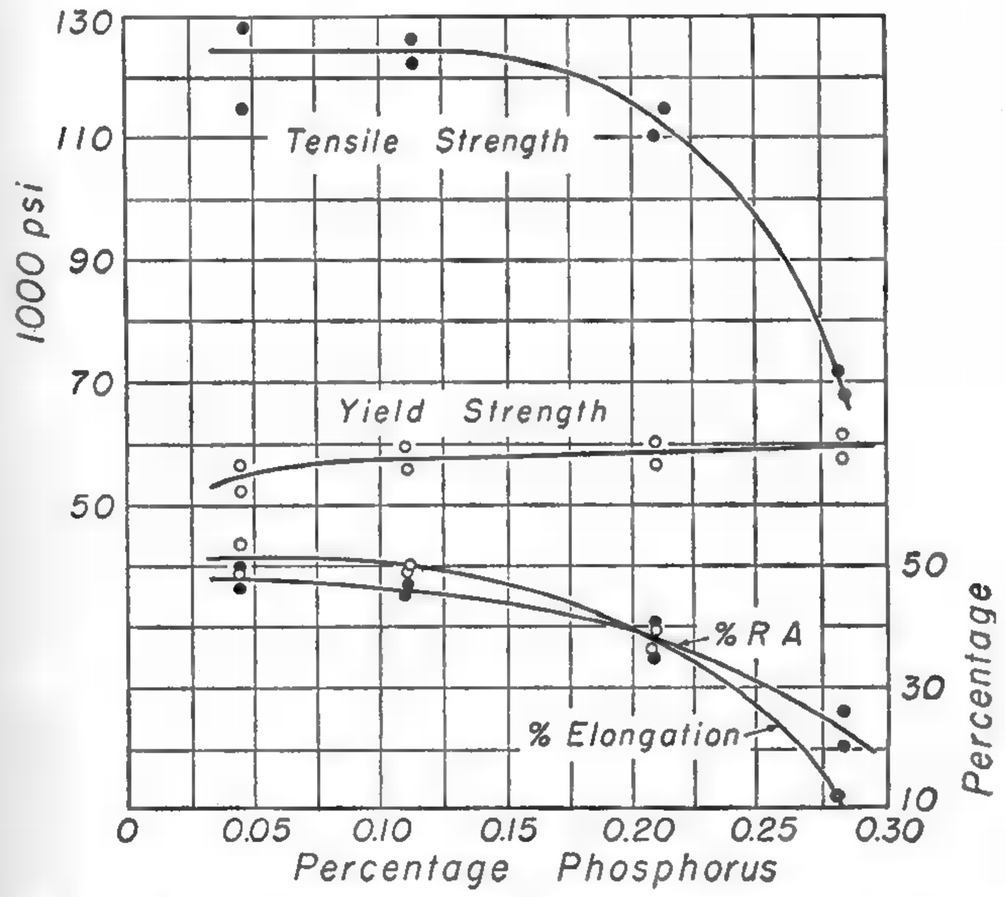

Fig. 4 Effect of phosphorus content on mechanical properties of austenitic manganese steel at room temperature (Previously unpublished results, American Brake Shoe Company)

For critical requirements 11% Mn is desirable as a minimum, though the improvement over 10% is slight. The maximum is rather arbitrary and probably depends more on the cost of the alloy than on metallurgical results, since acceptable properties may be produced up to at least 20% Mn.

Silicon is included chiefly for steelmaking purposes. Although it exceeds 1% infrequently, it may be employed up to about 2% to produce a moderate increase in yield strength and resistance to plastic flow under repeated impact. At about 2.2% a sharp reduction in strength and ductility begins; the range above 2.3% Si is virtually worthless for normal applications (Fig. 2).

Sulfur is seldom a factor in 13% Mn steel, since the scavenging effect of manganese, for which it is customarily added in simple steels, operates to eliminate it by slagging or fixing it in the form of innocuous rounded inclusions of manganese sulfide. Elongation of these inclusions in wrought steels may contribute to directional properties; in cast steel they are considered harmless.

Phosphorus is generally reputed to be harmless below 0.10%. However, this opinion is based on mechanical properties at room temperature. In amounts above 0.06%, phosphorus decreases the strength and ductility at elevated temperature, as determined experimentally by tension tests at 2100 F. This tendency is related to the formation of hot cracks in castings,[1, 2] contributing to the production problems of the foundry. Unless cracked castings escape inspection and go into service, a phosphorus content up to 0.10% is considered acceptable to the user (Fig. 3 and 4).

Other elements, such as nickel, molybdenum, chromium, copper and vanadium, may be added to the standard manganese steel to modify the usual properties.

Heat Treatment. The as-cast or as-rolled structure of manganese steel contains carbides and other transformation products that produce marked brittleness by their continuity. In small test castings, the tensile strength as cast will approximate 60,000 to 70,000 psi, with elongation values down to less than 1%. The standard toughening heat treatment involves austenitizing and water quenching, producing the normal mechanical properties.

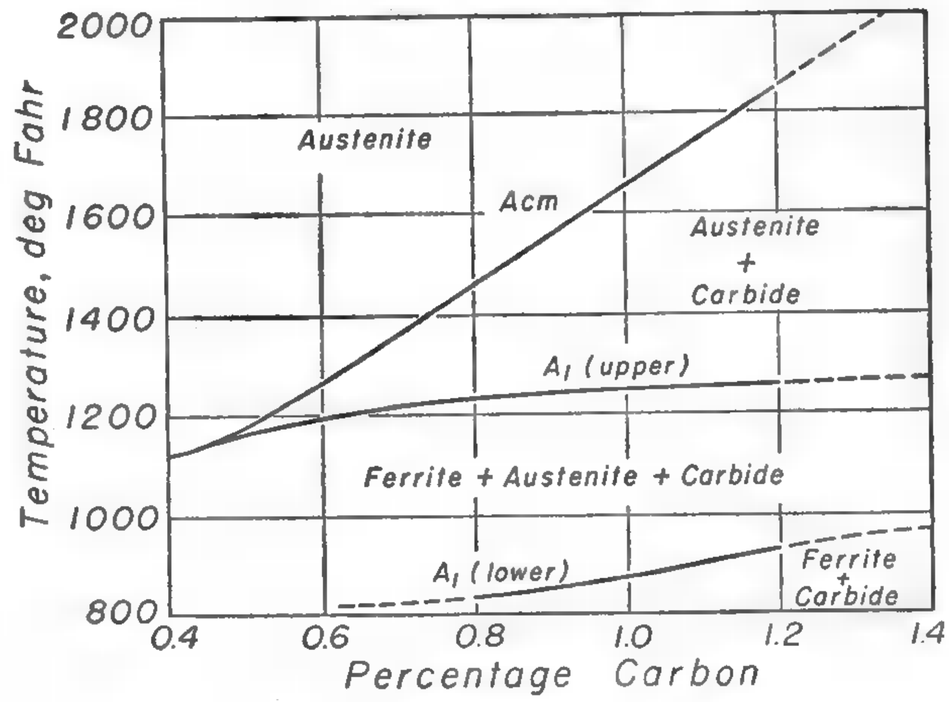

Fig. 5 Effect of heat treatment on 12.5% Mn steel (Modified from Bain, Davenport and Waring[3])

The austenitizing temperature should be high enough to ensure complete solution of carbon. Figure 5 may be used as a guide. The time at temperature is not considered critical, since above 1850 F equilibrium is probably established within 20 to 30 min.[3] An allowance is required, of course, for lag in heat transfer in heavy sections.

The speed of quenching is important, though difficult to accelerate beyond the rate fixed by heat absorption from a surface cooled by agitated water. This results in lower mechanical properties at the center of heavy sections. The effect can be judged quantitatively from the data in Fig. 6 and Table I.

Residual stresses from quenching, coupled with the lower properties of heavy sections, have operated to establish a practical maximum of 5 or 6 in. for the thickness of commercial castings. Stresses that develop during cooling in the mold operate on a much more brittle structure and are likely to produce cracks in heavy castings before heat treatment.

The relatively high austenitizing temperature, in combination with the high carbon content, causes marked surface decarburization and some loss of manganese. The skin may thus be partially martensitic at times, and is usually weaker than the underlying metal. Tensile deformation in service sometimes produces numerous cracks in this inferior skin, which terminate where the tough austenite of normal composition is reached. Service performance is not seriously affected unless critical fatigue conditions or very light sections are involved; in such instances premature failure may result. Under certain conditions, sections such as wrought sheets may be protected

Table I. Effect of Cooling Rate on the Mechanical Properties of Austenitic Manganese Steel[a]

See Fig. 6 for cooling curves of specimens tested

Plate Thickness Corresponding to Cooling Rate Observed, inches	Grain Size	Tensile Strength,[b] psi	Percentage Elongation[b] in 1 in.	Percentage Reduction[b] of Area	Izod V-Notch Test, foot-pounds
2	Coarse	91,700	37.0	35.7	101
2	Fine	118,600	45.5	37.4	99
3¼	Coarse	89,600	25.0	34.5	93
3¼	Fine	111,400	36.0	33.0	85
5½	Coarse	78,800	22.5	25.6	85
5½	Fine	102,000	32.0	28.3	74
7½	Coarse	65,700	18.0	25.1	57
7½	Fine	104,600	33.5	29.2	49

with covers, metal envelopes, or organic and inorganic coatings, thereby reducing the effect of decarburizing atmospheres used in heat treatment.

Reheating. The reheating of manganese steel parts in the field is much more serious than for ordinary structural steels. Instead of the usual softening and increase in ductility, manganese steel becomes embrittled if heated enough to induce partial transformation of the metastable austenite. As a general rule, manganese steel should never be heated above 500 F, either by accident or by plan, unless the standard toughening treatment is to be applied.

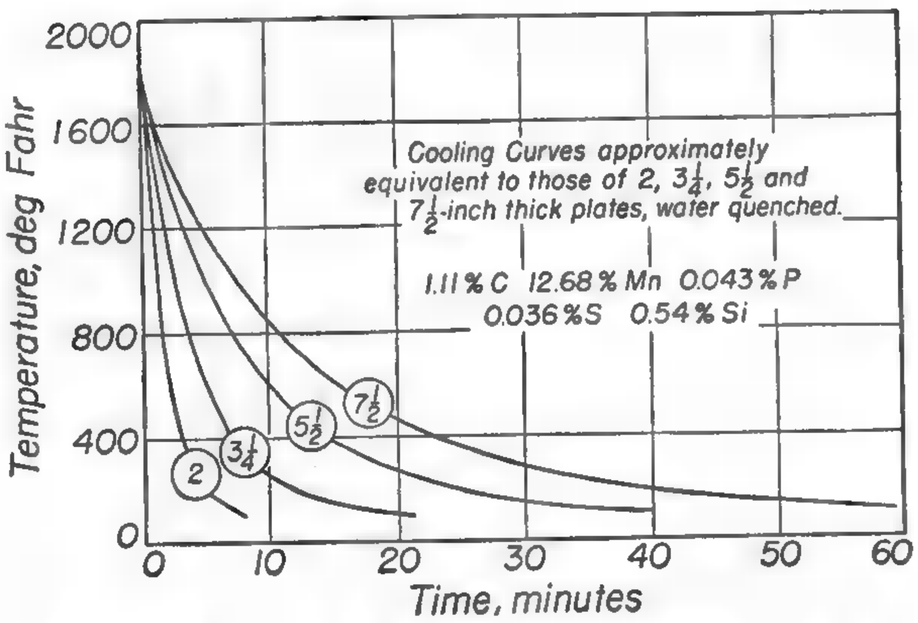

Fig. 6 Cooling curves for water-quenched specimens of which the mechanical properties are presented in Table I.

Both time and temperature are involved; lower temperatures require longer for the impairment to develop. Composition also has an effect. Figure 7 suggests the magnitude of the embrittlement. When large castings are mounted with a backing of molten zinc or lead, temperature should be controlled adequately. However, the most important complication from reheating arises during welding.

Mechanical Properties. The range of tensile properties produced in other alloy steels by heat treatment is developed approximately in manganese steel by work hardening. Thus, yielding signifies the beginning of work hardening and elongation is associated with its progress. There is little or no marked reduction of area by necking, because work hardening is greatest at the point of greatest deformation; the increased strength from working stops

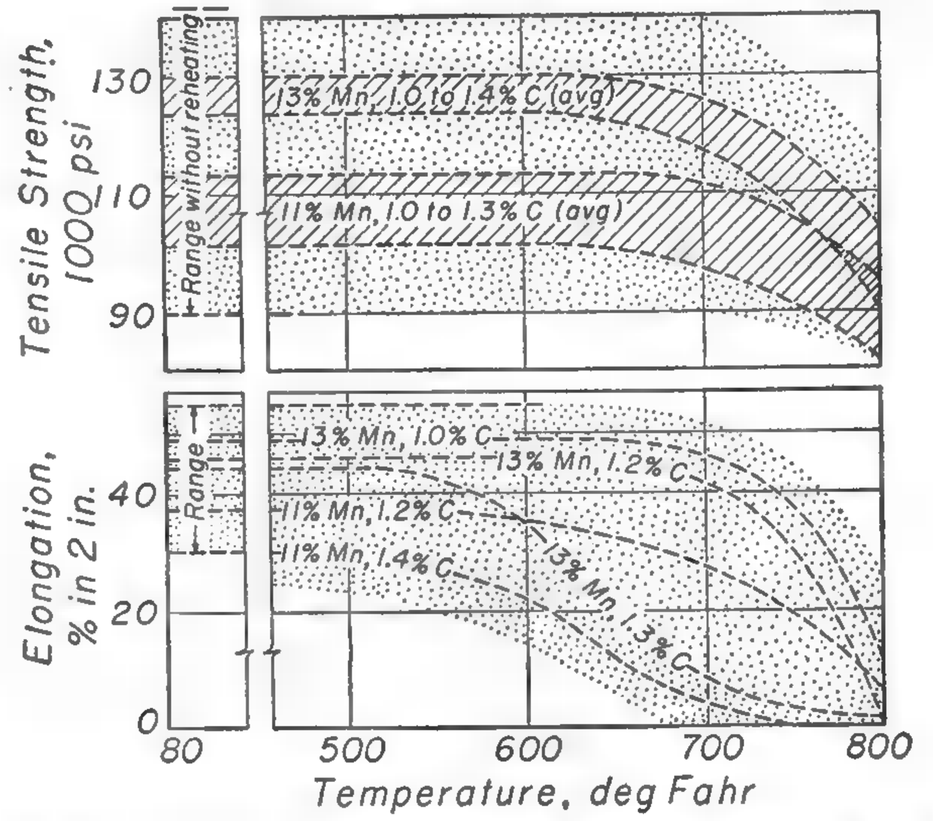

Fig. 7 Embrittlement from reheating austenitic manganese steel. Cast bars (1 in. in diam) reheated 48 hr at temperature indicated, after toughening. [Reference 4(o)]

elongation, and deformation then occurs elsewhere, until the hardening and reduction of area are substantially equalized throughout the specimen.

Representative tensile properties are listed in Table II. The true tensile characteristics of manganese steel are revealed better by the stress-strain curves in Fig. 8, however, which permit a comparison with a tough ferritic steel of about the same nominal tensile strength. The low range of yield strength is significant, and may prevent selection of this alloy where slight or moderate deformation is undesirable, unless the usefulness of the parts in question can be restored by grinding. However, if deformation is immaterial, the low yield values may be considered temporary; that is, deformation will produce a new yield strength, corresponding to the intersection of stress and strain co-ordinates in Fig. 8.

(d) Swanger, ASTM-ASME Symposium on Effect of Temperature on Metals, 1931, p 732

Tensile strength and ductility are affected somewhat by composition, as outlined above, by heat treatment, and considerably by grain size; the finer-grain specimens exhibit greater strength and elongation. The difference may be as much as 30%. It should be noted that the values sometimes quoted for cast bars may reflect the presence of internal defects, such as shrinkage cavities. The data in this article refer to sound specimens. Aside from the minor influence of directional properties, the chief differences between cast and wrought manganese steel are the result of differences in grain size.

Hardness is about 200 Bhn after toughening, but this value has little significance for estimating machinability or resistance to wear. The hardness will increase so rapidly from deformation that austenitic manganese steel must be evaluated on a distinctive basis.

Notched-bar impact test values are exceptionally high (Table V). Charpy test specimens are sometimes bent and dragged through the machine rather than fractured. Like tensile properties, impact resistance is influenced by grain size and heat treatment. The alloy remains tough at subzero temperatures. The austenitic alloys are apparently immune to hydrogen embrittlement, though with low carbon (0.02% ±) and high manganese contents this embrittlement has been produced.[5]

Fig. 8 Comparison of stress-strain characteristics of Hadfield austenitic manganese steel and high-strength heat treated alloy steel (Reference 4c)

NOTE. The true stress indicates that the stress value at every point on the stress-strain curve has been corrected for reduction of area.

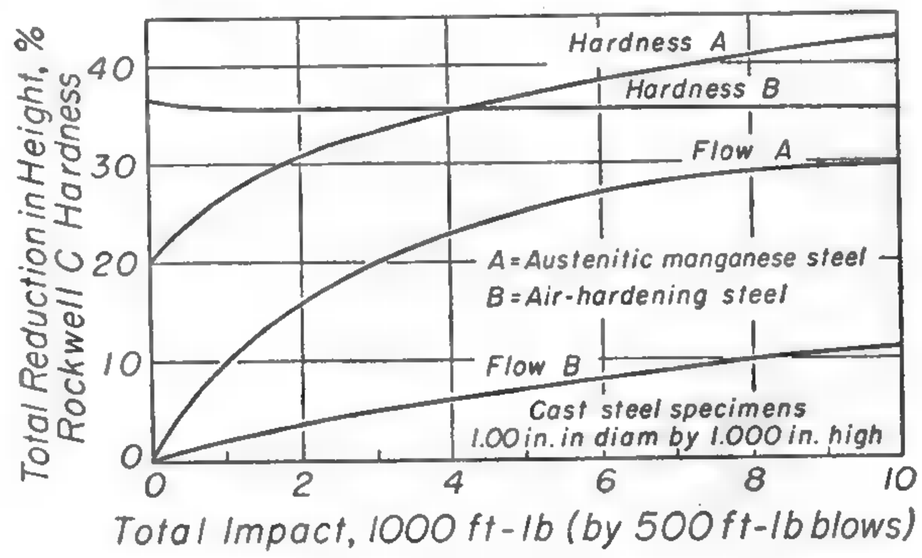
Resistance to crack propagation is high, and is associated with very sluggish progressive failures, permitting periodic observation of fatigue cracks, for example, and removal from service before complete failure occurs. This is a distinct advantage in railway trackwork.

Work Hardening. Manganese steel exceeds even the austenitic stainless steels in ability to work harden, and probably has no equal in this respect. The maximum hardness attainable in practice is about 550 Bhn. Hardness on the wearing surface of a railway frog after service has ranged from 495 to 535 Bhn. Niconoff[6,7] reports a maximum hardness of Rockwell C 49 to 52 after repeated impact on small specimens, while Goss[8] attained Rockwell C 58 after 80% reduction in cold rolling. Niconoff also deduced that a critical unit stress of 35,000 ft-lb per sq in. will be required for maximum hardening.[6] Hardening is produced by *deformation,* and any attempt to harden by working should make appropriate provision for this flow.

Work hardening is usually induced by impact, as from hammer blows. Light blows, even if they are of high velocity, will cause shallow deformation with superficial hardening, though the surface hardness may be high. Heavy impact produces deeper hardening, usually with lower maximum values. The course of flow under impact and the associated increase in hardness are illustrated in Fig. 9. Work hardening on bearing surfaces has been proposed as a substitute for carburized and hardened ferritic steels, to avoid warpage.[9]

Much energy is absorbed by work hardening. Thus sheet manganese steel is an efficient light armor for relatively slow-moving projectiles. If the velocity is high enough, however, to permit the projectile to shear through without some deformation, the protection becomes mediocre, and steels of higher yield strength appear preferable. (This is an effect that is not confined to manganese steel.) In such applications it has been found expedient to preharden by deformation, as in the deep drawing of Army helmets and cold forming of strip for use in body armor. The requirements of these operations necessitate careful control of the martensitic skin formed during the toughening treatment, since tensile deformation may produce cracks that render these thin products unsuitable for the intended use. The skin may not be sufficient to result in a noticeably defective product during manufacture, but may contain minute cracks that lower the subsequent resistance to further deformation. Solution and distribution of carbide is important in such applications. However, most of the impact blows encountered throughout industry are of low velocity, and this material is suitable; it is the preferred choice where high shock resistance, toughness, and absorption of energy are required.

Flow Under Impact. The low yield strength of manganese steel is sometimes a disadvantage. Plastic deformation from impact, as in railway frogs and crossings, increases the yield strength to levels more resistant to flow, but the associated change in dimensions is undesirable. In trackwork, low spots develop at critically pounded locations, resulting in a bumpy roadway and eventually requiring rebuilding with weld deposits. Flow resistance and yield strength are intimately related, and a number of methods for increasing them have been developed.



Steel	Composition, percentage C	Mn	Si	Ni	Cr	Mo	Heat Treatment Deg Fahr	Cooling

Fig. 9 Plastic flow and work hardening characteristics of austenitic manganese steel under repeated impact (with an air-hardening alloy steel for comparison) (Previously unpublished results, American Brake Shoe Company)

Additions of alloying elements and preservice hardening may be employed; the latter is more successful. Additions of vanadium, chromium, silicon and molybdenum are effective; however, vanadium and chromium reduce ductility at the same time (Fig. 1). The relative effects of adding an alloying element in comparison with preharden-ing are shown in Fig. 10. In some applications a dimensional allowance for flow may be required.

Fatigue Strength. The fatigue limit has been reported as 39,000 psi.[10] More recent experiments have provided the data of Table III.

Wear Resistance. Although 12% Mn steel is unquestionably the best metal for resisting certain types of wear,

it is not universally applicable. When this steel is being considered for abrasive service, the determining factor in selection should be toughness, not resistance to abrasion. If impact and shock are absent, as in a pipe carrying sand-laden water, a martensitic cast iron is a much better choice. If light or moderate impact is involved, the specification of a hardened steel may be justified, but careful judgment is necessary for sacrificing toughness in favor of abrasion resistance. If heavy impact is expected or a large safety factor is required, Hadfield's steel is the logical choice and the large annual tonnage goes chiefly into such applications.

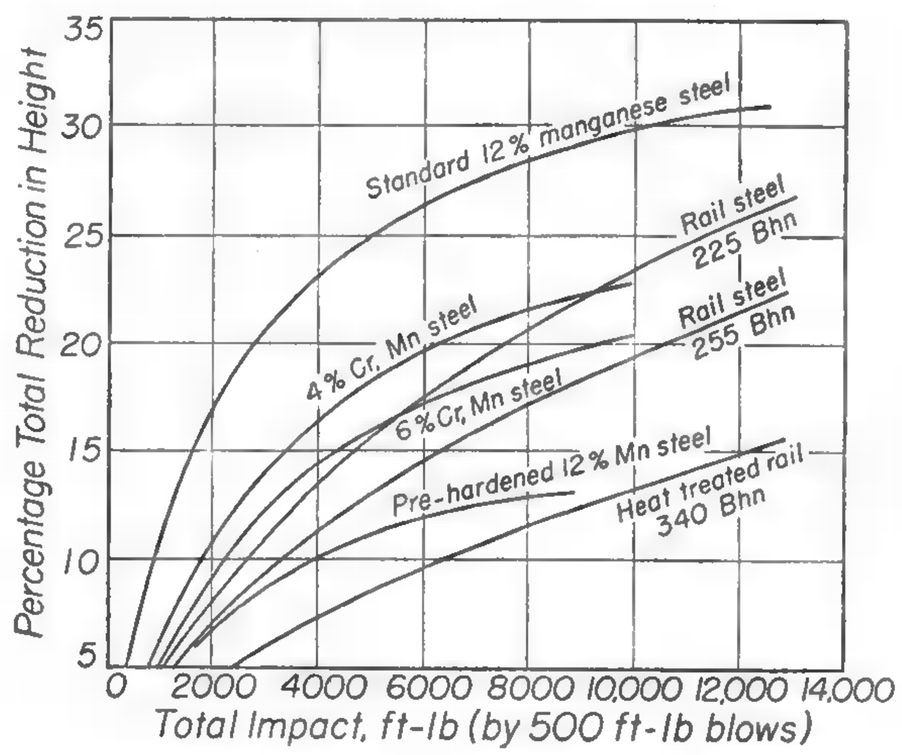

Fig. 10 Flow in austenitic manganese steel under repeated impact; specimens 1 in. in diam and 1 in. high (Previously unpublished results, American Brake Shoe Company)

It is sometimes believed that unless it has been work hardened, manganese steel has poor resistance against wear. This is not a valid generalization. The misunderstanding has probably developed because, where much impact and attendant work hardening are present, 12% Mn steel is so clearly superior to other metals that its performance is attributed to the surface hardening. However, controlled abrasion tests (as described on page 218 of this Handbook) have indicated that there are circumstances where the abrasion resistance of austenitic manganese steel is modified little by work hardening, and others where it will outwear some much harder pearlitic white cast irons in the absence of work hardening.

The relative resistance to abrasion of toughened manganese steel that has not been work hardened is shown in the article entitled "Wear of Metals" in this Handbook. The range of abrasion factors from 0.75 to 0.85 (in comparison with SAE 1020 steel as 1.00) has been established by many tests. If work hardened specimens are tested similarly, the values fall in the lower part of this range, but do not exhibit marked superiority. Some weld deposits of low-carbon manganese steel may give higher factors, though properly balanced weld deposits of nickel-manganese steel will fall within the expected range.

Weiss[11] has employed a similar test to rank many steels. Conversion of his test data to the "abrasion factor" form gives 0.42 for work hardened manganese steel in comparison with SAE 1010 steel as 1.00.

Laboratory wear tests are expected to be better controlled than field tests and to be reported more objectively; however, they seldom can include the full range of variables encountered in service. A summary of reports from practical experience is included below, as a guide to the better understanding of the serviceability of manganese steel. However, it should be recognized that the data are less precise quantitatively than those from rigorously controlled laboratory techniques.

In contrast with the uncomplicated abrasion involved above, a different type of wear is represented by Hall's[12] jaw-crusher tests. The loss in weight of the moving jaw in a machine that crushes about 800 lb of trap rock per day, was used as a criterion of wear resistance, yielding the data in Table IV.

Somewhat similar service is typified by stamp-mill shoes. With operating conditions that include 1550 ft-lb blows at the rate of 100 per min for a total of 21,600,000 times, manganese steel outwore by 25% the next best of 11 cast alloy steels.[4c]

In these applications that involve heavy blows, the very hard and abrasion-resistant, martensitic cast irons may exhibit a slower rate of wear, but early fracture usually terminates their life with a considerable portion of the original cross section unworn, while manganese steel may wear almost to paper thinness without fracture. Pearlitic white cast iron, which is about 400 to 450 Bhn is equally brittle but less resistant to wear. Comparative tests on log washer lugs indicated that the manganese steel was about 25% worn out with no breakage, while white iron lugs in the same period wore to the point of uselessness with 14% breakage.[4c] In clay-crusher rolls, white or chilled iron was outworn from two to three times.[4d] In grinding-barrel liners, cast irons had a life of two to three years as compared with ten years for manganese steel.[4c] Part of this superiority over white cast iron is attributed to greater freedom from breakage and spalling, but some superiority probably results from better intrinsic wear resistance.

Manganese steel chain, with endless links cast in interlocking molds, also provides resistance to wear in other circumstances. Three to nine times the life of heat treated steel chain has been observed.[4b,4c] The alloy is valuable in conveyers as well as in dragline chain subject to abrasion and carrying heavy loads.

Manganese steel is not adequately resistant to wear from an airborne stream of abrasive particles, as in a sandblast; consequently there is no apparent advantage in selecting manganese steel for such service.

In metal-to-metal contact, work hardening is a distinct advantage, decreasing the coefficient of friction and conferring resistance to galling if temperatures are not excessive. Compressive loads, rather than impact, provide the deformation required, and operate to produce a smooth hard surface that has good resistance to wear but does not abrade the contacting part. Sheaves, rails and castings for railway trackwork are common applications of this type. The alloy has also been used successfully in some water-lubricated bearings.

Field tests that involve intermittent metal-to-metal contact provide evidence that manganese steel can render distinctive service in such applications. Locomotive chafing

Table IV. Summary of Wear In Jaw-Crusher Service[12]

Material	Wear of Jaw Surface[a] Fixed Jaws	Moving Jaws

(a) Grams per square inch per 1000 lb of stone crushed

irons and plates of manganese steel gave an average mileage of 447,000 versus 84,000 miles for carbon steel parts.[4f] Wheels on a 6-ton gas locomotive were reported to show no appreciable wear after three years, while chilled wheel flanges were about one-third worn through in eight months and also caused more wear on the rails.[4d] A steel mill reports double life from manganese steel crane wheels, with freedom from spalling and from the diametral wear that characterizes carbon steel wheels.[4g] Blooming-mill-housing wearing-plates were in good condition after 16 years, while carbon steel plates required replacement every 2 years.[4g] Wearing-plates on ore-bridge haulage-drums were reported as good as new after 5½ years of service where ordinary cast steel wore about 3 years.[4g] Manganese steel sheave wheels are expected to last about four times as long as cast carbon steel and do not groove and cause excessive rope wear as do wheels of the type that does not work harden.[4c, 4h]

The properties of manganese steel at elevated temperature are inferior to those of Fe-Cr-Ni austenites. This, coupled with the tendency toward embrittlement, does not favor applications where frictional heat causes temperatures above 500 F (Fig. 6).

Since corrosion is a form of wear, it should be considered, because manganese steel is not corrosion-resistant. This type of steel rusts readily and where corrosion and abrasion are combined, as they frequently are in mining and manufacturing environments, the metal may deteriorate or be dissolved at an uneconomical rate.

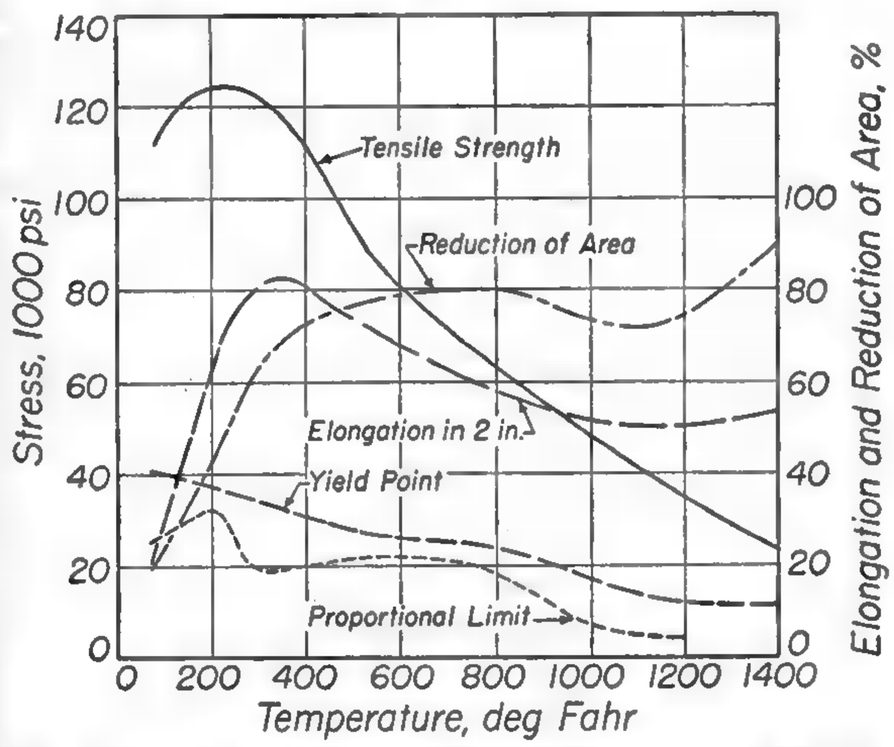

Fig. 11 Results of short-time tests of mechanical properties at elevated temperatures (Reference 13) Composition: 0.47% C, 14.77% Mn, 0.41% Si, 0.040% P, 0.004% ■

Effect of Temperature. The embrittlement produced by heating above 500 F is an argument against operation above this limit. Kanter [13] has reported data obtained from tension tests at elevated temperature on a 0.47% C, 14.8% Mn steel (Fig. 11). These data suggest that austenitic manganese steel has optimum properties between 200 and 400 F. It might be assumed that the nickel-manganese type, as used for welding-rod, would have good high-temperature strength because of its austenitic structure and the decreased tendency to transform. Gillett[14] has demonstrated that the creep rates are relatively high in comparison with the Fe-Cr-Ni austenitic alloys (Fig. 12). The creep rate of 0.0001% per hr at 800 to 950 F and at 2190 psi, is comparable with that of a balanced commercial 26% Cr, 12% Ni heat-resistant alloy at 1800 F.

Like most austenitic structures, manganese steel remains tough at low temperature. At minus 100 F, it retains from 50 to 85% of its room-temperature impact resistance (Table V). There is some evidence that this steel is considerably more brittle at the boiling point of liquid air (minus 300 F) but at all atmospheric temperatures, even in arctic climates, it has outstanding toughness. This provides a valuable safety factor in comparison with ferritic steels, when used in railway trackwork and mining equipment that must serve at subzero temperatures.

Thermal Expansion. The characteristics of expansion are similar to those of other austenitic materials. The expected change in length during heating is about 1½ times that of ferritic steels. A coefficient of linear thermal expansion of 0.000010 in. per in. per °F or 0.000018 in. per in. per °C is generally suitable at room temperature.

Magnetic Properties. The untransformed austenite of 13% Mn steel is virtually nonmagnetic with a permeability of about 1.03 or less (H = 24).[15] This permits use of the material where a strong, tough nonmagnetic metal is required, as in magnet cover plates, traveling crane collector shoes, generator and motor stator core parts, liner plates for storage bins holding materials that are handled by lifting-magnets, magnetic separator parts, instrument-testing devices, and parts in the magnetic field of electric furnaces.

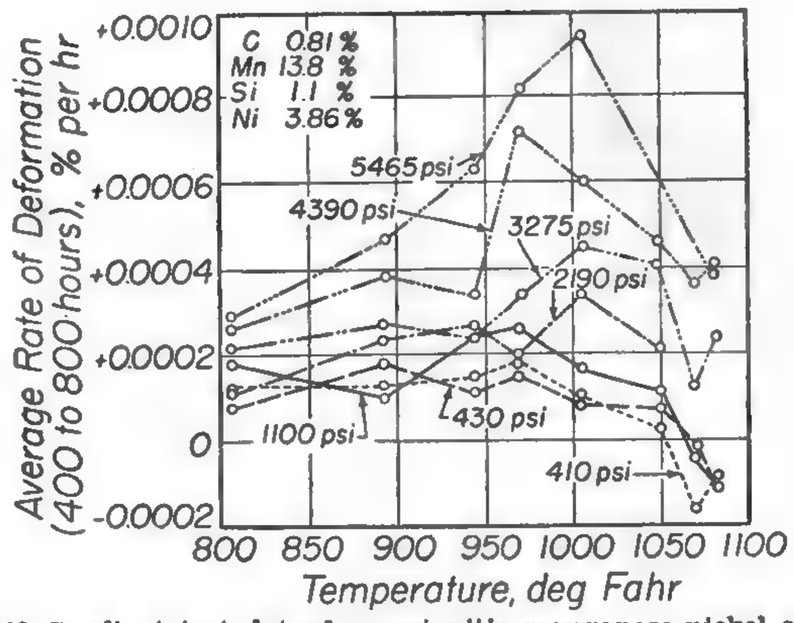

Fig. 12 Gradient test data for austenitic manganese-nickel steel in the form of rods ⅛ in. in diam. The test was carried out in a nitrogen atmosphere to avoid oxidation. (Reference 14)

The changes that occur in composition of the surface during heat treatment, may produce a magnetic skin. Permeability values of 1.3 ± have been obtained on specimens that have this martensitic surface layer. Frequently this layer does no harm, but if necessary it may be removed by grinding or prevented by suitable (although often expensive) measures during heat treatment.

Cast or wrought manganese steel is probably the most economical strong material for nonmagnetic parts if machining is not required. The cost of fabrication and a maximum operating temperature of 500 F should be considered decisive in its selection.

Lack of magnetic attraction is a disadvantage in handling systems that depend on magnetic separators to remove tramp iron ahead of crushers, grinders, or other machinery. To prevent passage by the separator and subsequent damage to the machine, it is advisable to cast soft steel inserts in parts of manganese steel that may be lost from working equipment and carried into the material being processed. The insert is designed to provide enough magnetism for removal by the separator.

Metallography. With its behavior of toughening after a water quench and embrittling after a tempering heat treatment, manganese steel appears as a paradox in contrast with conventional steels. However, an understanding of its sluggish transformation tendencies and of their dependence on temperature, will make apparent the close relationship of this steel with others. Above A_{cm} (Fig. 5) the steel becomes completely austenitic. The austenite is

not homogeneous in cast material, because carbon gradients result from the dendritic pattern of solidification. Diffusion during long holding at high temperatures will result in homogenization, accompanied by some improvement of mechanical properties. However, not enough change occurs to make this an addition to commercial practice.

Quenching, as with other steels, tends to suppress austenite transformation, with the difference that the critical cooling velocity is quite low below Ar′. (Grain boundary carbide precipitation between A_{cm} and Ar′ is the primary cause of impaired properties associated with slow cooling.) Isothermal transformation between 500 F and the upper A_1 temperature will develop acicular or pearlite structures, which appear slowly and require very long times for attainment of equilibrium. As with mixed structures in other steels, the mechanical properties of partially transformed austenite are poor—particularly when carbides or other brittle constituents form in large flat plates parallel to crystallographic planes. The mechanical properties are low also when pearlite, which seems to nucleate most readily at grain boundaries, develops in sufficient quantity to form an envelope around each grain. These structures account for the low ductility and reduced strength of austenitic manganese steel after reheating.

Grain refinement, which is suggested as desirable by the difference in properties of fine-grained and coarse-grained specimens, is possible but not feasible. Austenitization, after considerable transformation at subcritical temperature, will produce a fine grain size, but the long time required for producing sufficient transformation usually makes such treatment impractical. (*See* U. S. Patent 1,975,746.)

As the manganese content is lowered, there is an increase in the M_s temperature of initial martensite formation during cooling. M_s reaches room temperature at about 9.2% Mn with 0.5% C; 6.2% Mn with 0.8% C; and 4.6% Mn with 1.0% C. With manganese above 10%, M_s is below 32 F if the carbon content is 0.5% or more, while with the usual 1.10 to 1.20% C, M_s is probably below minus 330 F.[17] Thus, air hardening is possible only when the manganese content is less than 9%[18] and usually less than 7%. The constituents that are present after air cooling or after water quenching are given in the structural diagrams that accompany the article "Manganese in Steel" (page 465 of this Handbook). These represent less stable conditions than are shown in the phase diagrams for the C-Fe-Mn system given in the CONSTITUTION OF ALLOYS section.

Krivobok[15] and Hall[16] have provided excellent examples of the structures that may be encountered.

Preparation of specimens for critical microscopic examination is difficult. Great care is required to avoid cold work and disturbed surface layers. Cold worked scratches from early stages may be flowed over and concealed during fine polishing, only to become pronounced after etching. Similar flow may obscure grain boundaries whose character is an important criterion of the quality of heat treatment. Spurious structures may also result from tarnishing and corrosion caused by the atmosphere.

Nital etching, which reveals structure well, leaves a disturbing dark deposit. An etching cycle that removes this and gives generally satisfactory results is as follows:

> Etch 15 sec in 3% nital, rinse in ethyl alcohol, etch 15 sec in 10% HCl in alcohol, rinse 15 sec in ethyl alcohol. This is usually repeated three times, followed by 15 sec in 2% NH_4OH in alcohol, and rinsing in ethyl alcohol. The polished and etched face must be protected carefully from corrosion, particularly in humid atmospheres.

Transformation of austenite to martensite is apparently produced only by deformation, which results in the characteristic appearance of slip lines. The magnetic nature of these lines can be demonstrated by a special metallographic technique.[20] Transformation may contribute to work hardening; however the mechanism is not clear.

Low-Manganese Steels. As the manganese content is reduced below 10%, transformation occurs at higher temperatures, tensile properties decrease and it becomes increasingly difficult to retain the wholly austenitic structure by quenching. Some of the alloys that contain from 3 to 8% Mn are air hardening and may be utilized where toughness is not required. With about 4% Mn plus 0.5% C and 4% Mn plus 0.8% C the Jominy end-quench hardenability curves[17] are nearly flat at approximately Rockwell C 60 and 56, respectively. These compositions, which merge into the pearlitic steels when the manganese content is further reduced, have received little commercial recognition.

Low-Carbon Manganese Steels. Reduction of carbon, rather than manganese, produces materials that may exhibit satisfactory mechanical properties. The extremes are iron-manganese alloys.[21] They appear to be sensitive to hydrogen embrittlement[5] and, since the attainment of low carbon content is an added expense, they are unlikely substitutes for the 1.15% C, 13% Mn grade. Intermediate carbon contents (0.50 to 0.90%) are employed in welding-rods for austenitic manganese steel, usually with additional alloying elements. A machinable austenite, containing 0.3% C and 17 to 18% Mn, has been advocated in Germany for nonmagnetic parts.[22]

A 16% Mn steel with 0.10 to 0.25% C, 2% Ni, 1% Cu and sometimes chromium, has been suggested for light, high-strength wrought products.

Nickel-Manganese Steels. Additions of nickel to the standard grade of austenitic manganese steel produce no apparent change in yield strength, but there is a distinct trend toward higher tensile elongation (Table VI). The quenching rate is perhaps less critical, but quenching is still necessary in order to obtain the maximum toughness. Such additions of nickel may stabilize the lower-carbon types, and may therefore permit some control of the martensitic skin that sometimes forms during heat treatment.

A lower carbon content is much more effective in conferring toughness without quenching, and since added nickel seems to prevent the lower intrinsic toughness of the straight 12% Mn steels with low carbon content, a group of steels with 0.60 to 0.90% C and about 3% Ni has become popular for welding-rods, for wrought products, and occasionally for castings. Representative properties appear in Table VII. This alloy surpasses the standard grade in resistance to embrittlement that results from reheating up to 800 F.

Chromium-Manganese Steels. The ability of manganese to stabilize austenite has been utilized in low-carbon modifications of the 18% Cr, 8% Ni stainless steels by substituting manganese for some or all of the nickel. A correlated abstract by Mack[24] is a convenient reference for these alloys, which are reported to have good characteristics in regard to deep drawing, hot working and welding; better machinability than 18% Cr, 8% Ni steel; somewhat lower strength at elevated temperature; lower but generally satisfactory resistance to scaling; and less susceptibility to intergranular corrosion—but also lower resistance to corrosion except in sulfurous mediums.

As the chromium content is decreased and the carbon content is increased, the chromium-manganese steels gradually approach the Hadfield type. The chromium-manganese steels may have higher yield strength and resistance to flow (Fig. 1 and 10), moderately increased resistance to corrosion, and less susceptibility to embrittlement by reheating. The wear resistance is controversial; at present this special modification has no clearly established superiority over the standard grade.

Table VIII. Suitable Current Values for Welding Austenitic Nickel-Manganese Steel

Diam of Rod, in.	Bare Rod, d-c amperes	Coated Rod— d-c amperes	Coated Rod— a-c amperes
1/8	80 to 100	75 to 90	80 to 100
5/32	90 to 125	85 to 110	90 to 125
3/16	110 to 150	100 to 130	110 to 150
1/4	135 to 160	110 to 140	135 to 160

The lowest practical welding current will usually result in the least damage to the parent metal.

Manganese, chromium, nickel and silicon have been used together to produce a heat-resistant alloy suitable for service up to 1400 F.[25] An approximate range of composition is 0.30 to 0.35% C, 4 to 9% Mn, 2% Si, 6 to 9% Ni, and 10 to 12% Cr. This alloy has a limiting creep stress (for 0.0001% per hr minimum creep rate) of 4000 to 7000 psi at 1400 F and 1500 to 3000 psi at 1600 F. The composition must be balanced for maximum strength and structural stability. Above 1400 F the rate of oxidation is rather high.

Copper is sometimes employed in chromium-bearing austenitic manganese steels. Lorig[26] suggests from 1 to 5% Cu, with molybdenum and chromium each up to 3% and manganese between 2 and 9%, in order to obtain strength, toughness, and high sensitivity to work hardening. Experimental compositions near the middle of this range give tensile strength from 68,000 to 88,000 psi with 10 to 16% elongation.* These values are similar to those of 9% Mn steel. Copper and chromium added to the standard composition are reputed to improve yield strength and resistance to flow.[27] It is probable that the chromium is chiefly responsible.

Welding. Manganese steel may be welded with rods that deposit austenitic metal, but several features must be considered carefully. Austenitic stainless steel rods have been used but are not recommended. The best welding alloy is a low-carbon, high-manganese steel, containing enough of an additional alloying element (usually nickel) to compensate for the decreased carbon content, as previously described. Electric welding, with the shortest practical arc, is almost necessary. The primary consideration is minimum heating of the parent metal in order to avoid embrittling transformations or precipitation of carbide. This usually precludes the practice of preheating. Even under the most favorable circumstances some precipitation is expected and the resulting weld zones seldom equal the toughness of the normal parent metal. The weld itself may have good properties; it is the surrounding metal that suffers impairment.

The low heat conductivity and high thermal expansion also contribute to difficulties, combining to produce steep thermal gradients and high residual stresses. Weld metal is subjected to tension as it cools, and in order to minimize cracking, it is desirable to peen the weld while it is hot, thus producing plastic flow and changing the stress to compression. This hammering should be done promptly after a maximum length of 6 to 9 in. of the weld has been deposited.

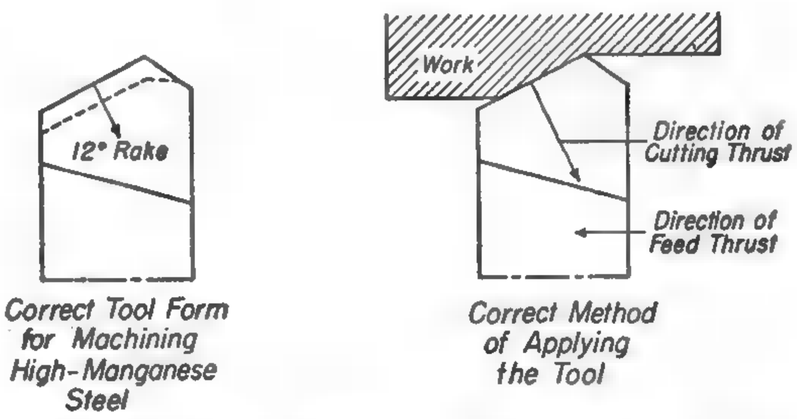
The heat of welding will accentuate the precipitation of carbide if work hardening of the base has preceded welding. For such material as in railway trackwork the cold worked metal should be removed by grinding before the new metal is deposited. A center punch mark provides a crude but convenient index of work hardening; grinding should continue until an indentation is readily produced.

If manganese steel is deposited on carbon or low-alloy steel, the transition zone may be too low in manganese and may develop a martensitic structure which, because of brittleness, may permit spalling of the weld deposit. Such use of an austenitic manganese steel overlay for wear resistance is not recommended; an air-hardening steel or cast iron is generally more satisfactory. However, hard surfacing of manganese steel is practicable if an alloy is employed that is more resistant to abrasion. Such surfacing is useful where the toughness of manganese steel is required only intermittently. Composite structures of this type should follow the principle of using the tougher of the two metals for the base.

Both bare and coated electrodes are used for welding; the conditions listed in Table VIII are suitable.

Machining. Manganese steel is so tough, and work hardens at the point of cutting tools to such an extent that frequently it is typed as commercially unmachinable. However, this steel can be cut with both cemented carbide and cobalt high speed steel tools. A good grade of sulfur-bearing cutting oil is beneficial. Moderately heavy cuts and slow speeds are advisable. Most commercial finishing is by grinding, and foundries specializing in the production of Hadfield steel are equipped to do almost all the required machining operations with grinders.

Machinability is increased by the embrittling that reheating develops between 1000 and 1200 F. Though not usually practicable, such a treatment may be a useful expedient if the part can be properly toughened afterward. Milling is not considered practicable.



Correct Tool Form for Machining High-Manganese Steel

Correct Method of Applying the Tool

Fig. 13 Machining austenitic manganese steel (Lea[28])

British practice is reported to depend less on grinding and to feature the following:[28]

1 Dry machining, with high temperatures at the tip of the cutting tool
2 High-cobalt high speed steel tools
3 Extremely rigid machine tools and chucking, to eliminate chatter
4 Tool design with 7-deg clearance and 12-deg rake (*see* Fig. 13)
5 Cutting speeds of approximately 12 to 14 ft per min, cuts approximately 3/16 in. and feed about 1/32 in. per rpm
6 Tools kept very sharp

Applications. The chief applications of austenitic manganese steel are in the industries of construction, mining, quarrying, oil-well drilling, manufacturing of steel, railroading, manufacturing of cement and clay products, dredging, and lumbering. This steel serves chiefly as parts in equipment for handling materials, rock crushers, grinding mills, dredge buckets, power-shovel buckets and teeth, pumps for handling gravel and rocks, and in a multitude of associated applications. An important use is in railway trackwork, such as frogs, switches and crossings, where the multiple impacts at intersections are especially severe. Austenitic manganese steel resists metal-to-metal wear; therefore it may be used in sprockets, pinions, gears,

*From previously unpublished data assembled at the American Brake Shoe Company

wheels, conveyer chain and various wearing plates, shoes, or other contact members. Nonmagnetic parts, required for lifting-magnets, for induction furnaces and special electrical equipment, represent an expanding field of usefulness.

High-Strength Low-Alloy Structural Steels

By H. W. Gillett*

IT IS not feasible to quench and temper some large steel structures, for example, bridges, railroad cars and ships. Moreover, steels that harden during quenching present difficulties in welding. The use of ordinary structural steel for making large structures that cannot be heat treated, and for welding, requires that design be based on the low yield strength of the steel (25,000 to 30,000 psi) and on the endurance limit, which for unnotched specimens approaches the yield strength.

There is an obvious need for steels that are stronger in the as-welded or normalized condition so as to allow the saving of weight. Stronger structural steels were at first provided by increasing the percentage of one or more of the three cheap elements—carbon, manganese and silicon. Such steels were used in riveted structures. The cold formability of these strengthened steels was decreased, and their hardenability made them poorly adapted for welding.

To secure freedom from weld hardening, and a better compromise between yield strength and cold formability, it was necessary to decrease the carbon content and to add alloying elements. In the presence of effective amounts of alloying elements, the practical limits of carbon content for normalizing, without production of martensite or bainite, are 0.07 to 0.17%; the usual range is 0.10 to 0.15%. Alloying elements are selected according to the need for making the austenite moderately sluggish during cooling, so that the pearlite transformation, during air cooling, will occur at as low a temperature as possible in order to secure fine pearlite instead of coarse. Yet the steel must not be so sluggish that any austenite is retained to form bainite or martensite at still lower temperatures.

The cementite in the finely distributed pearlite is undoubtedly the major source of strength, since carbon-free ferrite would need to be very highly alloyed if the desired strengths were to be obtained, but the strengthening of the ferrite matrix is an indispensable adjunct. At this low carbon level, carbide-forming elements, such as manganese, chromium and molybdenum, are distributed between the cementite and the ferrite; a considerable proportion of these elements is dissolved in ferrite and strengthens it. Hence these may be used as well as the elements that do not replace iron in cementite in steel. Silicon, copper, nickel and phosphorus are effective in that they strengthen ferrite.

The potency of the elements is in approximately the following order, and the percentages employed are about as shown here:

Carbon	0.10 to 0.13	
Phosphorus	0.03 to 0.12	
Molybdenum	0.10 to 0.25	(when used)
Manganese	0.20 to 1.20	
Silicon	0.05 to 0.75	
Copper	0.10 to 0.90	
Chromium	0 to 0.85	
Nickel	0 to 1.80	

Phosphorus, commonly 0.10%, is used in the compositions that have accounted for the largest tonnages of these "mild alloy" steels made in the U. S. In such an amount phosphorus strengthens steels of this carbon content, without producing the cold brittleness that has barred high phosphorus content in steels of higher carbon content. Because phosphorus may cause a banded structure, with streaks of high phosphorus concentration, when the steel is cast into large ingots, 0.25% C + P is the maximum used. Molybdenum, unusually effective as a strengthener, is recovered quantitatively from remelted scrap, and all that is added to the charge, whether as ferro-alloy or as oxide, is recovered without loss by oxidation.

Manganese may either be kept at the lowest content that will give clean steel or, more commonly, may be raised well above that content. With most furnace practice there is some uncertainty as to the percentage recovery of manganese, and when large amounts are added in

* Chief Technical Adviser, Battelle Memorial Institute, Columbus, Ohio

the cheapest form (high-carbon ferro-alloy) the carbon content of the melt must have been decreased correspondingly. A point of carbon is an important matter in these steels. When more than 1% Mn is employed, few other strengthening elements are added and these other additions are made for control of grain size. About 0.10% V accompanied the high manganese content for this purpose in some of the earlier steels.

Chromium has effects similar to those of manganese in these steels. Chromium is cheaper as high-carbon than as low-carbon ferrochromium. One steel containing about 0.85% Cr, together with 0.40% Cu and about 0.11% P, for resistance to atmospheric corrosion, has been found to produce a particularly adherent type of rust. The chromium content of up to 0.50%, used in some other steels for the strengthening effect, confers no notable corrosion resistance by itself.

Silicon is normally used in amounts sufficient to kill the steel, usually 0.15% or more, though in at least one steel of this class, semikilled to give a high ingot yield, silicon content is kept low. In some other steels, the silicon content is increased considerably beyond that in ordinary killed structural steel, so as to use the strengthening effect of silicon since it is one of the cheapest alloying elements. Objections to high silicon content in basic melting practice, and a tendency toward dirtiness when around 1% Si is present, have operated to keep the silicon at 0.75% or less, though some early foreign steels used it as the major alloying element.

To confer resistance to atmospheric corrosion, copper was used, at about 0.20%, long before it was generally used as a strengthener. Its effect on resistance to corrosion is enhanced when copper is used in conjunction with phosphorus. Like molybdenum, copper is recovered quantitatively from scrap and from additions, since these elements are oxidized less readily than iron. This reluctance to oxidize brings a limitation to the use of copper, since while scaling in the soaking pit or the heating furnace, a steel high in copper forms a film of copper beneath the scale. This film may penetrate into the steel intergranularly and may cause surface checks during hot rolling. Such behavior limits copper additions (for wrought products, not for castings) to from 0.40 to 0.50% unless special precautions are taken in heating, or unless the high copper content is accompanied by at least half as much nickel as copper, preferably more than half.

When the copper content is greater than 0.75%, the copper-containing steels can be precipitation hardened. The copper is retained in solid solution, even at the rate of cooling obtained in normalizing large sections, but is precipitated out when the steel is reheated to about 850 to 950 F, increasing the yield strength considerably and decreasing the ductility slightly. At about 1% Cu the increase in yield strength is 10,000 to 20,000 psi and occurs regardless of what other alloying elements are present.

A steel has been used containing 0.12% C, 0.60% Mn, 0.01% Si, 1.40% Ni, 0.95% Cu and 0.25% Mo. The mechanical properties are:

Condition	Tensile Strength, psi	Yield Strength, psi	Elongation in 2 in., per cent	Reduction of Area, per cent	Bhn
Normalized	73,500	57,000	36	70	155
Normalized plus 4 hr at 1000 F...	84,500	71,500	31	67	185

Since rapid cooling is not necessary to keep the copper in solid solution, ready for precipitation hardening, the increased strength caused by precipitation hardening can be obtained at the center of a large section. Formability in the solution treated condition is better than in the riveting grade of steel not precipitation hardened which has yield strength equal to that produced in this steel by the final precipitation hardening.

Nickel strengthens much as copper does, but causes neither intergranular attack under scale nor precipitation hardening. With regard to atmospheric corrosion, nickel has much the same effect as copper though not so great. Like molybdenum and copper, nickel is recovered quantitatively from scrap and from additions. Next to molybdenum, nickel is the most expensive of the elements used in these steels. Because of its cost, it is seldom used alone, but is commonly accompanied by a considerable copper content, since copper, in permissible amounts, has an approximately equal strengthening effect.

The nickel, copper and molybdenum contained in scrap are retained when remelted. As in the NE steels for heat treatment, the content of these elements in available scrap can be used as the basis on which to build up the composition to the desired level.

Since the mild alloy steels are benefited by fine grain, aluminum, titanium, or zirconium is the final addition to killed steel, especially when low-temperature notched-bar impact resistance is sought. Care is necessary in making such additions, in order to allow separation from the melt of oxides and nitrides that may form clumps and produce laminations during rolling.

With proper choice and suitable amounts of alloying elements, it is possible to produce formable, weldable mild alloy steel that contains 0.10 to 0.15% C, with yield strength 50,000 to 55,000 psi, tensile strength 70,000 to 80,000 psi, and approximately 25% elongation in 8 in. for as-rolled or normalized sections of ½ to ¼ in. In sections of ¾ to 1 in., the yield and tensile strengths are lower.

Table I. Chemical Compositions of High-Strength Low-Alloy Structural Steels

(a) Or less vanadium, with a low content of titanium

With a few points more carbon or with very low finishing temperatures in rolling, a riveting grade can be obtained with 65,000 to 75,000 psi yield strength and 80,000 to 90,000 psi tensile strength. The elongation is 15 to 20% and there is some sacrifice in cold formability and weldability. The ductility figures given are for longitudinal specimens. Depending on cleanliness and whether or not the steel is cross-rolled, the results of tests made in the transverse direction—and especially in the direction of the plate thickness—may, of course, be lower.

For steels that have a yield strength of about 50,000 psi, the endurance limit and endurance ratio for unnotched specimens are surprisingly high—very close to the yield strength. This is particularly evident in the phosphorus-strengthened steels.

The mild alloy steels that ordinarily contain 0.20% Cu or more—particularly when accompanied by the 0.10% P that is present in many of them—have resistance to atmospheric corrosion superior to that afforded by ordinary structural steels that contain no copper. However, all these steels (including the Cu-P-Cr steel, balanced to secure maximum corrosion resistance) *start* to rust as quickly as ordinary structural steel and, when unsightly rusting must be avoided, all of them require painting.

The modulus of elasticity of these steels is the same as that of ordinary steels. When they are used in the thinner sections made feasible by their yield strength, endurance limit, and resistance to corrosion, whatever stiffness is needed must be engineered into the structure, as by the use of box sections. Table I shows some compositions that have a yield strength of 50,000 psi in the low-carbon (0.10 to 0.15% C) welding grade, and that have been in commercial use or are advocated for such use.

* Properties of some of the high-strength low-alloy steels at low temperature are included in the article on page 204 of this Handbook.

The alloying elements needed for strength, without having to resort to cold finishing, range from a total of about 1%, when the more potent elements are relied upon chiefly, to around 2% or more when less potent elements are used.

While some superficial gradations exist in mechanical properties, formability and weldability among the various compositions, on the whole the series is considered as a unit by the designer and, at least as a first approximation, any steel that meets the mechanical specifications in the section to be used is considered replaceable by any other steel in the series. That is, within the limits of composition favored by the peculiarities of phosphorus, silicon and copper, composition is not an important factor. That each major producer of steel has a pet composition is largely ascribable to the existence of certain patents, familiarity with the processing schedule for one composition, and a desire to be unique.

The availability of scrap that contains copper, nickel and molybdenum, and future changes in the price of these and the other alloying elements, can be expected to direct more attention toward the possibilities of shifting the composition day by day to allow most economical utilization of raw materials and less insistence on a particular chemical composition. The user is concerned with the maintenance of the desired mechanical properties rather than with the composition.

Development of these mild alloy steels so that the static strength and the endurance limit of standard structural steel are doubled, without loss of weldability or much difference in ability to be cold formed, has been no mean accomplishment. The virtues of these steels deserve to be brought more forcefully to the attention of the designer. The saving in weight through the use of these steels justifies the additional cost in many applications. Lighter weight is an advantage in the completed structure, and also reduces the cost of transporting the steel.

Cold Finished Carbon Steel Bars and Shafting

By H. W. Graham*

THE cold finishing of steel may be defined as the process of reducing the cross-sectional area of material such as bars and shafting, without the use of heat. There are five cold finishing methods: cold rolling, cold drawing, cold drawing and grinding, turning and polishing, and turning and grinding.

Bars and shafting are cold finished for one or more of the following reasons: special accuracy of size, a smooth or bright finish on the surface, improved mechanical properties and better machinability.

The selection of the method most suitable for cold finishing a specific piece of work depends on the size of section and the physical characteristics desired. For example, the usual practice is to cold draw the smaller round bars, about 3¾ in. in diam or less, and to turn the larger sizes. Whenever a superior finish or more accurate size is required, the material is ground. Turned and polished bars, usually more than 1⅛ in. in diam, are furnished when steel is desired that has mechanical properties characteristic of hot rolled bar stock, plus accuracy of dimensions, and a finish that is reasonably free from the normal surface imperfections of hot rolled bars.

Description of Cold Finishing Processes. Since the surface defects and imperfections present in the hot rolled product are accentuated by cold drawing, it is necessary that the hot rolled material for this purpose be prepared with care, to assure the proper surface quality, size and finish in the cold finished steel. The surface requirements of hot rolled bars for cold finishing are similar to those of forging steel; that is, the surface must be substantially free from seams, pits and excessive scale.

Before cold drawing, the hot rolled material is usually immersed in a bath of 4 to 8% sulfuric acid at about 150 F until the scale is completely removed. The material is then washed and dipped in a lime solution, which neutralizes any acid remaining on the bars and also serves as a rust preventive and a lubricant in the finishing. Drawing through a die, straightening, and cutting to length complete the sequence of operations.

Cold Rolling. Finishing by cold rolling involves passing the cleaned hot rolled bars repeatedly through a set of rolls, thereby subjecting the material to a light reduction during each pass until the final size is obtained. Cold rolling imparts a bright surface finish, accurate size, and an appreciable increase in the tensile strength, with an even greater increase in the yield strength.

Cold Drawing. In this method, a hot rolled bar of virtually any shape, after being cleaned of scale, is pulled cold through a die with bore section generally $\frac{1}{32}$ to $\frac{1}{16}$ in. smaller than the diameter or thickness of the hot rolled stock. The amount of draft, however, may be varied from $\frac{1}{64}$ to ⅛ in., depending on the composition of the material being drawn, the size of the hot rolled bar, and the mechanical properties desired. The effects of cold drawing are similar to those of cold rolling; the final product has a bright surface finish and accurate size, with the tensile strength and particularly the yield strength substantially increased.

Cold Drawing and Grinding. When cold drawing alone or turning and polishing impart inadequate accuracy in size or inadequate surface finish, straightness or concentricity, grinding may follow cold drawing. The mechanical properties of this type of cold finished product remain unchanged from those of the cold drawn bar.

Turning and Polishing. Whereas cold drawing reduces the cross-sectional area by subjecting the bar to compressive and elongating forces, turning and polishing accomplish the same result by removal of metal from the diameter. Usually the bar is finished thereafter in a combination straightening and polishing machine. By this method, close accuracy of dimensions is obtained, similar in degree to that achieved by cold drawing, but the finish of the surface is somewhat brighter. Surface decarburization is removed along with surface seams and other minor defects not affected by the cold drawing operation. Since the steel has not been cold worked in any appreciable manner, the mechanical properties of the hot rolled bar follow through to the turned and polished product.

Turning and Grinding. In this process, after the rough and imperfect surface of the hot rolled bar has been removed by turning, the bar is ground, usually in the centerless type of machine. The resulting product has a finish and characteristics similar to those of cold drawn and ground material, except that the mechanical properties of the hot rolled material have not been changed.

Size and Finish. From the above discussion, the various methods of cold finishing may be grouped as follows, according to superiority of the size and finish produced.

Accuracy of Size	*Finish*
First—Turning and grinding or cold drawing and grinding	Turning and grinding or cold drawing and grinding
Second—Turning and polishing or cold drawing	Turning and polishing
Third—Cold rolling	Cold drawing or cold rolling

One of the outstanding advantages of cold finished steel is the close dimensional tolerance that can be maintained. Cold finished bars are straightened commercially within $\frac{1}{32}$ in. in 5 ft. Rounds for shafting purposes are held considerably closer, and even more exacting requirements of straightness can be met by special processing in straightening.

* Vice President and Director of Technology, Jones & Laughlin Steel Corporation, Pittsburgh

Mechanical Properties. Table I gives average mechanical properties of cold drawn, hot rolled steel bars of the various grades listed. The data presented are general in nature and therefore should not be interpreted as values necessarily obtainable for all sizes and conditions. Also the stress-strain diagrams in Fig. 1 give a general idea of the marked increase in tensile strength, and particularly yield strength, that occurs in this process. The tensile strength is increased less than the yield strength; but since permanent distortion is a function of the yield strength rather than of the tensile strength, this effect on cold drawn materials is of vital importance in applications in machinery.

Table I

Average Mechanical Properties of Cold Drawn Steel

Sizes, ⅝ to 2 in. in diam; Test specimens, 2 by 0.505 in.

AISI Steels	Tensile Strength, psi	Yield Strength, psi	Elongation in 2 in. per cent	Reduction of Area, per cent	Brinell Hardness Number
C-1010	67,000	55,000	25.0	57	137
C-1015	71,000	60,300	22.0	55	149
C-1020	75,000	63,700	20.0	52	156
C-1025	80,000	68,000	18.5	50	163
C-1030	87,000	73,900	17.5	48	179
C-1035	92,000	78,200	17.0	45	187
C-1040	97,000	82,400	16.0	40	197
C-1045	102,000	86,700	15.0	35	207
B-1112	87,000	73,900	17.0	45	183
C-1120	78,000	66,300	19.5	49	159
C-1117	80,000	68,000	19.0	51	163
C-1118	82,500	70,100	18.5	50	167
C-1137	105,000	89,200	16.0	35	217
C-1141	112,000	95,200	14.0	30	223

The increase in yield strength is accompanied by a decrease in elongation and in the reduction in area, but not enough to interfere greatly with the use of cold drawn materials where the higher yield strengths are necessary. A cold drawn bar that has properties intermediate between the extremes in yield strength and elongation, can be obtained by annealing or normalizing treatments.

Because of desirable mechanical properties, lower cost and superior machinability, cold drawn bar stock is often used as a substitute for heat treated bars. Also, in applications where other combinations of properties are desired along with the more accurate size tolerances, hot rolled bars may be heat treated in accordance with the requirements, and then turned and ground, or turned and polished.

During the past few years, considerable attention has been given to strain annealing cold drawn bars in the vicinity of 500 to 1100 F. Heating at temperatures between approximately 500 and 600 F increases the tensile and yield strengths slightly without sacrificing ductility. Higher temperatures relieve cold working strains to a limited degree and increase the ductility of the material. Such treatments have virtually no deleterious effect on the accuracy of size or smooth finish of the cold drawn bar, thus preserving intact some of the properties of cold drawn steel and modifying or enhancing other features.

Machinability. Another important advantage of cold finished materials is machinability superior to that of hot rolled products. This superiority comes from several features, including an improved machining quality in the steel itself, resulting from the effect of cold drawing; and if cold finished by any of the standard methods, better machining performance (because of freedom from hot rolled scale), close accuracy of size, and a greater degree of straightness. These advantages are recognized generally by those interested in machining quality, as indicated by the large percentage of cold finished steels used by machine shops, particularly for automatic screw-machine work where the machining requirements are most exacting and severe.

Shafting. It seems appropriate to include in this discussion a brief mention of shafting formulas; more detailed discussions are published in bulletins of the American Standards Association.

Shafts for transmission of power are subjected to transverse and torsional forces. The loads producing these forces are the torque resulting from the resistance offered

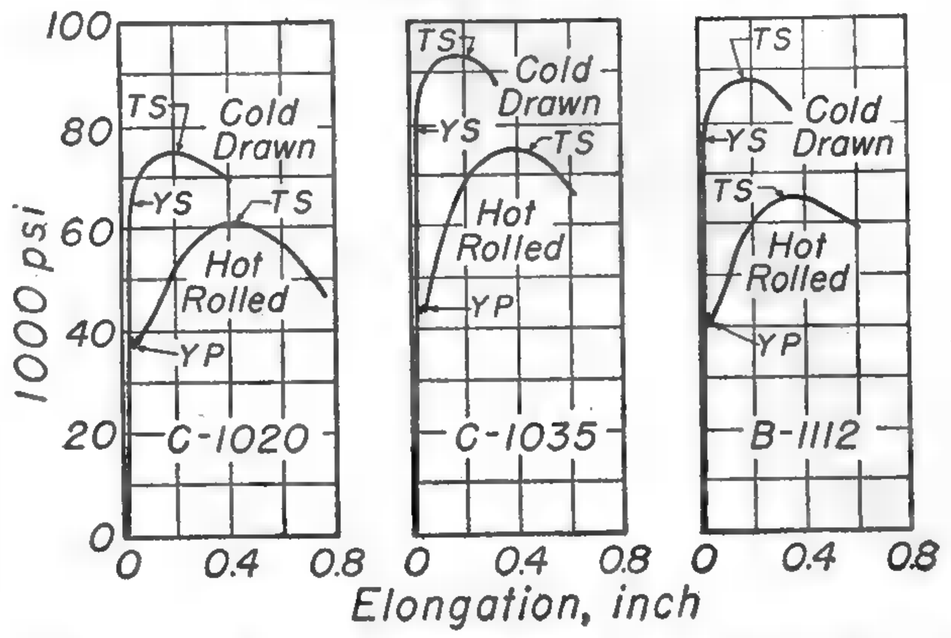

Fig. 1 Typical stress-strain diagrams of hot rolled and of cold drawn steels. (*TS* = tensile strength, *YS* = yield strength, *YP* = yield point)

by the power load to the revolving shaft; the belt pull, the weight of pulleys, gears, sprockets, drums and the weight of the shaft itself. Therefore, in designing a shaft, it is necessary that the stresses to which the shaft is subjected should be within the safe limits of the material used.

For ordinary transmission of power through shafting, experience has shown that when velocity of rotation and spacing of shaft hangers are kept within defined limits, the following formulas fulfill all practical requirements of design. The limitations of these formulas are that the shafts be supported at no greater intervals than 8 ft and that the rpm be no greater than 400.

D = diameter of shaft, in inches
N = number of revolutions per minute
H = horsepower

For head shafts..... $H = \frac{D^3N}{125}$

For line shafts..... $H = \frac{D^3N}{90}$

For short countershafts and single power transmitters ..... $H = \frac{D^3N}{50}$

Conclusion. Because the uses of cold finished steels are numerous, no attempt has been made here to cover them completely. The more common uses include spark plug shells, radio speaker cores, bolts, nuts and screws, gears and pinions, chain pins and rolls for silent chains, motor and transmission power shafting, motorcycle crank axles, oil pump shafts and gears, piston pins, steering gear arms, bushings, pins and worms, tie rods, wringer rolls, gun parts, commutators, and parts for typewriters, sewing machines and cash registers. Particularly large quantities of cold finished steels are used in the manufacture of automobiles, motorcycles, sewing machines, typewriters, adding and calculating machines, textile machinery, shoe machinery, railroad equipment, agricultural implements and electrical equipment.

Wire Rope or Cable

By H. C. Boynton* and A. J. Morgan*

WIRE ROPE is one of the most reliable structural materials. A particular safety feature is that inspection of the surface will indicate when the rope should be replaced. The wear and broken wires disclosed by such inspection, where corrosion is not present, will provide some indication of the remaining strength. Slings made from wire rope, employing proper fittings, furnish the safest method for handling material.

The terms "cable" and "wire rope" are generally considered synonymous. However, when the term "cable" is substituted for "wire rope", it is usually preceded by a descriptive adjective that places it in a more definite class, such as a "track cable" on a cableway, or "bridge cable", as used in suspension bridges.

Five grades of wire rope are used commercially:

Grade	Approximate Carbon Content
Iron	0.05 to 0.15%
Traction Steel	0.20 to 0.50%
Mild Plow Steel	0.40 to 0.70%
Plow Steel	0.65 to 0.80%
Improved Plow Steel	0.70 to 0.85%

There are four standard constructions of wire rope, namely, 6 x 7, 6 x 19, 6 x 37, and 8 x 19. The figures mean that the rope is composed of 6 strands of 7 wires each, 6 strands of 19 wires, and so on. There are, however, many variations in strand construction and the number of wires per strand may vary from 7 to 61, or even more should conditions require more.

To attain the different physical properties required in the various constructions, the individual wires of which a wire rope is composed are specially heat treated and then cold drawn. This sequence of processes produces the necessary toughness and strength. Therefore, any attempt to eliminate the effect of service overstraining by annealing or by any form of further heat treatment, such as is given to chain, would obviously destroy the original properties of the wire, obtained by the cold drawing, and would ruin wire rope.

Qualities of Wire Rope. *Iron Rope (0.05 to 0.15% C).* Iron rope is low in strength and soft compared with steel rope; consequently it will stand little abrasion. Iron rope is pliable and tough, but it is limited to uses where the abrasion is slight and the drums and sheaves are large. It is ordinarily used on drum-type passenger elevators, for compensation and governor ropes, or for transmission of power by wire rope. It is not adapted to general hoisting or to guy ropes. Iron rope is usually furnished only in the 6 x 7 and 6 x 19 standard construction.

Traction Steel Rope (0.20 to 0.50% C). This rope was developed particularly to meet the requirements of traction elevators; that is, high resistance to fatigue, combined with pliability and enough softness to ensure that the rope will not cut the sheaves. Traction Steel rope, therefore, is not so strong as the Mild Plow Steel grade of rope.

Mild Plow Steel Rope (0.40 to 0.70% C). This is a good grade where higher-strength ropes are not required. The most general application is for standard tool drilling in the shallow oil fields and for drilling water wells and blastholes.

Plow Steel Rope (0.65 to 0.80% C). Ropes made from Plow Steel wires are of high strength and unusual toughness, capable of giving good service on many installations where conditions are not unusually severe.

Improved Plow Steel Rope (0.70 to 0.85% C). This grade of rope is generally given a trade name by the manufacturers. It is a high-strength rope recommended instead of the Plow Steel grade where abrasion is severe or the rope is subjected to severe shocks, vibrations, or fatigue stresses. This rope is particularly adapted for severe duty in mines, for logging lines, scraper, dredge and rigging ropes, heavy cranes, ballast unloader ropes and excavating machinery.

Constructions of Wire Rope. *Standard Coarse Laid Rope.* The 6 x 7 wire rope construction called "Standard Coarse Laid Rope", is made of 6 strands of 7 wires each, closed around a fiber core. It is much stiffer than standard hoisting rope and requires larger sheaves. This rope is used for heavy hauling, for wire rope transmissions, tramways, well drilling and sand lines.

*Standard 6 x 19 Construction or Standard Hoisting Rope.** This rope is made of 6 strands, each of which is formed by laying 19 wires together. The strands are finally closed around a fiber core. It is generally accepted that rope made with strands having not less than 16 and not more than 25 wires each, belongs to this general 6 x 19 class. This rope construction, ordinarily

Fig. 1 (Left) Seale construction (6 x 19)
(Right) Filler Wire construction (6 x 25)

considered flexible, is used more generally than all other constructions for hoisting and other rope uses.

Table I gives the important sizes and properties for a Standard Hoisting Rope of 6 x 19 construction made from Mild Plow Steel, Plow Steel and Improved Plow Steel. The two constructions most generally furnished under the 6 x 19 Improved Plow Steel are the 6 x 19 Seale construction and the 6 x 25 Filler Wire construction, as illustrated in Fig. 1.

Table I. Properties of Standard Steel Hoisting Rope (6 x 19 Fiber Core)

Diameter, inches	Approximate Circumference, inches	Approx Weight, lb per ft	Approximate Strength in Tons of 2000 lb — Mild Plow Steel	Plow Steel	Improved Plow Steel
2¾	8⅝	12.10	....	254.0	292.0
2½	7⅞	10.00	....	212.0	244.0
2¼	7⅛	8.10	....	174.0	200.0
2⅛	6⅝	7.23	....	156.0	179.0
2	6¼	6.40	121.0	139.0	160.0

5/16	1	0.16	3.22	3.71	4.26
¼	¾	0.10	2.07	2.39	2.74

6 x 37 Rope Construction. When each of the six strands of the rope is composed of not less than 26 or more than 46 wires, the construction is generally considered in this class. This rope construction is generally known as Extra Flexible Hoisting Rope and is usually recommended instead of Standard Hoisting Rope when the sheaves are found to be too small for Standard Hoisting Rope. The wires in this rope are necessarily much finer than those used in the Standard Hoisting Rope with 19 wires to the

* John Roebling's Sons Company, Trenton, N. J.

* The 6 x 19 construction is probably used more often than the others; consequently it is called "Standard".

strand, and consequently are less able to withstand severe abrasion.

8 x 19 Rope Construction. This construction (8 strands of 19 wires each, closed around a fiber core) is generally used where sheaves of small diameter must be employed and where the abrasion is light. This rope construction is generally considered to be an Extra Flexible Hoisting Rope and sometimes may be considered interchangeable with 6 x 37 rope construction. The metallic area of the 8-strand rope is not so great as that of the 6-strand rope, but under severe bending conditions, the decrease in strength is largely offset by the greater pliability. This rope distorts from its circular cross section more readily than a 6-strand rope, so conditions of service that cause crushing require a 6-strand in preference to an 8-strand rope.

Proper Working Loads. It is never advisable for the working load of wire rope, particularly of running ropes, to exceed one-fifth of the breaking strength. This means that the factor of safety should be not less than five. To determine the maximum working load, the breaking strength is divided by the factor of safety. For example, a 1-in. diam 6 x 19 Improved Plow Steel Rope has a breaking strength of 41.8 tons (Table I), and with a factor of safety of five, the working load would not be greater than 8.36 tons.

Factors of safety in excess of five, varying up to eight and even more, are often required for safe and economical operation. The correct factor of safety for a wire rope should be determined by careful and thorough consideration of all pertinent data, including the following: all loads; acceleration; deceleration; rope speed; rope attachments; the number, size and arrangement of all sheaves and drums; existing conditions causing corrosion and abrasion; length of the rope being used; economical rope life; and the possible danger to life and property.

Sizes of Sheaves and Drums. To obtain the most economical service from wire rope, sheaves and drums should be examined carefully for proper size, free running, and suitable groove diameters. It is advisable to design the sheave and drum equipment so that the tread diameters are approximately as follows:

Recommended Average Diameters for Sheaves and Drums

For 6 x 7 rope,	72 times rope diameter	
For 6 x 19 rope,	45 times rope diameter	
For 6 x 30 rope,	45 times rope diameter	(Style G)
For 6 x 37 rope,	27 times rope diameter	
For 8 x 19 rope,	31 times rope diameter	
For 18 x 7 rope,	51 times rope diameter	

For economical service, various conditions allow, and often require, changes from these diameters. For example, on larger hoisting installations, sheaves for use with a 6 x 7 rope are sometimes set at 96 times the rope diameter, and for a 6 x 19 rope, sometimes as high as 90 times the rope diameter.

It is also true that for certain classes of service, ratios smaller than these are possible and economical, although larger diameters give increased life. It is advisable never to allow the sheave and drum diameters to be set below the following:

Minimum Diameters for Sheaves and Drums

For 6 x 7 rope,	42 times rope diameter	
For 6 x 19 rope,	30 times rope diameter	
For 6 x 30 rope,	30 times rope diameter	(Style G)
For 6 x 37 rope,	18 times rope diameter	
For 8 x 19 rope,	21 times rope diameter	
For 18 x 7 rope,	34 times rope diameter	

Rope and cable subjected to intense sheave or drum pressures or operating under conditions of severe heat, are often manufactured with a metallic core instead of the usual fiber core. This core may be in the form of a strand or an independent wire rope. If such a core is used, the rope strength given in Table I may be increased by 7½% and the rope weight by 10%.

Storage. Particular care should be taken to avoid damage of a wire rope while it is in storage. The rope should be stored in a dry place, free from chemicals or gas from chemicals, in order to prevent destructive corrosive action on the steel. Also any exposure to excessive heat may injure the fiber core.

Handling. In handling, care should be taken not to twist or untwist the rope. Kinks of any nature or the pulling down of loops to small diameters should be avoided. The wires are damaged beyond the elastic limit at such points and will break rapidly in subsequent service, producing a condition that is erroneously termed a bad spot in the wire rope. A spot like this is caused by a kink placed in the rope before or during service.

Cutting. Before the actual cutting operation, proper servings* should always be placed on each side of the point where the rope is to be cut. Such a precaution is absolutely necessary in order to prevent the unlaying or the rotating of the strands. It is advisable to use a minimum of three servings on each side of the cut.

Attachments. There are several ways in which the rope ends may be secured. The best one, developing 100% of the rope strength, is a socket connection.

In preparing the wire for socketing, the fiber core is entirely removed and the "brush" of separated wires is dipped in acid. The "brush" should never be dipped beyond three-quarters of its length, so that no trouble from corrosion difficulties may occur later. Moreover, a slight film of hydrochloric acid acts as a flux to assist in the amalgamation of zinc to the wires of the brush.

A thimble spliced in one end of the rope is often used for an attachment. Its efficiency varies between 75 and 90% of the rope strength, depending on the size of the rope. The thimble connection is also used with wire rope clips. This attachment has about the same efficiency as the splice. However, in order to obtain maximum efficiency, it is essential to apply the clips one rope lay apart, to tighten them securely and to place the U-bolts of the clips always on the dead end of the rope. "Rope lay" means the length of rope in which a strand makes one complete revolution about the rope axis. The use of incorrectly designed clips or unsuitable clip attachments results in strengths as low as 60% of the ultimate strength, or less. The thimble is also used with 3-bolt clamps and this efficiency, when the clamps are properly designed, is about the same or is greater than that obtained by using clips. Clips and clamps should be tightened after about an hour of operation and at regular inspection intervals after that. In all these connections employing the thimble it is essential that a proper design of wire rope thimble be used. It should have a large enough eye and should furnish the proper support to the rope.

Lubrication. The subject of lubrication for wire rope should be given careful consideration. Light applications of a comparatively thin oil are usually sufficient for elevator ropes that are not exposed to the elements; the conditions to be met in a mine shaft require a much heavier lubricant and a protector against corrosion.

It is not possible for manufacturers to place sufficient lubrication within a rope to last throughout its entire life. It is essential that a wire rope be lubricated internally as well as externally to reduce internal friction and to provide protection against corrosion. When corrosion starts inside a wire rope, the injurious effect can seldom be seen and cannot be arrested before the service and the safety of the wire rope are affected. It is preferable to use lubricant recommended by the manufacturer of the rope.

When the correct lubricant is applied properly, it will penetrate thoroughly into the rope and, after cooling, will adhere to the wires sufficiently not to drip off, and will form a plastic coating on the wire. The lubricant should also be free from ingredients that would injure the rope. Unsuitable lubricants that harden on the surface will result in more damage than benefit, because while keeping subsequent lubricants out, they let in and keep in moisture, thus accelerating corrosion.

In the American Engineering Standards Committee Paper, dated Feb. 24, 1927, is a set of rules for the selection of lubricants for wire rope.

Sheave and Drum Grooves. Improper sheave or drum grooves are undoubtedly responsible for more damage to wire rope than any other single factor causing ropes to

* Servings, sometimes called "seizings", are soft wire fastening secured around the rope to maintain its manufactured condition.

give irregular and uncertain service. It is essential that the grooves be large enough for operating with new ropes. The grooves are generally worn down by service; the amount of wear depends on the radial pressure and the material of which the sheave is made. The grooves wear to the diameter of the worn rope operated over them and consequently become small for the new rope. This causes the new rope to receive extra abrasion and distortion, both of which are very detrimental. Sheaves and drums should be inspected before the installation of new rope, and where the groove diameters have worn smaller than indicated by the limits given below, the sheaves should be replaced or remachined so that the groove diameter will correspond to the following limits:

Nominal Diameter of Rope, in.	Recommended Clearance, in. — Minimum	Maximum
1/4 to 5/16	1/32	1/32
3/8 to 3/4	3/64	1/16
7/8 to 1 1/8	1/16	3/32
1 3/16 to 1 1/2	1/16	1/8
1 5/16 to 2 1/4	3/32	3/16
2 5/16 and larger	1/8	1/4

Removal of Ropes From Service. It is first necessary to determine the factor of safety to which a rope may deteriorate without danger. This precaution is important. Though in some places the breaking of a rope would not endanger life or property, failure in other types of service would be very dangerous. Consequently the minimum factor of safety must be set. In general, ropes are likely to break rapidly if the outside wires have been reduced 50% of their diameter by abrasion. With some ropes, many wires start breaking before this amount of abrasion is reached. It is, therefore, the number and the distribution of the broken wires, together with the amount of abrasion, that indicate the remaining strength of the wire rope. The correct way to count a rope for broken wires is to count the number of such broken wires by strands per rope lay. Then the worst rope lay counted should be the one on which to base the estimate of remaining strength or on which to base the decision as to whether or not the rope should be removed from service. The rapidity with which broken wires develop indicates the degree of fatigue. Where the broken wires develop rapidly, the rope should be carefully watched, since it will, undoubtedly, have to be removed soon thereafter.

When corrosion occurs in a wire rope, it is impossible to estimate the remaining strength or to state whether or not the rope is safe. Since corrosion causes the wires to become more or less brittle, the reliability of the rope may become seriously impaired because of the rapid accumulation of broken wires. If these are not detected, the rope may fail in subsequent service. Even though a test for ultimate strength is made on a sample representative of the worst-appearing condition, as determined by visual inspection, there is no definite assurance that the sample tested is typical of the worst section in the remainder of the rope. Hence, even if this test proves satisfactory, there is still no positive assurance that the remainder of the rope is in as good or better condition than the piece tested. However, corrosion can be controlled by suitable lubrication.

Long life for wire rope depends on the following factors: use of the proper quality of wires; right construction for the installation at hand; large sheaves, with proper grooves; correct lubricants, applied properly for internal and external lubrication; prevention of corrosion; careful supervision to prevent "kinking" or "looping" in the installation, and overloading in service; a regular count of broken wires, to observe the development of fatigue.

Wire rope is one of the most reliable of structural materials, but it should be realized that a wire rope is essentially a machine, composed of many parts that function as a unit with the individual wires acting as bearing surfaces; and as such the rope is subjected to pressure and wear. It will be readily apparent that the ultimate service of wire rope will depend primarily on maintenance and care.

Sling and Crane Chain

BY THE SUBCOMMITTEE ON CHAIN*

THIS article deals with the care and selection of wrought iron chain, high-test steel chain and alloy steel chain. It does not cover stud-link anchor chain or corrosion-resisting steel, acid-resisting bronze, monel metal or chain larger than 2 in. in section.

Iron chain may be repaired by a competent blacksmith and, with proper equipment, can be satisfactorily annealed. However, steel chain should never be repaired by the user, unless the user is fully equipped for the proper welding, heat treating, proof testing and inspection. It is highly recommended that steel chain be returned to the manufacturer for repairing, since it is very important that all repairs be proof tested and inspected by trained personnel to verify the welding and heat treating.

Chain Dimensions. Table I, showing representative link dimensions and chain weights, is taken from ASTM Specification A 56–39 for Iron Crane Chain. Data for other grades of chain vary somewhat from these, according to the practice of the manufacturer. Where precise dimensions are required, a chain manufacturer should be consulted.

Types of Chains

Wrought Iron. The approximate chemical composition of chain made from this material includes less than 0.06% C and 0.06% max Mn. The average mechanical properties of wrought iron for chain are as follows: tensile strength, 47,000 psi; yield strength, 28,000 psi; elongation, 25%; and reduction of area, 40%. Wrought iron chain has good resistance to impact, to notching or bruising and to corrosion. Iron chain is subject to embrittlement at low temperatures; the impact strength is reduced to one half the normal value at 32 F and to one fifth at minus 4 F. At or below these temperatures, special care should be taken, and if possible the chain should be warmed before use. (Refer to Bureau of Standards Circular C-447, 271, Dec 1, 1943.) Repeated peening of the chain links against one another causes work hardening. Under impact, the hard skin produced by work hardening is broken, localizing the stress and eventually resulting in failure. The work hardened skin may be softened by periodic annealing of the chain.

* The members of this subcommittee are N. J. Gebert, *Chairman* (American Chain Division of American Chain & Cable Company, Inc.), A. D. O'Connor (Sun Shipbuilding & Dry Dock Co.), H. F. Parker (Columbus McKinnon Chain Corporation) and E. W. Taylor (S. G. Taylor Chain Company).

Table I

Link Dimensions and Chain Weights for Iron Crane Chain

Trade Size, inches	Actual Size of Material, inches	Inside Length of Link, inches	Inside Width of Link, inches	Approximate Number of Links per foot	Weight, pounds per 100 feet

Table II. Breaking, Proof and Safe Working Loads of Wrought Iron Chain

Trade Size, inches	Average Breaking Load, pounds	Minimum Proof Test Load, pounds	Safe Working Load, pounds
3/8	7,950	3,020	2,385
1/2	14,145	5,375	4,240
5/8	22,095	8,395	6,630
3/4	31,800	12,080	9,540
7/8	43,245	16,430	12,960
1	56,550	21,490	16,950
1 1/8	66,800	25,380	20,040
1 1/4	82,500	31,350	24,750
1 3/8	99,800	37,920	29,910
1 1/2	118,700	45,100	35,600
1 5/8	139,500	53,000	41,800
1 3/4	161,600	61,400	48,450
2	211,100	80,200	63,300

The strength properties of wrought iron chain are shown in Table II.

Annealing Treatment of Wrought Iron Chain. The following periodic treatment of wrought iron chain is used generally to remove the effects of work hardening. Unless the treatment is carried out regularly, the chain may fail under impact or repeated loads.

Heating. The chain should be heated to the temperatures given in Table III, and held at temperature for the time specified. The heat should penetrate the work material thoroughly and the top, center and bottom of the charge should reach approximately the same temperature. A sufficient number of thermocouples should be used to assure uniform temperature throughout the charge.

Table III. Annealing Treatment for Wrought Iron Sling and Crane Chains

Diameter of Chain Link, in.	Annealing Temp, deg Fahr	Time of Holding at Temp, hr	Cooling Medium
1/4 to 1/2	1350 to 1375	1/2	Air
5/8 to 1	1350 to 1375	1	Air
1 1/8 to 1 1/2	1350 to 1375	1 1/2	Air
1 5/8 to 2	1350 to 1375	2	Air

Cooling. After the chain has been held at the annealing temperature for the specified time, the charge is pulled onto the cooling platform or onto the floor. The chain should be spread in single layers, with enough space between chains for uniform cooling to room temperature.

After the chain has been annealed, it should be proof tested and reinspected for defective welds and links. By burning off dirt and grease adhering to the chain, the annealing treatment facilitates inspection.

High-Test Steel. The chemical composition of chain made from this material corresponds approximately to SAE 1020. In the heat treated state the average mechanical properties of this material are as follows: tensile strength, 85,000 psi; yield strength, 55,000 psi; elongation, 28%; and reduction of area, 45%. This chain has excellent resistance to impact loading and work hardening, with minimum elongation of 20% at the break. There is no known record of high-test steel chain work hardening to a detrimental degree, so it should never be necessary to heat treat again

Table IV. Breaking, Proof and Safe Working Loads of High-Test Steel Chain

Trade Size, (a) inches	Average Breaking Loads, pounds	Minimum Proof Test Load, pounds	Safe Working Load, pounds
1/4	8,550	4,275	2,150
5/16	12,100	6,050	3,025
3/8	17,100	8,550	4,275

1	97,000	48,500	24,250
1 1/8	121,000	60,500	30,250
1 1/4	150,000	75,000	37,500

(a) Where accurate link dimensions are required, consult the manufacturer.

Table V

Proof and Safe Working Loads of Alloy Steel Chain(a)

Trade Size, inches	Minimum Proof Test Load, pounds	Safe Working Load, pounds
1/4	5,500	2,750
5/16	8,800	4,400
3/8	13,200	6,600
7/16	17,600	8,800
1/2	22,500	11,125
9/16	27,500	13,750
5/8	33,000	16,500
3/4	46,000	23,000
7/8	57,500	28,750
1	77,500	38,750
1 1/8	89,000	44,500
1 1/4	115,000	57,500

(a) Because some manufacturers use material of exact size and some use material 1/32 in. oversize, breaking loads are not given. Where these figures or accurate link dimensions are required, the manufacturer should be consulted.

to remove such effects. Good resistance to low-temperature embrittlement is also characteristic of this chain.

The strength properties of high-test steel chain are shown in Table IV.

Alloy Steel. Material used in the manufacture of this chain is fine-grain alloy steel, and the types in general use contain 0.25% max C.

Exact compositions vary according to the manufacturers' practices, but the types now in use approximate SAE 2320, 4615, 4620 and 8620. When heat treated, these materials develop average mechanical properties, as follows: tensile strength, 125,000 psi; yield strength, 100,000 psi; elongation, 17%; and reduction of area, 60%. Alloy steel chain has excellent resistance to embrittlement at low temperatures.

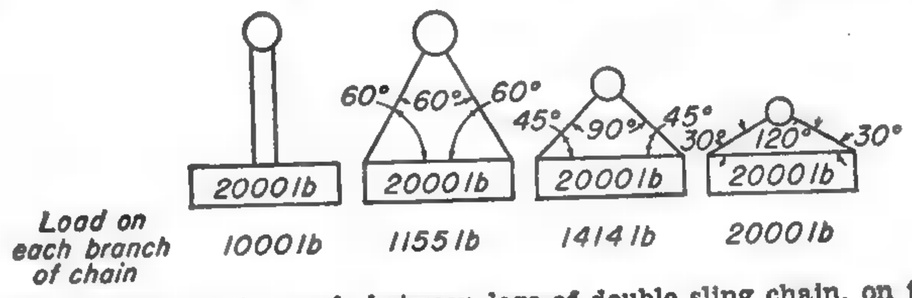

Fig. 1 Effect of the angle between legs of double sling chain, on the load on each branch

This chain also has high resistance to wear because of its hardness, and has a minimum elongation of 15% at break. For all practical purposes this chain is not affected by work hardening.

The proof loads and safe working loads of alloy steel chain are shown in Table V.

General Information

Proof Test. The proof test is the actual load in pounds applied to the complete sling-chain assembly by the manufacturer, before shipment of the chain. This load should not be confused with the safe working load. Usually the proof test is twice the safe working load.

Angle of Sling Chains. The angle between legs or branches of a double sling chain should always be taken into consideration. As this angle increases, the angle decreases between the legs and the piece being lifted. This greatly reduces the safe working load of the chain because, as the angle between the two legs of the chain increases, the tension in each leg is also increased. Thus the tension in each leg varies directly with the sine of the angle between the chain and the horizontal (Fig. 1).

Sling Chain Inspection

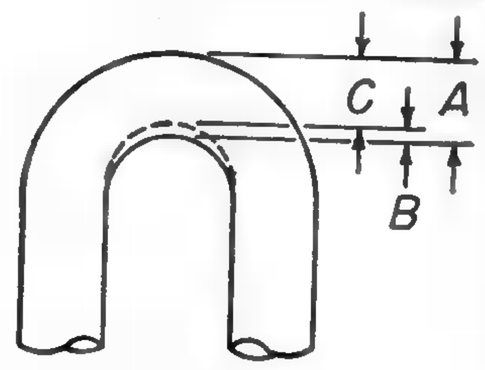
1 For preliminary inspection, hang chain in vertical position, if practical. Chain should hang reasonably straight if links are not distorted.

2 Check for stretch and clearance between the links. Stretch is best indicated by a narrowing of the links. All links should remain entirely free and should have reasonable operating clearance so that the chain remains flexible. If binding or lack of clearance exists, narrow links should be removed. Stretched links are a positive sign that the chain has been overloaded.

3 Check each link for wear by lifting it from its seat and inspecting visually for grooving. If grooving has caused a greater reduction in diameter than that shown in Table VI, the link should be removed.

Table VI. Permissible Wear of Chain

Trade Size, inches	Actual Diameter of New Stock, inches — A	Maximum Permissible Wear, inches — B	Minimum Safe Dimension at Worn Part of Link, inches — C
¼	9/32	1/32	7/32
5/16	11/32	1/32	9/32
3/8	13/32	1/32	11/32
7/16	15/32	1/32	13/32
½	17/32	1/32	15/32
9/16	19/32	1/32	17/32
⅝	21/32	1/32	19/32
¾	25/32	1/32	23/32
⅞	29/32	1/32	27/32
1	1 1/32	1/32	31/32
1⅛	1 5/32	1/32	1 3/32
1¼	1 9/32	1/32	1 7/32



4 Make link-to-link inspection, looking for bent links; cracks in weld areas, shoulders or other sections; scores or markings that would weaken the chain (transverse markings are most dangerous); corrosion pits; lifted fins on either electric or forge welded chain, usually indicating overload; and excessive peening, particularly in iron chain. Check rings and pear-shaped links for all the above faults. Check hooks for opening and for cracks, scores, pits and so on.

5 Unless full and adequate facilities for repair are available, chain showing the above faults should be returned to the manufacturer for reconditioning.

Table VI shows the maximum permissible amount of wear for given sizes of chain.

Care of Sling Chains. A sling chain is one of the most important pieces of equipment in any plant, since it not only lifts and conveys but must also safeguard life and property. Every reasonable care should be taken not to damage, overload or distort the links or attachments. A thorough periodic inspection of sling chains is strongly recommended.

Care should be taken to avoid overloading a sling chain, since the damage caused by this careless operation will greatly shorten the life of the chain and may result in dangerous and costly failure.

It is imperative to avoid impact loading on chains, because great damage to a sling can be done by a relatively small drop of a weight even lighter than the safe working load.

The following precautions should be observed in using sling chains:

1 Take up slack and then start load slowly.
2 Protect sharp corners to prevent damage to chain and load.
3 Keep chain free from twists, knots and kinks.
4 Lift from center of hooks, never from the point.
5 Distribute the load evenly on all legs.
6 Have sling chains inspected and reconditioned regularly.
7 Periodic annealing of iron sling chains has been found beneficial when carefully performed under proper supervision.
8 If iron chain must be used in extremely cold weather, warm it slightly before using.
9 Do not connect two pieces of chain by means of bolts or pins.

Composite Steels

By T. S. Fitch*

A COMPOSITE STEEL has been defined as one that consists of two or more components, of which the smallest comprises at least 3% of the total mass. The components may be joined by casting, welding or other processes.

Characteristics. Using a composite steel may result in one or more of the following advantages: (1) a hard working area with a tough backing, (2) reduction of the cost of material where one of the components is expensive, and the cost of production is not too great, (3) improved resistance to shock, (4) protection against corrosion and oxidation of the surface, (5) special physical properties as a result of combining dissimilar materials—such as thermostatic effect in lead-in wire for electric bulbs, to match the thermal expansion of glass, (6) the possibility of drilling the backing after the article has been hardened, and the possibility of a certain amount of straightening, if warpage has taken place, (7) a damping effect on the vibration of the composite steel as a whole, and therefore less chattering, because each component has a period of vibration of its own.

The chief disadvantage of composite steels, in both production and fabrication, is warpage. This may result from differing expansion characteristics or from an unbalanced arrangement of the components so that the stresses in one section of the piece do not offset those in another section. In many instances the quality of the weld is extremely important, and not all the methods to be described necessarily result in satisfactory welds; the application for which the composite material is to be used, may determine the best method to employ.

Examples of composite steels of various types are shown in Fig. 1 to 6, with typical applications listed.

* President, Washington Steel Corporation, Washington, Pa.

Blacksmith or Forge Weld Method. The "blacksmith's weld" or "forge weld" method is the oldest used for producing composite steels, and is also the simplest, but it is limited to carbon steels and certain low-alloy steels.

The Casting Process. In this method, probably the oldest that has been used for tonnage production, a composite ingot is produced by pouring one metal onto or around another. The technique has many variations, so only the general methods will be mentioned:

1 The earliest application was probably for making "soft-center" plowshares. Molten high-carbon steel is cast about a previously positioned iron insert so that the iron comprises about one-third of the cross section and is located centrally. Since the insert must be reasonably clean, it is usually pickled just before casting. Also the insert should be completely enveloped by the molten metal, because no weld is actually produced in the ingot when one metal is cast around a relatively cold insert. If there is space for air to penetrate between the insert and the cast metal before further working, an excessive amount of oxide will form on the surface of the insert and the cast metal. With carbon steels it is possible to produce a bond even if the insert is not entirely enveloped, but the weld will be somewhat inferior.

In this country, mild steel is cast around cold alloy inserts (particularly stainless steel inserts) as a commercial practice. The process is described in the article entitled "Stainless Clad Steels" on page 545 in this Handbook. It is especially important for the inserts to be as clean as possible when the mild steel is cast and for them to be enveloped completely by the cast steel.

2 There have been attempts to cast metal onto or around a preheated insert. When alloy inserts are heated without some surface protection, in a furnace where gas, coal or oil is burned, a poor weld results.

3 In England, particularly, successful composite steels have been produced by casting one steel into a mold divided by a removable partition. Then the partition is removed and the second steel is cast quickly in the mold. Since both metals are in the fluid or nearly fluid condition, good welds may be produced.

4 It is possible to improve the bonded condition of a composite steel by increasing the surface area of the insert. To accomplish this increase in area, serrations are cut in the insert as shown in Fig. 7.

5 Where the strain on the weld is not great, a satisfactory composite casting can be made by "keying" the insert into the backing. Figure 8 shows how an insert might be cut and held mechanically in the casting.

6 In one of the newest methods the insert is electropickled for removal of all oxide and is then moved wet into a plating bath to obtain a protective coating by electrodeposition. This coating is usually iron because iron is easy to weld onto, produces no zone of weakness as copper would, and also has a high melting point. The electroplated insert is then placed in a mold and the molten metal is cast around it as already described. Excellent welds are produced by this method.

7 In another method, a coating is placed on the side of the mold wall before casting. This coating is composed chiefly of ferroalloy of the desired parent metal plus certain chemicals, so that controlled cladding ($\frac{1}{64}$ to ½ in. thick) results when the molten metal is cast into the mold. This method can also be adapted so that cladding can be placed on previously cast or forged articles.

The casting method, ordinarily the least costly, is generally convenient for tonnage work and permits production of sections irregular in themselves or containing irregular inserts.

The Cementation Process. The cements used in this process are, in many instances, complicated combinations in which the basic constituents are iron filings, silicomanganese, ferrosilicon, nickel and borax. Some of these cements are so effective that it is necessary merely to squeeze out the excess, and after the cement has hardened, a good bond results. For large sections, a heavy press is advisable, but for small tools (such as tool bits for lathes) the components may be squeezed with a pair of tongs and held until cold. These cements require temperatures in the vicinity of 2300 F. The producers recommend that the surfaces be machined before cementation.

One of the latest refinements of this general process has been applied for combining nonmetallic material with metallic claddings; for example, wallboard is made with a thin cladding of stainless steel by putting a special cement on the nonmetallic surface, placing the stainless steel sheet thereon and then sending the cemented materials through rolls to bond the two components together.

Fusion Welding Processes. Whenever more than about 3% of one metal is deposited on the surface of a steel base metal by fusion welding, the resulting article is a composite steel. Certain types of articles that are made in this way are described under the title "Facing or Surfacing by Welding", in this Handbook; production of other composite steels by fusion welding is discussed below.

When the components are small enough, the penetration of the welding heat may be sufficient to produce a strong joint between them. For example, in the making of composite die sections it may be desirable to weld a piece of steel 1 by 1 in. to a section of mild steel 1⅛ by 2¼ in., as indicated in Fig. 9. The welds are made along the lines *AB* and *CD* and, with proper control of the arc, good fusion may be effected to a depth of ½ *AC* during each welding operation; thus the finished section will be completely fused throughout the weldable plane *ABCD*.

Electric resistance welding has been adapted successfully to the making of composite hacksaw strips. Low-voltage, high-amperage current is conducted through rolls to the mild steel strip and the high speed steel strip, which are held firmly together by the rolls (Fig. 10).

For applications in which a cheap steel is faced with an expensive alloy that resists corrosion or heat, such composite steels are often produced by "spot welding" one to the other. The result is a large number of welded spots

surrounded by nonwelded areas; consequently the material is held together less securely than a composite sheet or plate having a homogeneous welded condition.

The Assembly Process. This method consists in joining together prefabricated bars or plates and then subsequently reworking the assembly to the desired finished form. For a complete description of this process, the reader may refer to the article entitled "Stainless Clad Steels" on page 545. This method is advantageous in many instances because of greater flexibility, when used for small quantities, than with any of the casting methods; also the relative proportions of the components can be controlled more accurately. Generally the assembly process is somewhat more costly than the casting process.

Backings. Only recently has special consideration been given to the backing materials used in the production of composite steels. The problem is complicated by conflicting requirements, especially where the insert is placed so that it is likely to pull the bar out of shape. An important consideration is the desired mechanical characteristics of the backing material in the finished article; for example, a composite hacksaw steel should have a backing component that is as tough as possible without becoming too hard during the hardening of the blade; whereas a composite stainless plate should ordinarily have a soft back that may be readily formed. For an article that is to be heat treated, it would be ideal for the two alloys of the composite to have the same coefficient of thermal expansion, in order to eliminate warpage. From the producer's viewpoint it would be ideal if the two metals had equal rates of elongation so that the composite product could be worked similarly to solid steels.

SAE 1020 is the steel most often used for backing. This alloy is relatively inexpensive, easily obtained, readily formed even after hardening, and comparatively simple to weld. However, if a fairly tough backing steel is preferred, then SAE 1020 is not the best type. Its coefficient of expansion differs appreciably from that of the alloys customarily used for inserts, which means difficulty in any heating or cooling operation; the rate of elongation is more rapid than that of the usual insert alloys; and enlarged grains develop when the composite product must be annealed after working. In spite of these drawbacks, SAE 1020 has been and probably will continue to be the usual commercial backing for most applications.

In instances where the comparative coefficients of expansion are most important, a silicomolybdenum steel (0.10% C, 0.20% Mn, 1.50% Si, 0.50% Mo) has proved satisfactory. Also SAE 2340 has given good results. The coefficients of expansion of these steels are more like the coefficients of tool steels, particularly high speed steels, than are the coefficients of any other relatively inexpensive steels that have been tried.

For applications such as chipper knives when the knife must have a tough backing component to absorb severe shocks, the following composition has proved excellent: 0.28 to 0.34% C; 0.45 to 0.65% Mn; 0.35 to 0.55% Si; 0.020% S and P max; 0.85 to 0.95% Cr; and 0.20 to 0.25% V.

For applications such as hacksaw blades, where it is desirable to produce some hardening effect in the backing steel, the following composition has proved satisfactory: 0.42 to 0.50% C; 0.50 to 0.65% Mn; 0.20 to 0.40% Si; 0.020% S and P max; 1.25 to 1.45% Ni; and 0.50 to 0.65% Cr. After proper hardening, this alloy affords a backing that has springiness and superior resistance to abrasion. It is somewhat more difficult to weld properly, but this disadvantage can be overcome by the proper choice and adaptation of method.

Heat Treatment. The difficulties in the heat treatment of composite steels depend on where the inserts are located, relative proportion of inserts to backing component, relative composition, and suitability of equipment. Considerable experience is usually necessary before fully satisfactory results are obtained, but a composite steel can usually be straightened somewhat after hardening and tempering.

Design. The location of the inserts is important only when the coefficients of expansion differ. If a tool steel and backing steel had the same expansion rate, the warpage would be no worse than on a solid piece of either steel. When the insert is placed symmetrically within the mass of the composite cross section, there is no abnormal warpage, because the deformational stresses offset one another; for example, a composite bar that has a high-carbon, high-chromium alloy steel center uniformly surrounded with SAE 1020, will not pull out of shape during heat treatment. When the insert is along one edge or covers one flat surface entirely, the composite steel may bow; when the insert is in one corner, the bar may be pulled out of shape in two directions, so this form is the most difficult to heat treat.

Relative Proportions. The smaller the amount of tool steel in comparison with the amount of backing, the less will be the likelihood of warpage.

Relative Compositions. The greater the difference in the thermal properties of the component metals, the greater will be the warpage during heat treatment. Since the thermal properties are determined primarily by the composition and also depend somewhat on grain size, it is obvious that the relative compositions are important.

Air Cooling. Any composite steel made of materials that can be cooled in air, may be held straight in a press after being removed from the furnace. In some instances, particularly where the insert is in one corner, a special die with a groove is made for the press so that the bar is sure to be straight lengthwise as well as flatwise.

Multiple Heat Treatment. Small composite sections are heat treated best in pairs. About the maximum convenient size is ⅝ by 6 in. Bars larger than this have too much distortional strength. To hold them, such large clamps would be required that handling would be inconvenient, and unless the clamps were carefully designed, nonuniform heating might result. The intention of this multiple heat treating method is to arrange the bars within the group in such a way that the stresses will offset one another. A typical example is shown in Fig. 11.

Presetting Method. In this method considerable experience is required in learning precisely how much and in what direction to deform the bar before heat treatment, so that the stresses during treatment will cause the bar to return to adequate straightness. This method is not recommended when the insert comprises 40 to 60% of the mass.

The section should be treated so that, after tempering, the insert will be convex. The material may be straightened when the tool steel is under compression because the backing steel will elongate readily.

Annealing and Normalizing. The simplest method of producing composite steels in which the insert mass is unsymmetrically arranged in the backing, is to make the assembly or ingot twice the size of the finished form so that the stresses will offset one another at least partially. Two typical forms are shown in Fig. 12.

Testing. Because of the presence of materials with dissimilar characteristics, composite steels present a peculiar and often difficult testing problem. It is not feasible to prescribe testing methods that will apply in all instances, because of the numerous modifications in composite steels. The following comments are intended to be helpful in establishing and interpreting tests.

The simplest method of testing the welded condition is the bend test. For material clad on one side it is recommended that one piece be bent with the cladding on the outside and a second piece with the cladding on the inside of the bend. It is advisable to bend every piece back again, because an improperly welded composite steel may bend one way without showing a fracture at the weld.

A more severe and reliable test of the welded condition may be made by pulling a specimen that has been prepared as shown in Fig. 13, in a tension-testing machine.

Welded flat specimens for the tension test may be pulled satisfactorily and the results will usually be found reasonably accurate. In round specimens that are machined from bar stock, the proportion of inserted material to backing material may be changed by machining. Allowance should be made for this in evaluating results.

The reliability of the various methods of hardness testing depends chiefly on the thickness of the piece to be tested. Samples $\frac{3}{16}$ in. or thicker may be tested safely by Rockwell hardness-testing devices or by any of the testing machines that incorporate the drop-and-rebound principle, such as the scleroscope. Samples thinner than 0.0625 in.

are tested best on machines of the drop-and-rebound type. Actually the surest practice is to grind or otherwise remove all the steel except where the hardness is to be tested.

In making cup tests on specimens of clad sheet and strip, there will be some variation, depending on the direction in which the cup is drawn; if the insert material is on the inside of the cup, the draw tends to be better. The reason for this is that the soft backing material supports the harder insert material during the draw. Users who wish to determine the drawing properties, should draw the material so that the stainless steel is on the same side as in the finished product. When reporting cup tests, it should be stated whether the cladding was inside or outside.

General. Two methods are in common use for indicating the location and extent of the insert in a composite steel—acid etching and heat coloring. A warm 50% nitric acid solution will reveal the insert in approximately 30 sec. The acid may be washed off with warm water; and lacquer, oil or vaseline may then be put on the etched plane to protect it from subsequent corrosion. Heat coloring is often used when the insert is a tool steel or SAE steel that can be turned straw-color or light blue if the end is exposed to a temperature that does not affect adversely the structure of any of the components. The colored plane should be protected with lacquer, oil or vaseline. Heat coloring renders the insert more readily visible but is not so fast as the acid-etch method.

When any machine work is done on a composite tool steel before heat treatment, a hardening effect results and thus a strain is set up. This strain is relieved preferably by normalizing before the hardening process. The warpage during hardening and tempering may thus be reduced. This machine strain is not a serious factor on short sections. 18 in. or less.

During fabrication, composite steels have decided advantages. For example, a tool steel composite bar may be 25% tool steel, and the remainder soft steel that can be machined more quickly. Composite steels in which the inserted material is symmetrically arranged, may be cold drawn faster. Clad plates can be bent or formed more readily than solid material of the same composition.

The fusion welding of composite steels (not referring to the production of the composite steel itself) requires special precautions:

1 Because of the tendency of the alloying elements in the insert to migrate into the unalloyed steel, it is well to select a welding rod that has higher alloy content than the insert steel; this tends to replenish any loss resulting from migration.

2 In electric-arc welding, the amperage should be maintained as low as efficient because excessive heat may admix the backing and insert steels. In high-alloy composite steels, the carbon in the tool steel might be reduced sufficiently to impair the desirable properties; also the backing might be embrittled locally by carbon enrichment.

3 Thick composite steels (⅜ in. or more) should be beveled away from the insert; then a small bead is laid down along the abutting insert edges, the two plates are turned over, and the back is filled in with whatever rod suits the conditions.

4 In the stainless clad steels a stabilizing element such as titanium or columbium should be added to the stainless composition to avoid intergranular corrosion in subsequent welding; thus annealing can be eliminated after welding.

5 High-grade electrodes of the shielded-arc type, or gas filler rods are recommended.

A skilled operator with suitable equipment can soon learn to weld composite steels satisfactorily.

Stainless Clad Steels

By L. C. Grimshaw*

PLATES and sheets of mild steel faced with stainless steel have been produced commercially for about ten years. The layer of stainless steel usually constitutes 10 to 20% of the thickness of the plate or sheet; either one or both sides may be coated. Such clad steels have been developed largely to reduce the cost of stainless plates, particularly for the many applications where only one side of the plate needs to be stainless.

Strength of Bond. The bond between the mild steel and the stainless "cladding" must be strong enough to withstand stresses incident to fabrication into the finished product. Stainless clad steels are produced that can be bent, spun into deep heads, and deep drawn without damage. Often the bond must be strong enough to withstand great stresses caused by a difference of expansion between the stainless facing and the backing when the material is heated and cooled repeatedly.

Methods of Bonding. Two clean pieces of mild steel will weld together readily if hammered while being heated. High-carbon steel and mild steel can be welded similarly though less easily, and usually with the aid of a flux. Indeed, the first commercial use of laminated steel was probably such a combination used for turning plows, manufactured by John Lane in 1868.

Nickel and mild steel, and copper and mild steel, can be welded together by heat and pressure alone. High-alloy steels cannot be successfully welded to mild steel by this method without considerable modification; they were first successfully welded by "casting on", a method relatively old, and often referred to in technical publications at the turn of the century.

Casting. Stainless clad sheets and plates are produced successfully by casting methods. In one casting method, two cleaned sheets of stainless steel are placed face to face with a separating material between them, and are fusion welded together around the edges. These two sheets are then set upright in a mold, and mild steel is poured all around them. The composite ingot is hot rolled until it has received the desired amount of reduction; the edges of the rolled composite plate are trimmed off and it separates into two sheets, each clad on one face with stainless steel.

Temperature control during casting is important. Since there is oxide on the surface of the stainless steel insert in the ingot, no effective weld can be made until this oxide is broken up by elongation into small islands.

Because of the fusion weld required in their fabrication, it is important from an economic standpoint that the clad plates be made large in size. There is a limit to the amount of reduction that can be given by hot rolling before the material between the two stainless sheets fails to separate them because of thinning out. The above method has been used to produce plates as thick as 1¼ in., but only of small size (1500 to 2000 lb) and not thinner than 18 gage.

A different method for producing stainless clad plates by casting is said to be used successfully in England. Grooves are cut in opposite sides of a mold, in such a position that a spacer plate slid down in these grooves divides the mold in a ratio of about 3 to 1. Mild steel is cast into the larger space. After a short time the spacer plate is withdrawn and stainless steel is cast into the remaining space. After cooling, two such ingots are surface ground, and their stainless faces are placed face to face with separating material between them. "Straps" of mild steel are then fusion welded all around the sides to hold the two-high assembly together. The assembly is then heated, rolled, and separated into two clad plates by shearing off the edges.

This method would seem to be subject to all the limitations of the first casting method described above.

Facing With Weld Metal. A method now in the early stages of development appears to be especially suitable for the production of thick plates in which the stainless steel may well be much less than 10% of the plate thickness. The stainless steel (usually 18–8) is deposited on

* Metallurgical Engineer, Composite Steel Division, Jessop Steel Company, Washington, Pa.

the mild steel slab from electrodes. This forms a good weld, and only enough hot rolling need be given to the slab to eliminate the cast structure of the stainless steel; to facilitate discovery and elimination of pinholes in the deposit; and to smooth the surface.

Other Welding Methods. In another method of bonding, a thin sheet of iron, placed between the stainless and the mild steel, is fusion welded around the edges to prevent scaling, and is then heated and hot rolled. The thin sheet of iron is said to have a beneficial cushioning effect, and after a great deal of elongation by rolling, a satisfactory weld can be made. Oxides are troublesome, and the results are too uncertain for this method to be used commercially. No matter how carefully stainless steel is cleaned, it becomes covered with an invisible oxide film as soon as it is exposed to air, and before a weld can be made, the oxide thus formed must be broken into small islands by elongation during rolling. It is undoubtedly easier to weld stainless steel to iron of low carbon content than to iron of high carbon content. A variation of the method above would be to decarburize the surface of the mild steel before attempting to make the weld, and to leave out the thin piece of sheet iron. A zone of pure iron in the weld is a zone of weakness, and should be reduced as much as possible.

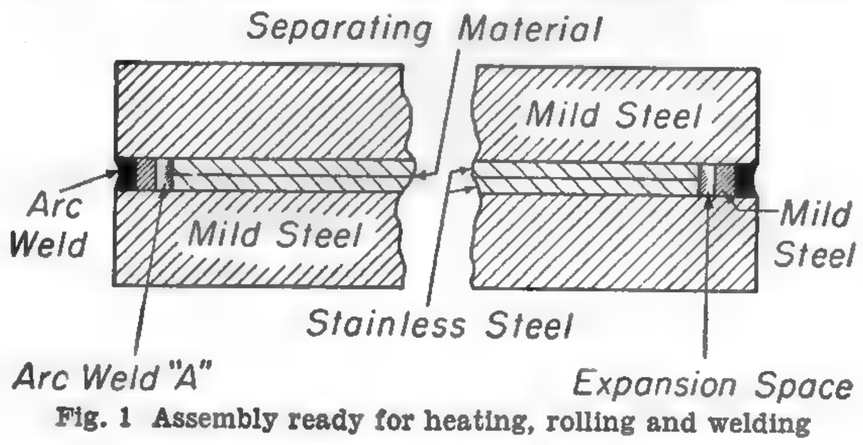

Fig. 1 Assembly ready for heating, rolling and welding

A commercial method that is used increasingly, produces a good weld after the invisible oxide film has been removed from the stainless steel by anodic pickling in hydrochloric acid. Electrolytic iron is then deposited on a chemically clean surface. Iron plating is begun while the stainless steel is still wet with acid and free from oxide film. The iron plating is usually about 0.012 in. thick. Any kind of steel plated in this manner with electrolytic iron will weld to mild steel if heated and rolled. When stainless clad plates are produced commercially by this method, "separating material" is placed between the juxtaposed faces of two sheets of stainless steel, and a watertight fusion weld is made around the edges of the sheet. The unit is then pickled, iron plated and placed between two thick plates of mild steel. This assembly is fusion welded together around the edges, both to hold it together as a unit during hot rolling and to exclude air that would cause scaling on the surfaces to be welded. It is then heated and hot rolled. During the first pass a weld is made; then rolling is continued to produce plates of the desired size. The composite assembly behaves like mild steel, and may be cross rolled if necessary to increase the width. When the edges are trimmed off, the composite plate separates into two plates, each clad on one face with stainless steel.

If the stainless steel is austenitic (the 18–8 variety) it will expand a great deal more than the mild steel when it is heated for rolling, and so must be left free to expand laterally between the mild steel plates. Such an assembly ready for heating, rolling and welding, is shown in Fig. 1. No expansion space is needed for martensitic or ferritic stainless steels.

During hot rolling, even with little reduction, an excellent, oxide-free weld is made. Diffusion soon eliminates the zone of electrolytic iron in the welded plate, since this zone is less than 0.002 in. after 12 to 1 reduction of the two-high assembly. Diffusion is rapid while the plate is hot. Such plates may be spun readily into deep heads, or may be drawn.

Stainless clad plates are produced successfully also by iron-plating stainless steel in the above manner, and casting mild steel around it. The surface of the stainless steel is as free from oxide as in the assembly method, and it is more satisfactory to cast mild steel against the iron plating than against the stainless steel itself.

Separating Material. In most of these methods, whether by casting or assembling, it is common practice to prepare a "sandwich" with mild steel outside, stainless sheets inside, and separating material in the center. The "sandwich" is held together as a unit either by an excess of cast metal or by fusion welding the edges. The difference in the hot working properties and in expansion of the stainless and mild steel tends to produce curled plates. By rolling as a "sandwich", curling is prevented. Hot rolling of single clad sheets is not done unless the finished sheet can be straightened cold. Hot straightening is impracticable, since the straightened sheet curls again when cooling, particularly if clad with 18–8 stainless steel.

The separating material used in two-high assembles is commonly a mixture of aluminum oxide and lacquer, spread like paint thinly and evenly over the steel surface. The lacquer dries in a short time, leaving the fine oxide powder adhering to the steel. Any inert oxide can be used, but sodium silicate should not be substituted for lacquer unless all moisture is driven off at a high temperature before the sheets are assembled for rolling.

Resistance Welding. Another commercial method of making stainless clad plates is to bond a stainless sheet to a mild steel plate by a special method of resistance welding. The electric current does not pass through the thickness of the mild steel plate; instead it passes from one spot on the stainless sheet through the surface of the mild steel to another spot on the stainless sheet only a short distance away. This method bonds by means of a great number of resistance welds, placed close to one another all over the sheet. Such a sheet is never rolled except in forming rolls. The bond, though discontinuous, is strong enough to withstand the stresses incident to heat treatment and to fabricating into spun heads. By this method composite plates of any convenient size are produced, and thick plates are covered with a protecting sheet of stainless steel, far less than 10% of the plate thickness. Many large tanks, cracking vessels and chemical towers have been made in this way.

Uses of Stainless Clad Steels. Stainless clad steel may be useful either because of lowered cost (in comparison with solid stainless steel), improvement of physical properties, or both. Lowered cost seems obvious, but is actually difficult to attain. The stainless sheets used for cladding must have at least one perfect surface and must be flat. The mild steel plates must also be flat if the assembly method is used. The fusion welding of an assembly is expensive, and stainless rod must be used for weld *A* (Fig. 1). If casting is used, there is waste by trimming.

Since clad plates are rolled in pairs, one clad plate is always left over when only a single clad plate is desired.

However, many clad sheets are used because of the physical properties obtained. If the weld is a good one, cooking vessels such as those used in the varnish, canning, and soap industries are best when made of stainless clad steels; for although the inside of such vessels is required to be stainless, a solid stainless steel vessel is subject to hot spots and low heat conductivity. The clad vessel combines the stainless surface with the excellent heat conductivity of mild steel.

The 12 or 28% Cr ferritic stainless irons are often desired for use, but they are difficult to fusion weld. This problem is solved by substituting ferritic stainless iron as cladding on mild steel, and such clad steels are finding increasing applications.

Austenitic steels, such as 18-8, have a coefficient of expansion greater than that of mild steel, so for stainless clad plates used at elevated temperatures the bond must be good. The high quality of many commercial bonds is proved by the wide use of such material at elevated temperatures. If the fabrication of the steel vessel requires fusion welding, and intergranular corrosion is feared, an 18-8 steel that contains a stabilizing element is advisable, because a stabilizing heat treatment at 2000 F is undesirable when applied to the mild steel backing, and would also probably warp the vessel.

Nickel and Nickel-Alloy Clad Steels

By W. G. Theisinger* and F. P. Huston*

NICKEL-CLAD steels are composite materials consisting of a base of open hearth steel that has a layer of pure nickel or an alloy of nickel and chromium bonded to it on one or both surfaces.

The composite plate is formed by pressure-welding the clad material to the steel slab in a rolling mill at a temperature of about 2200 F. Thorough cleaning and protection of the bonding surfaces during heating insures an intimate bond between the cladding and the base plate. A reduction ratio ranging between 8 to 1 and 16 to 1 is generally used. A solid solution of nickel and iron is formed at the junction of the two metals.

The ratio of the cladding material to the base plate is usually expressed as a percentage of the total thickness of the composite plate. For example, a ½-in. plate clad 10% on one side only, consists of about 0.45 in. of steel and about 0.05 in. of pure nickel; a ½-in. plate with 20% cladding, consists of about 0.10 in. of pure nickel and 0.40 in. of steel. The same order of thicknesses of cladding is produced for plates clad on both sides. It is the usual practice when cladding both sides to use an equal thickness of either nickel or the nickel-chromium alloy, although different thicknesses may be applied. For special purposes plates may be obtained that are clad on one side with nickel and on the other side with the nickel alloy. Nickel-clad steels are regularly supplied with standard claddings of 5, 10, 15 and 20%, with flange-quality steel that has a minimum tensile strength of 55,000 psi, as the standard base metal.

Properties of Pure Nickel for Cladding. The modulus of elasticity of commercially pure nickel is 29,000,000 to 30,000,000 psi, which is essentially the same as for steel, and the hot working range is likewise similar to that of steel. The coefficient of expansion of nickel is close to that of steel.

The fact that the modulus of elasticity of nickel is the same as that of steel is important in a composite material such as nickel-clad steel plate and insures equal distribution of stress across the section of the plate with no sudden change at the interface between nickel and steel.

Properties of Nickel-Clad Steel. Results obtained from an 8-in. tensile test specimen of nickel-clad steel ½ in. thick and with 10% cladding are as follows:

	Tensile Strength, psi	Yield Point, psi	Elongation, % in 8 in.	Reduction in Area, %
Clad	60,600	40,400	30.0	57.2
Plate	60,800	40,200	30.5	59.0

To determine the value of bond between the nickel and steel, a clad surface was placed at right angles to the striking face and with one blow of a power hammer a 1-in. cube, with one face clad 20%, was flattened cold to ⅜ in. in thickness without rupturing the bond. To test the strength of the bond after sudden changes of temperature, a 10% clad plate (18 by 9 by ½ in.) with stiffeners welded to the steel side was heated to 900 F and quenched in water at room temperature. No separation of the nickel layer occurred after quenching 30 times.

Treatments for Nickel-Clad Steel. Cold bending, flanging, forming, beveling and the like, can be carried out readily on nickel-clad steel. Ordinarily, and especially when shearing and punching, the nickel side should be up so as to prevent damaging the surface and to throw the burr on the steel side.

Annealing. Annealed plate is required for severe cold working operations; for example, in pressing heads and die work. To anneal, heat the plate between 1650 and 1750 F, hold at temperature from 1 to 3 min, and allow the plate to cool in the air.

A fuel of low sulfur content (not more than 0.5%) should be used to prevent embrittlement of the nickel layer. A covering of lime on the nickel surface is helpful.

Heating. When nickel-clad steel is heated, either for annealing or for hot working, the plate is charged into the furnace, which is at temperature. The atmosphere should be reducing and the flame should not strike the surface.

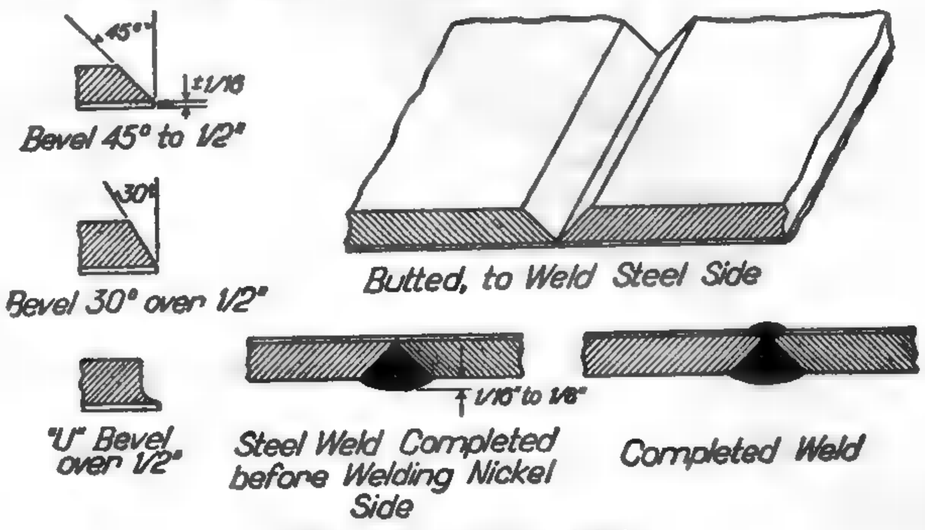

Fig. 1 Beveled butt joints

Hot Working. The hot working of nickel-clad steel entails no unusual difficulties if the proper conditions for heating are maintained. No change need be made from the usual practice for steel, in regard to temperatures, amount of work done on each heat, or the general methods used in performing the work.

Joining. Nickel-clad steel plates and heads may be joined to form pressure vessels and tanks by gas or electric welding, or riveting and calk welding. With all methods, the nickel surface should be made continuous by welding all junctions in the nickel side of the joint with nickel filler metal. In general, the resistance of such welds to corrosion is not inferior to that of the nickel surface.

Table I. Tension and Bend Tests of Welds

	Tensile Strength, psi	Yield Point, psi	Elongation, % in 2 in.
Full section	65,300	40,700	25.0
Reduced section	59,800	40,300	22.2
Bend Tests			
Steel weld, outside surface	31.0% elongation in 1 in.		
Nickel weld, outside surface	37.0% elongation in 1 in.		

Metal-arc welding is the method generally used. The plates are beveled as shown in Fig. 1, and the vessel is assembled by "tacking" on the steel side. The weld on the steel side is then made with a covered steel electrode; no change from standard practice for welding plain steel is required. A narrow groove on the nickel side is then chipped to a depth at which the chip no longer shows parting. The width and depth of the groove vary with the thickness of the cladding layer, but should be kept to a minimum. The width is usually ¼ in. and should never exceed ⅜ in., even in 1-in. plate. The welding on the nickel side is done with coated nickel electrodes. If two beads are required, the slag should be completely removed from the surface of the first bead before the second is deposited. Butt welding is most commonly used, though the lap and the butt-and-strap joint are also used.

Because carbon-arc welding is necessarily slow, this method is used only occasionally for welding nickel-clad steel, but it yields strong, dense welds of high ductility.

Acetylene welding gives satisfactory joints in nickel-clad steel and no change from regular procedure is needed in welding the steel side. However, in welding the nickel side it is important to maintain a slightly reducing flame, since the intense flame that yields entirely satisfactory welds in steel gives brittle and spongy welds in nickel. Bare nickel wire for gas welding is used without flux.

* Manager, Technical Plate Sales, Lukens Steel Company, Coatesville, Pa.
* Development and Research Division, The International Nickel Company, Inc., New York.

Nickel-clad steel may be welded in all positions encountered in erection work by any of the methods mentioned. In vertical welding it is advisable to start the weld at the top and work toward the bottom rather than the reverse.

Welds in nickel-clad plate meet the requirements of the ASME Boiler Code. Samples of plates welded as described above were stress relieved at 1150 to 1200 F and gave the results shown in Table I.

Design. A continuous nickel surface should be maintained in the fabrication of pressure vessels and other equipment. Jackets are welded or riveted to clad vessels and any type of bottom outlet, either in solid nickel or nickel-clad steel, may be attached. Forged, tapped welding flanges in solid nickel are used. Virtually any formed shape obtainable in steel is obtainable also in the nickel-clad material. The material responds readily to hot spinning, hot and cold pressing, and hand shaping.

Nickel-Chromium Clad Steel. The alloy containing 78 to 80% Ni, 12 to 14% Cr, and 6 to 8% Fe, combines a high degree of resistance to corrosion with high strength and good working properties.

Nickel-chromium clad steel and nickel-clad steel are manufactured similarly, can be fabricated with the same facility and can be welded by similar procedures. In welding the clad surface of the plate, a covered electrode containing 80% Ni and 20% Cr is used. This insures deposited metal of approximately the same composition and resistance to corrosion as the cladding.

Nickel-Copper Clad Steel. The alloy containing 67% Ni, 30% Cu and 1 to 2% Fe, combines several desirable features of both nickel and copper under corrosive attack.

Nickel-copper clad steel and nickel-chromium clad steel are manufactured similarly, can be fabricated with the same facility and welded by comparable procedures. In welding the clad surface of the plate, a covered electrode of approximately the same composition as the cladding is used.

Copper-Covered Steel Wire

By L. C. Whitney*

ENGINEERING requirements often demand a combination of properties in a material that is not found in any single common metal or alloy. Copper-covered steel wire is an example of this. The copper exterior provides high electrical conductivity and good resistance to corrosion, and the steel core allows the development of tensile strengths considerably above those attainable in hard drawn copper and bronze wires.

To produce this material, a round steel billet with its surfaces properly prepared is preheated in a mold, and molten copper is poured around it. After solidification, the composite billet is hot rolled to a rod, which is then heat treated or annealed and drawn into wire of the desired size.

The casting of molten copper around a heated steel billet with properly prepared surfaces produces a weld between the two metals. This weld withstands subsequent heating, hot rolling, and cold drawing; the finished wire may be bent, twisted or deformed without causing a separation of the two metals.

This composite wire is produced commercially in two grades based on the electrical conductivity of the material. They are the 30% and 40% grades, a designation which indicates the electrical conductivity as a percentage of that of a solid copper wire of the same cross-sectional area. The electrical resistance, measured on each coil, is less than the limits shown in Table I.

* Chief Metallurgist, Copperweld Steel Co., Glassport, Pa.

Table I. Electrical Resistance of Copper-Covered Steel Wire

Rated Conductivity	Max Average Resistance for Entire Coil, ohms per cir mil-ft at 68 F	Max Resistance for Any Part of Coil, ohms per cir mil-ft at 68 F
30%	35.26	39.18
40%	26.45	28.59

In addition to the two grades having specified conductivities, two other grades are based on the tensile strength of the wire. These are designated as "high-strength" and "extra high-strength" grades. Detailed information on the properties of individual wire sizes is given in Table II.

To insure a uniform coating of copper of the desired thickness on the wire, all coils are tested with a magnetic testing device which measures the thickness of copper accurately at any given point. By means of such equipment, it is possible to guarantee a minimum thickness of copper at any point around the circumference of the wire.

Physical and electrical constants and specifications for copper-covered wire are as follows:

Average weight of wire. 8.15 ■ per cu cm at ■ F. (Equivalent values are 3.533 lb per in.-ft and 0.002775 lb per cir mil-1000 ft)

Coefficient of linear expansion. 0.0000072 per ° F

Temperature coefficient of electrical resistance for wire. 0.0021 per ° F

Modulus of elasticity. 24,000,000 psi

Corrosion-Resistant Castings

By E. A. Schoefer*

CASTINGS are classed as corrosion-resistant if they are capable of sustained operation when exposed to attack by corrosive agents at operating temperatures that create metal temperatures lower than 900 F. Ferrous alloy castings for such service fall into the following groups: iron-chromium ("straight chromium" alloys); iron-chromium-nickel (chromium in excess of nickel); and iron-nickel-chromium (nickel in excess of chromium).

Nickel-base and other nonferrous alloys also employed for their resistance to corrosion, are discussed elsewhere in this Handbook. The ferrous castings used for corrosion resistance include many alloys of the same general type as those used for their resistance to corrosion or structural damage at elevated temperatures above 900 F. As a rule, such heat-resistant alloys contain considerably more carbon than the corrosion-resistant grades, but the distinction between the classes is rather vague and there is overlapping in the temperature range from 900 to 1200 F. Thus, the terms "corrosion-resistant" and "heat-resistant" are relative and are arbitrarily differentiated by the operating temperature of the material.

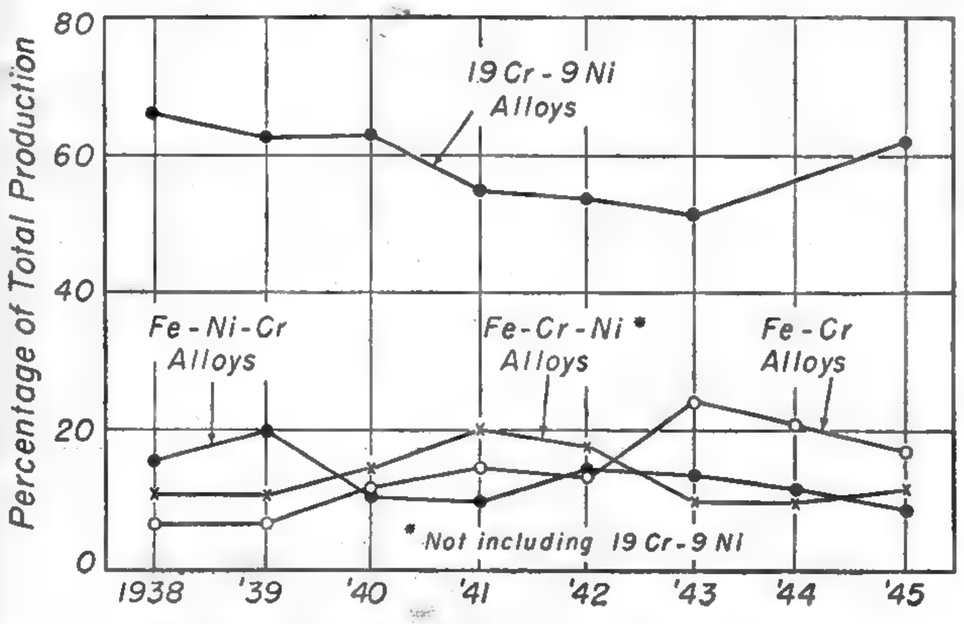

Fig. 1 Production of corrosion-resistant castings (Alloy Casting Institute)

Corrosion-resistant castings, as defined, are used in equipment for chemical plants, food processing, oil refineries, textile mills, pulp and paper mills, sanitation, building construction, transportation, and miscellaneous services that involve handling corrosive substances.

Alloys that contain from 18 to 22% Cr and 8 to 12% Ni are by far the largest group of corrosion-resistant castings. The straight chromium compositions are also produced in considerable quantities, particularly the hardenable alloys that contain from 11.5 to 14.0% Cr. Other alloys with chromium in excess of the nickel content are used for special service conditions, as are the alloys that contain nickel in greater amounts than chromium. A summary by percentage of total production for each of these groups in recent years is shown in Fig. 1.

General Physical Properties. Mechanical properties are given in the descriptions of the individual alloy types. Table I shows mean coefficients of thermal expansion, moduli of elasticity in tension, and densities.

Manufacture. Castings produced in the various compositions for resistance to corrosion, may be made from heats melted in electric-arc furnaces with either acid or basic linings; or in high-frequency induction furnaces with acid, basic or amphoteric linings. The production of sound, satisfactory castings requires care, especially when the

* Executive Secretary, Alloy Casting Institute, New York

castings are to be used under pressure, and foundries producing such castings have developed special techniques for this work. Castings may be made by the static method, by centrifugal pouring, or by precision casting (*see* article entitled "Precision Casting", page 54).

Heat Treatment. Castings used for their resistance to corrosion are almost always subjected to heat treatment. For the hardenable ferritic-martensitic straight chromium compositions, the heat treatment is primarily for the purpose of obtaining desired mechanical properties. Austenitic alloys, such as the 19% Cr, 9% Ni type, on the other hand, are heat treated to increase their resistance to corrosion. These latter alloys are usually heated to a temperature of 1900 to 2100 F and are quenched rapidly in air, water or oil in order to ensure the solution of carbides. When the alloys are quenched from 1900 F or higher, it is most important that a rapid cooling rate be maintained through the range 1600 to 1000 F, since in this range carbides may precipitate along the grain boundaries, thus making the alloy subject to intergranular corrosion.

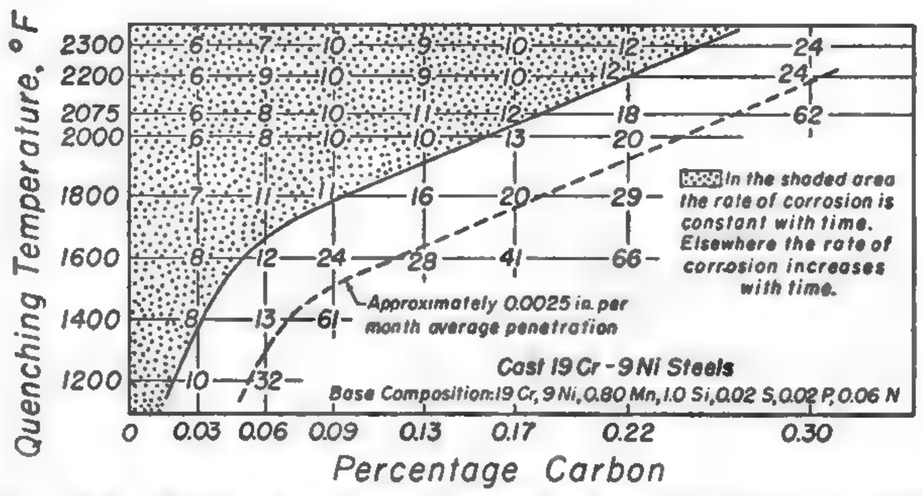

Fig. 2 Effect of carbon content on resistance to corrosion in boiling 65% nitric acid. Specimens were quenched in water after ½ hr at the temperatures indicated. Numbers on the graph indicate the penetration in ten-thousandths of an inch per month, calculated from the average loss in weight during five 48-hr periods in boiling nitric acid. (See Reference 1 for details, including micrographs of the alloys.)

Heat treatment for the 12% Cr alloy castings usually consists of air cooling or oil quenching from about 1800 F, and then tempering between 600 and 1400 F, depending on the final properties desired. Tempering at about 900 F results in a marked loss of impact resistance.

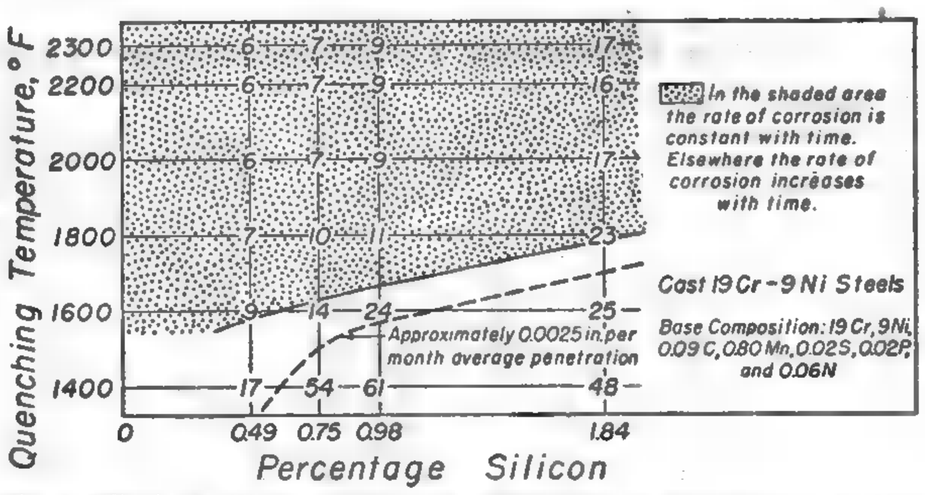

Fig. 3 Effect of silicon content on resistance to corrosion in boiling 65% nitric acid. (See caption for Fig. 2.)

Proper quench-annealing of the 19% Cr, 9% Ni alloys produces desirable carbide-free structures. Such structures render the alloys immune to intergranular attack as long as the metal is not exposed to temperatures in the carbide precipitation range from 800 to 1600 F. The quenching temperatures required depend on the carbon and silicon contents of the alloy. If molybdenum is present, it must also be considered in determining the quenching temperature that will result in a carbide-free material. Figures 2, 3 and 4 show the relations between rates of corrosion in 65% boiling nitric acid, the microstructures, the quenching temperatures, and the carbon, silicon and molybdenum contents, respectively, of a series of 19% Cr, 9% Ni alloys. The solid curves on these charts form the boundary between alloys with constant rates of corrosion and those with rates that increase with time. All alloys to the left and above the broken curves have average rates of corrosion slower than 0.0025 in. per month, as measured by five 48-hr test periods in boiling nitric acid. In general, it is advisable to select a quenching temperature that is somewhat higher than indicated by the solid line for the composition under consideration.

Where castings are to be welded without subsequent heat treatment, the injurious effect of carbide precipitation that results from the heat of welding, can be eliminated by the addition of columbium to the alloy. The carbon in the alloy combines preferentially with the columbium, so columbium carbides rather than chromium carbides are precipitated. Depletion of chromium at the grain boundaries is prevented by this action; therefore intergranular corrosion does not occur.

Columbium-containing alloys that have been heated to sensitizing temperatures around 1200 F, although not subject to intergranular corrosion, have over-all corrosion rates, when tested in nitric acid, somewhat greater than those for columbium-free, quench-annealed alloys of the same nickel, chromium and carbon content. For columbium-containing alloys in the sensitized condition, rates of corrosion comparable with the rates for quenched alloys, can be obtained by balancing properly the chromium, carbon, manganese and silicon.

Where the usual quench-annealing practice is difficult or impossible, a 24 to 48-hr heat treatment at 1600 to 1800 F is helpful in improving the resistance of castings to intergranular corrosion. Except for alloys of very low carbon content, however, this treatment fails to produce material with as good resistance to intergranular corrosion as properly quench-annealed material. The effect of extended heating at various temperatures is shown in Fig. 5 and 6 for alloys that contain 0.06 and 0.12% C.

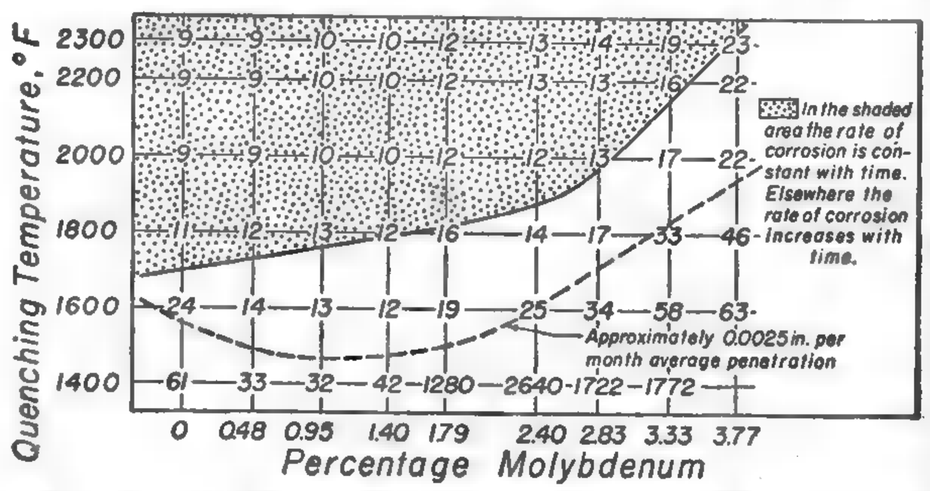

Fig. 4 Effect of molybdenum content on resistance to corrosion in boiling 65% nitric acid. (See caption for Fig. 2.)

Iron-Chromium Alloys. The so-called straight chromium alloys are made in the compositions listed in Table II.

Table II. Composition Limits of Iron-Chromium Corrosion-Resistant Castings

ACI Type	Composition, percentage — Carbon	Manganese	Silicon	Chromium	Nickel
CA-15	0.15 max	1.00 max	1.50 max	11.5 to 14	1.00 max
CA-40	0.20 to 0.40	1.00 max	1.50 max	11.5 to 14	1.00 max
CB-30	0.30 max	1.00 max	1.00 max	18 to 22	2.00 max
CC-50	0.50 max	1.00 max	1.00 max	26 to 30	4.00 max

Type CA. Castings made from this alloy are used extensively for applications that require high resistance to oxidation and also resistance to erosion. A considerable tonnage is utilized for valve trim. Castings are made from two alloy grades: 0.15% C max, and 0.20 to 0.40% C. Of the two, the low-carbon grade is the more popular. The mechanical properties of the alloy can be altered by heat treatment. Figure 7 shows typical values obtained, after various treatments, for an alloy containing 0.14% C and 0.56% Ni. As the nickel content is increased in these alloys, there is an increased tendency for the material to air harden when air cooled from 1500 F. This is an important consideration when the alloy is softened before machining.

Type CB-30. The 20% Cr alloy has greater resistance to corrosion than the CA type, but the material is only slightly hardenable by heat treatment. Castings of this alloy are used for valve bodies and trim, and for contain-

ers for nitric acid. When the 20% Cr alloy is used for service in contact with nitric acid, the carbon content is customarily limited to 0.20% max. Because of difficulty in casting low-carbon alloys of the CB type, the carbon content is usually from 0.20 to 0.30%. As carbon content is increased, however, the corrosion resistance is impaired. In recent years the CF type (19% Cr, 9% Ni) has replaced

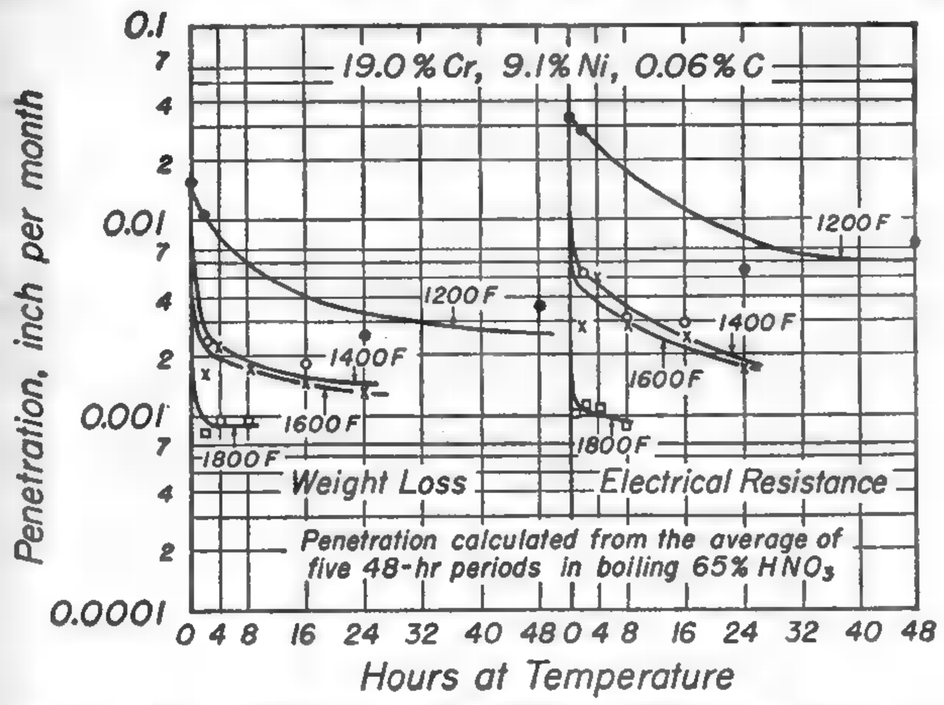

Fig. 5 Effect of holding at temperatures of 1200 to 1800 F for 2 to 48 hr on corrosion rate in nitric acid. Alloy composition: 0.06% C, 19.0% Cr, 9.1% Ni. As cast, heat treated in muffle furnace. Penetration average, five 48-hr periods in boiling 65% nitric acid (Reference 2)

the CB grade in many applications, and production of the straight chromium type has consequently declined.

Typical mechanical properties of a 20% Cr alloy, oil-quenched from 1850 F and tempered at 1400 F, are:

Tensile strength, psi	75,000
Yield strength, psi	50,000
Elongation, per cent in 2 in	15
Brinell hardness number	170

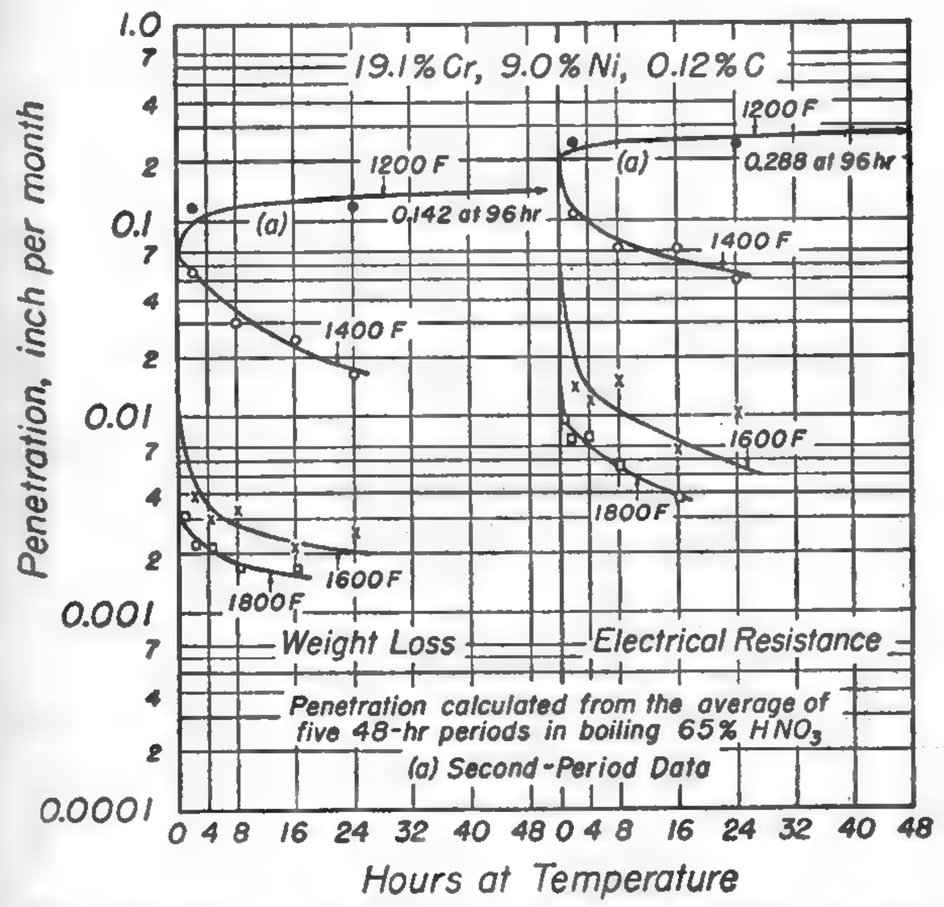

Fig. 6 Same as Fig. 5 except that this alloy contained 0.12% C, 19.1% Cr, 9.0% Ni (Reference 2)

Type CC-50. Alloys that contain about 28% Cr and up to 4% Ni are resistant to oxidizing corrodents and have been used extensively in contact with acid mine waters. Castings may be used in the as-cast condition without heat treatment. Typical mechanical properties of the CC-50 type are:

Tensile strength, psi	65,000
Elongation, per cent in 2 in	2
Brinell hardness number	212

In the CC type of alloy containing more than 2% Ni, strength and ductility are improved by increasing the nitrogen content to 0.15% or more.

Machinability of all the straight chromium alloys is as good or better than that of annealed 19% Cr, 9% Ni type alloys. Weldability is fair. Castings made of these compositions are usually preheated between 400 and 800 F before

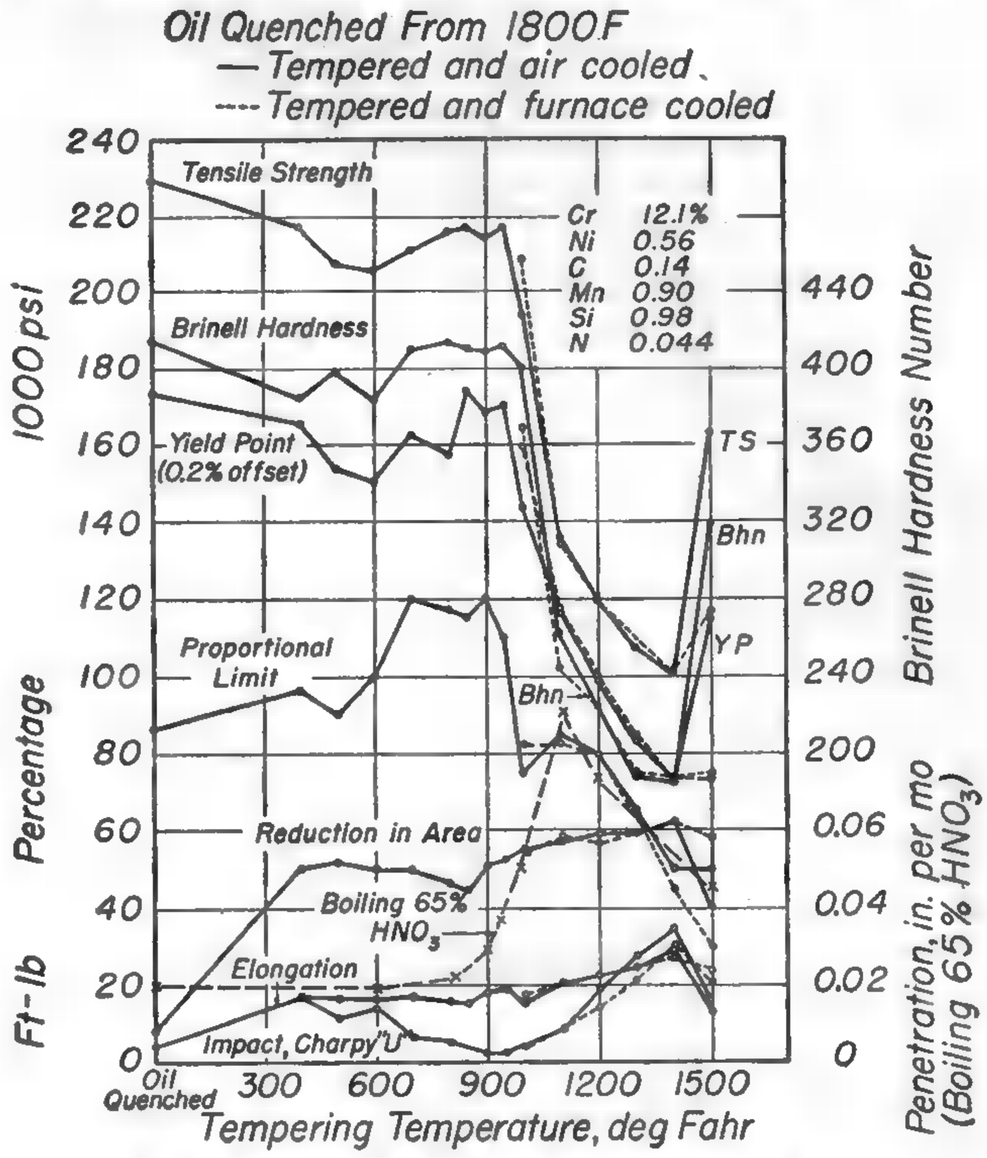

Fig. 7 Mechanical properties of 12% Cr steel casting (Alloy Casting Institute, previously unpublished data)

being welded. After welding, the alloys are heated between 1100 and 1400 F and are then cooled in air.

Iron-Chromium-Nickel Alloys. Ferrous alloys in which the chromium content exceeds the nickel content are made in the compositions listed in Table III.

Table III. Composition Limits of Iron-Chromium-Nickel Corrosion-Resistant Castings

ACI Type	Composition, percentage				
	Carbon (max)	Manganese	Silicon	Chromium	Nickel
CE-30	0.30	1.50 max	2.00 max	26 to 30	8 to 11
CF-*	0.07; 0.10 0.16; 0.20	1.50 max	2.00 max	18 to 20	8 to 10
CG-12	0.07; 0.10 0.16	1.50 max	2.00 max	20 to 22	10 to 12
CH-*	0.10; 0.20	1.50 max	2.00 max	22 to 26	12 to 15
CK-25	0.25	2.00 max	2.00 max	23 to 27	19 to 22

* These alloys are made in several carbon grades, designated CF-8, CF-16 F (free-machining), CF-20, CH-10, CH-20.

Type CE-30. This alloy has been used in considerable quantities for valves, fittings and pumps handling sulfite liquor in the paper industry. Type CE alloys can be made with a higher carbon content than the CF type composition, without suffering the injurious effects of carbide precipitation. In the as-cast condition the CE alloys have a structure consisting of austenite, ferrite and carbides; because of this structure the metal is less susceptible to intergranular corrosion than alloys of the CF type. For this reason, type CE alloys are useful where castings cannot be heat treated effectively or where they must be welded without subsequent heat treatment.

Although the CE alloys are often used in the as-cast condition, the ductility and resistance to corrosion may be improved somewhat by quenching the material from about

2000 F. Nominal mechanical properties of the as-cast alloy are as follows:

Tensile strength, psi	90,000
Yield strength, psi	50,000
Elongation, per cent in 2 in.	15
Brinell hardness number	197

Type CF. Alloys with about 19% Cr, 9% Ni and less than 0.20% C constitute the most widely used group of corrosion-resistant alloys. When properly heat treated, the alloy is resistant to a great variety of corrodents, and is usually considered the best general-purpose alloy. Structurally, the alloys are austenitic and nonmagnetic, although the low-carbon grade shows slight magnetic permeability. By proper balance of the nickel, manganese and nitrogen

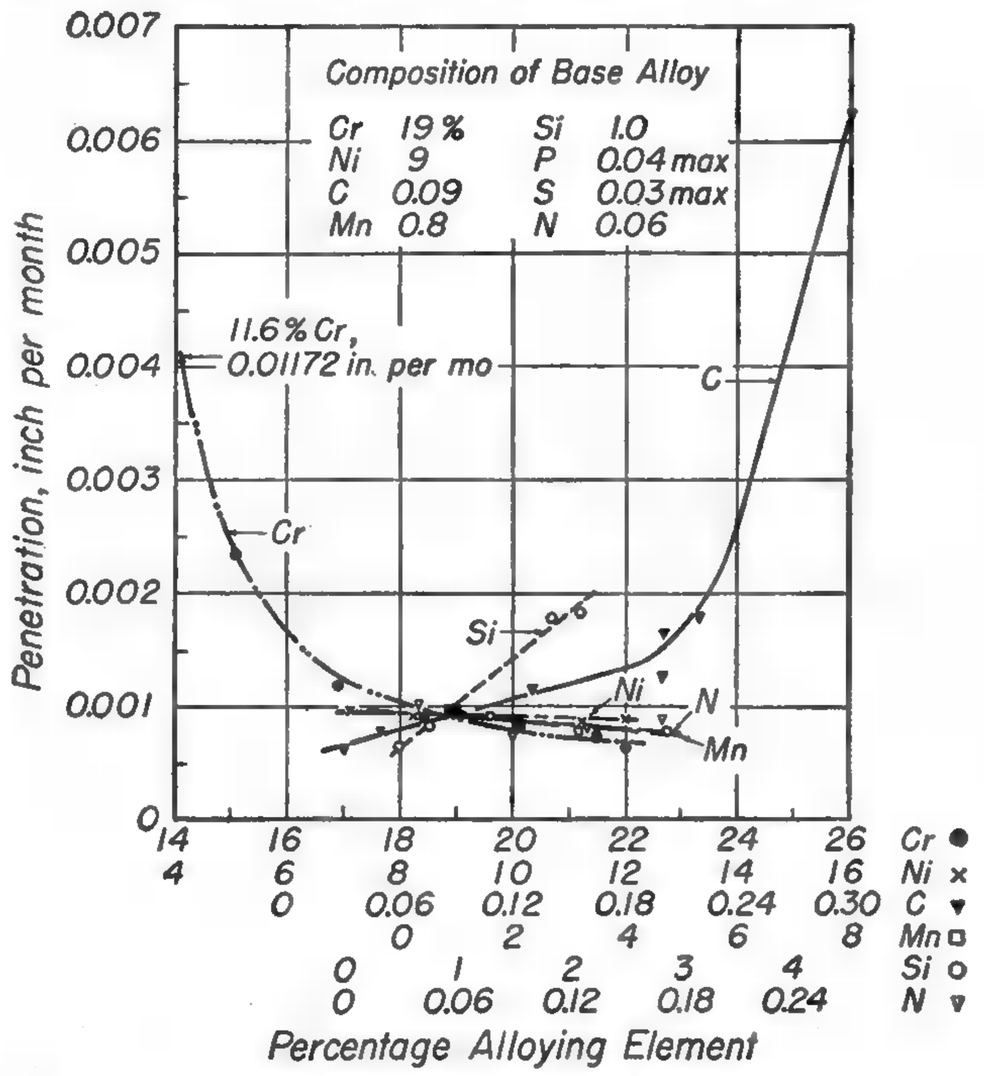

Fig. 8 Effect of composition on rate of corrosion penetration as determined from quench-annealed specimens in boiling 65% nitric acid (Reference 3)

contents, the low-carbon grade also may be made completely nonmagnetic. Because of their austenitic structure, CF type castings are not hardenable, but they have excellent ductility and toughness with fairly high tensile strength.

Table IV. Mechanical Properties of Type CF Alloys (19% Cr, 9% Ni)

Property	ACI Type CF-8	CF-20	CF-8M[a] CF-12M[a]	CF-8C[b]
Tensile strength, psi	80,000	83,000	88,000	85,000
Yield strength, psi	40,000	42,000	45,000	44,000
Elongation, per cent in 2 in.	55	55	50	45
Brinell hardness number	140	163	156 to 170	149

(a) Containing 2 to 3% Mo
(b) Containing columbium eight times the carbon content, 1% Cb max

For best resistance to corrosion, this type of material is made in the low-carbon grade, designated CF-8, containing 0.08% C max. The medium-carbon grade, CF-20, with 0.20% C max, is used satisfactorily under less corrosive conditions than those where the low-carbon type is employed.
